11  
12 **5 ABSTRACT:**  
13

14 **6** Discretely-spaced reinforced concrete (RC) energy pile rows have been proposed to be installed  
15 **7** at the mid-height of soil slopes. While the pile row can provide mechanical reinforcement to the  
16 **8** slopes, the piles can potentially be used to (i) intercept solar energy from roadways for heat storage  
17 **9** in the ground to mitigate extreme high carriageway temperatures and also (ii) to extract shallow  
18 **10** geothermal energy for road surface de-icing. In this study, a series of centrifuge model tests were  
19 **11** conducted to evaluate the shearing behaviour of unsaturated silt with and without reinforcement  
20 **12** by conventional piles and energy piles. Three-dimensional **finite element** coupled vapour-water-  
21 **13** heat transport analysis was also performed to further understand the effects of pile heating on the  
22 **14** responses of temperature and pore water pressure of the soil. The measured and computed results  
23 **15** revealed that the primary effect of pile heating was an increase in soil hydraulic conductivity due  
24 **16** to the heat-induced reduction in water viscosity. The heated soil had enhanced water flow and  
25 **17** hence developed higher suction. When subjected to translational slip, the silt reinforced by a row  
26 **18** of closely-spaced RC energy piles exhibited a more ductile shearing response and a lower peak  
27 **19** shear resistance, compared to that reinforced by conventional piles. The peak bending moments  
28 **20** mobilised in the energy piles in the stable stratum were also smaller. At larger shear displacements,  
29 **21** however, the shear resistance converged to a similar value, regardless of the suction and tempera-  
30 **22** ture. These suggest that the piles modified with additional energy transfer functionality can con-  
31 **23** tinue to act as reinforcement, potentially preventing soil from a sudden brittle failure, without at-  
32 **24** tracting additional flexural stresses onto the piles.

4 26 **INTRODUCTION**

5  
6 27 Extreme winter rainfalls and snowfalls due to climate change in the European temperate regions  
7  
8 28 have caused increasing numbers of failures and disruption to road/railway embankments, bringing  
9  
10 29 significant socio-economic losses (Sassa & Canuti, 2009; Huges *et al.*, 2008). While slope stability  
11  
12 30 can be improved by soil nailing and piling (amongst other methods), traffic disturbance associated  
13  
14 31 with road icing in winter is mitigated using de-icing salt, which aims to inhibit the crystallisation  
15  
16 32 of water into ice and increase the grip of tyres. However, excessive use of salt can create environ-  
17  
18 33 mental problems such as flooding due to the potential blockage of drainage as well as soil and  
19  
20 34 water contamination due to the leaching of chlorine ions, potential chloride attack of reinforced  
21  
22 35 concrete of pavements, bridges and retaining structures along with practical problems associated  
23  
24 36 with salt storage and logistics and the environmental impact of quarrying large amounts of salt. In  
25  
26 37 summer, extreme high summer temperatures (e.g., 38.7 °C in UK, July 2019; which broke the all-  
27  
28 38 time maximum recorded temperature held by the UK Met Office) can also heat up the asphalt of  
29  
30 39 the road as high as 50 °C. Such high temperatures lead to bitumen softening and damage due to  
31  
32 40 rutting of the wearing course. While gritters might be brought in to spread dust and sand for road  
33  
34 41 surface stabilisation, other measures are needed to reduce the thermal load of the road surface for  
35  
36 42 protecting the infrastructure and preventing traffic disturbance.

37 43 Discretely-spaced reinforced concrete (RC) pile rows have been a common engineering  
38  
39 44 method for improving slope stability (e.g., Poulos, 1995; Kourkoulis *et al.*, 2012; Al-Defae &  
40  
41 45 Knappett, 2014) through the mobilisation of pile flexural strength (Smethurst & Powrie, 2007) and  
42  
43 46 soil arching between the piles (Kourkoulis *et al.*, 2010; Girout *et al.*, 2016). An innovative and  
44  
45 47 sustainable proposal advanced by the authors is to modify RC piles used for this purpose to be RC  
46  
47 48 energy piles (Fig. 1). Solar energy may be intercepted and stored in heat-carrier fluid in a pipeline  
48  
49 49 buried in the road pavement. The heat harvested can be pumped to the piles and the ground for  
50  
51 50 heat storage when the road surface temperature is high. This operation leads to pile heating relative  
51  
52 51 to the cooler surrounding soil. Using the same system, shallow geothermal energy at the bottom  
52  
53 52 part of the piles (where soil is relatively warmer) may be extracted by the piles for road surface  
53  
54 53 de-icing in winter months. The near-surface soil is affected by the winter atmospheric condition,  
54  
55 54 and the soil temperature here would normally be lower than that in the pile carrying heated fluid.  
56  
57 55 Hence, pile heating would also take place at shallow depths (where a slip surface may form) during  
58  
59 56 this winter operation.

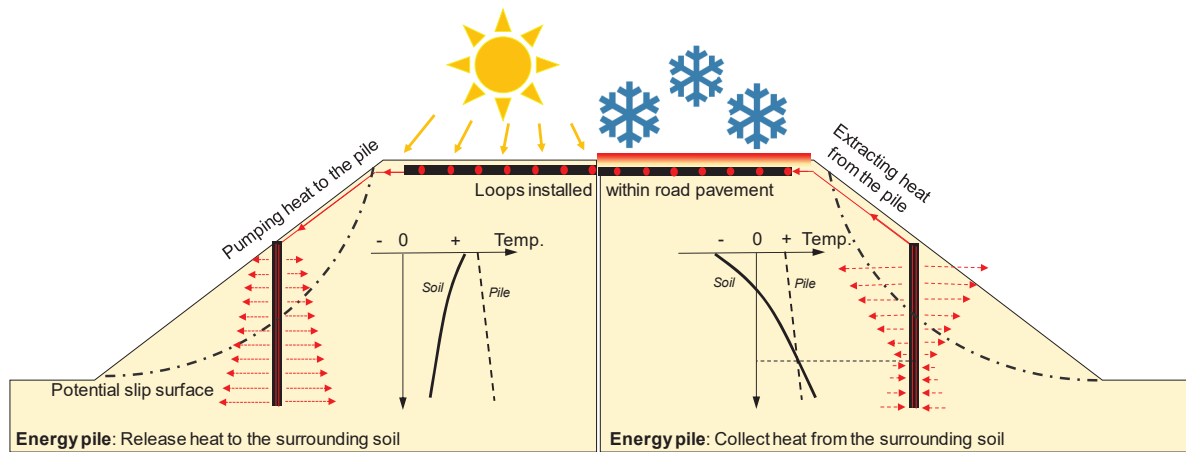

Figure 1. A schematic diagram showing the use of discrete energy pile row for slope stabilisation and road surface de-icing in “summer” and “winter” operation modes, respectively

Centrifuge modelling has been chosen as the principal research tool to study the fundamental mechanisms of the thermomechanical interaction between energy piles and unsaturated soil and hence to evaluate any effect of pile heating on the lateral behaviour of the soil-pile reinforcement system. By using a geotechnical centrifuge, testing a  $1:N^{\text{th}}$  model at  $N$  times of the Earth’s gravity ( $g$ ) through centripetal acceleration recreates stress levels that are close to much larger full-scale prototype systems (Taylor, 1995), correctly capturing the stress-dependent thermomechanical soil behaviour at homologous points. Indeed, there are physical model and centrifuge tests that have focused on the axial thermomechanical pile behaviour for building applications (Ng *et al.*, 2014; 2015; Goode & McCartney, 2015; Stewart & McCartney, 2014; Wu *et al.*, 2019). However, flexural thermomechanical pile behaviour, relevant to the system in Fig. 1, has never been studied before.

Correctly modelling the flexural behaviour of RC piles in a centrifuge is challenging as it requires careful selection of modelling materials to capture not only the nonlinear elasto-plastic-brittle behaviour (Knappett *et al.*, 2011), but also thermal properties such as thermal expansion coefficient of the energy pile (Vitali *et al.*, 2016). Additionally, effects of pile thermal loading on the changes in temperature and pore water pressure (PWP) fields in unsaturated soil (Leung *et al.*, 2020), and eventually the shear response of the energy pile-reinforced soil, are not well understood.

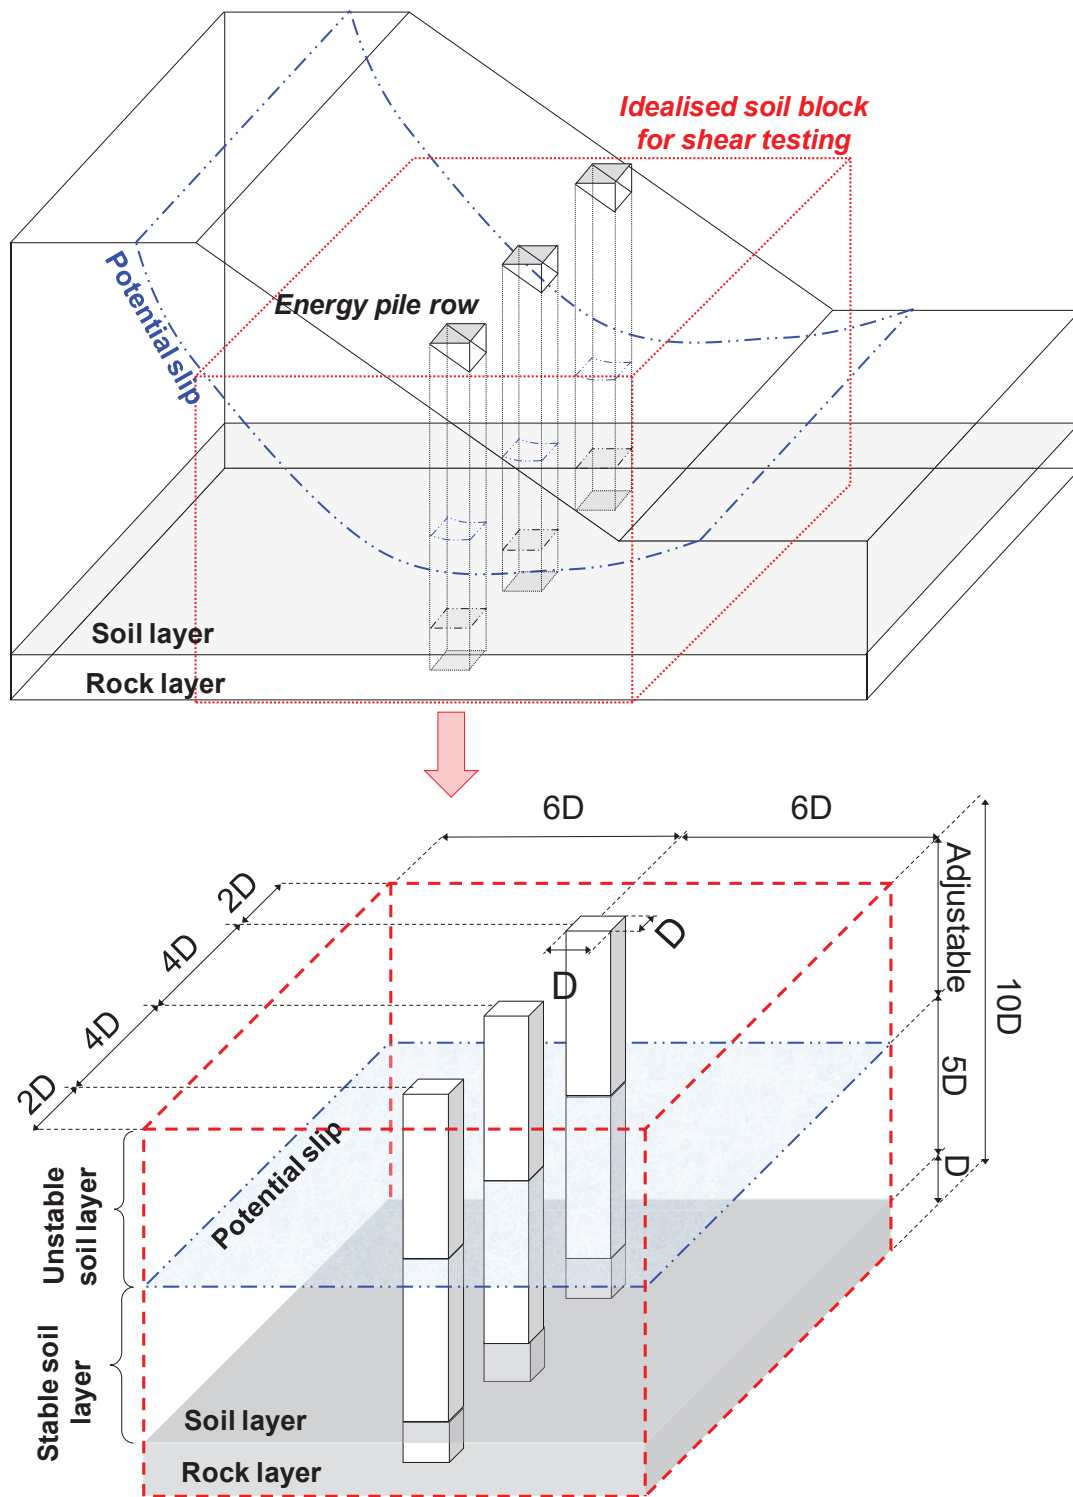

This paper aims to investigate and quantify the effects of pile heating on the flexural soil-energy pile interaction within soil translational slip and subsequently to understand the implications of energy pile use on the primary stabilisation function of the pile reinforcement. A series of

1  
2  
3  
4 80 centrifuge model tests was carried out to measure any changes in the soil PWP due to pile heating  
5  
6 81 and how these changes may have affected the lateral behaviour of an unsaturated soil reinforced  
7  
8 82 by a row of discretely-spaced energy piles. To assist in the interpretation of the centrifuge test data,  
9  
10 83 three-dimensional (3-D), **finite element**, water-vapour-heat transport back-analysis was addition-  
11  
12 84 ally performed, with emphasis on the influences of pile heating on the soil water regime.  
13  
14 85

## 15 86 **PROBLEM SIMPLIFICATION**

16  
17 87 The system of interest involves complex thermomechanical interaction between unsaturated soil  
18  
19 88 and multiple energy piles in a sloping ground. Since the key objective of this study is to determine  
20  
21 89 the thermo-hydro-mechanical behaviour of closely-spaced piles and the soil in their immediate  
22  
23 90 vicinity for a given depth of soil slip, only a block of representative soil around piles, instead of  
24  
25 91 an entire slope, was modelled in the centrifuge (Fig. 2). Following this simplification, the shear  
26  
27 92 capacity of the soil-pile system can be determined by imposing a uniform translational displace-  
28  
29 93 ment onto the back of the boundary of the “unstable” soil above a predefined horizontal slip. These  
30  
31 94 simplifications are deemed realistic when: (i) the piles are sufficiently far from both the crest and  
32  
33 95 toe of the slope; (ii) there exists a predefined slip; and (iii) the position of the slip is not modified  
34  
35 96 by the presence of piles (Kourkoulis *et al.*, 2012). For condition (i), previous analyses (Poulos,  
36  
37 97 1995; Kourkoulis, 2009) have shown that uniform loading applied at distances greater than  $5D$   
38  
39 98 (where  $D$  is pile diameter or width) away from the back of piles would introduce a reasonably  
40  
41 99 uniform displacement profile across the unstable soil. When the three conditions are satisfied, the  
42  
43 100 ultimate load acting on a row of stabilising pile would be a function of only the sliding depth, the  
44  
45 101 pile configuration, and both the pile and soil properties.

46  
47 102 The simplified block of a soil-pile system shown in Fig. 2 was tested in the centrifuge. Each  
48  
49 103 pile has an aspect ratio (diameter : length) of 1:10. In total, three piles were considered within this  
50  
51 104 block and they were socketed to a rigid bottom stratum for a length of  $1D$ . The piles were spaced,  
52  
53 105 centre-to-centre, at  $4D$ , which is typical of field conditions (e.g., Smethurst & Powrie, 2007). The  
54  
55 106 distance between the piles and the back of the model boundary was  $6D$ . The distance between the  
56  
57 107 edge piles and the model boundary was  $2D$  (i.e. half of the pile spacing), so the block can be tested  
58  
59 108 under a plane strain condition, representing a repeating cell as part of a long piled slope.

112 discrete row of three reinforced concrete energy piles in the geotechnical centrifuge

## 113 CENTRIFUGE TEST PROGRAMME

### 114 *Test plan*

115 In total, four centrifuge tests were designed to evaluate the shear behaviour of a discrete energy  
116 pile row in unsaturated soil. All centrifuge tests were conducted using the 3.5 m radius Actidyn  
117 C67 geotechnical beam centrifuge at the University of Dundee, UK (Brennan *et al.*, 2014), all at  
118 24 *g* ( $N = 24$ ). Test 1 was a shearing-only test of an unsaturated silt without pile reinforcement.  
119 Test 2 was also a shearing-only test of the same soil type but reinforced by a discrete row of three  
120 conventional RC piles. Tests 3 and 4 were similar to Test 2, but reinforced by a row of three energy  
121 piles in each case and tested thermo-mechanically. Tests 3 and 4 represented the “operation” and  
122 “shutdown” modes of the system (further details below), respectively.

123

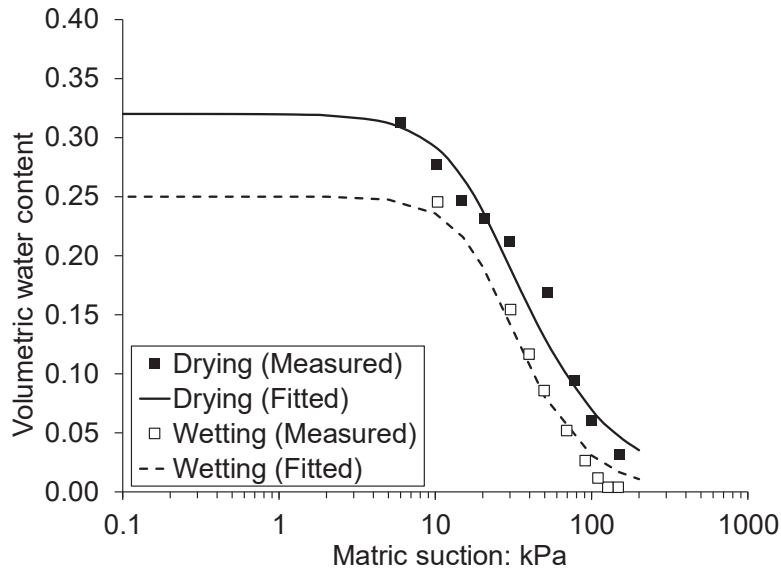

### 124 *Test soil*

125 The soil type tested was A50 silt with silica quartz content of more than 99.5%. The silt had a  
126 specific gravity of 2.65, and the particle diameters for 10%, 50% and 90% passing (i.e.,  $d_{10}$ ,  $d_{50}$   
127 and  $d_{90}$ ) were 0.004, 0.04 and 0.1 mm, respectively. Hence, the ratio between the thickness of a  
128 LDSA sample and  $d_{50}$  was 7500. This is well above 4700, beyond which the friction angle would  
129 be expected to become independent of sample size and almost the same as that obtained from  
130 drained torsional simple shear (Wu *et al.*, 2008). The drying and wetting water retention curves  
131 (WRC) of the silt, compacted to a dry density of 1.58 g/cm<sup>3</sup> (equivalent to 95% degree of compac-  
132 tion; adopted in all the centrifuge tests) with an initial water content (by mass) of 18.5%, are shown  
133 in Fig. 3. The silt had an air-entry value of approximately 20 kPa, and it loses almost all the mois-  
134 ture as the matric suction reached 100 kPa. A noticeable hysteresis loop was observed after expe-  
135 riencing a cycle of drying and wetting. Based on constant-head permeability tests, the saturated  
136 hydraulic conductivity of the silt, determined at the same soil compaction level, was  $8.3 \times 10^{-7}$  m/s.  
137 Direct-shear tests on saturated and unsaturated silt over ranges of net normal stress (5 – 200 kPa)  
138 and suction (0 – 90 kPa) were conducted. The test data was interpreted by the Mohr-Coulomb  
139 failure envelop in the effective stress space:

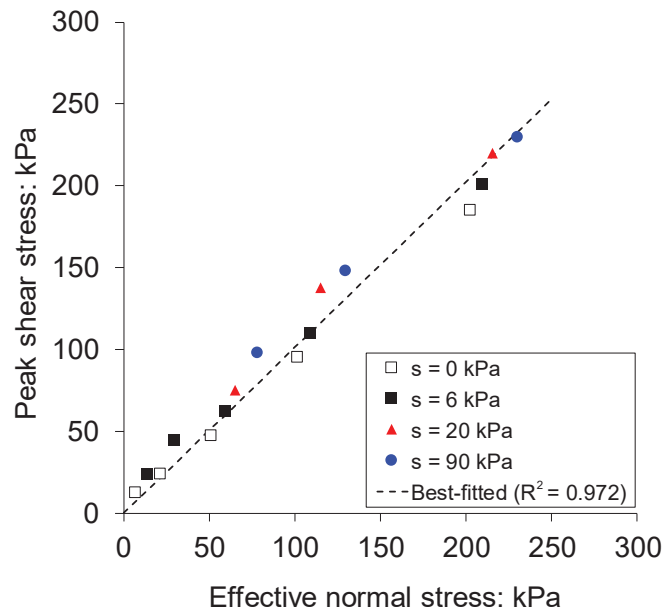

$$140 \tau = c' + [(\sigma - u_a) + \chi(u_a - u_w)] \tan \phi' \quad (1)$$

141 where  $c'$  is cohesion;  $\sigma$  is total normal stress;  $u_a$  is pore air pressure (atmospheric);  $u_w$  is pore wa-  
142 ter pressure;  $\phi'$  is friction angle; and  $\chi$  is an effective stress parameter, which may be defined as

1  
2  
3  
4 143  $(s/s_e)^{0.55}$ , after Khalili & Khabbaz (1998), where  $s$  and  $s_e$  are the matric suction (i.e.  $(u_a - u_w)$ ) and  
5  
6 144 air-entry value, respectively. Based on the results shown in Fig. 4, the silt had a peak friction angle  
7  
8 145 of  $45.3^\circ$ . The quartz-based silt, at dry condition, had a coefficient of thermal expansion of  $0.55$   
9  
10 146  $\mu\epsilon/^\circ\text{C}$  and a thermal conductivity ( $\lambda$ ) of  $6.5$  W/(m K) (Cardarelli, 2008). Other silt properties are  
11  
12 147 summarised in Table 1.

148  
149 Figure 3. Drying and wetting WRCs of the silt, fitted with the van Genuchten (VG; 1980) equation.  
150 Fitting coefficients for the drying curve are  $a = 0.00062$  kPa $^{-1}$ ;  $n = 1.09$ ;  $m = 36.2$ ;  $\theta_s = 0.32$  and  
151  $\theta_r = 0$ , and those for the wetting curve are  $a = 0.04$  kPa $^{-1}$ ;  $n = 2.5$ ;  $m = 0.25$ ;  $\theta_s = 0.25$  and  $\theta_r = 0$ .

152

154 **Table 1.** Properties of the silt used in the physical model tests

Parameter	Value
<i>Index properties</i>	
Specific gravity [-]	2.65
$d_{10}$ (particle diameter with 10% passing) [mm]	0.004
$d_{50}$ (particle diameter with 50% passing) [mm]	0.04
$d_{90}$ (particle diameter with 90% passing) [mm]	0.1
Maximum dry density [ $\text{kg}/\text{m}^3$ ]	1.66
Optimum water content [g/g]	0.191
<i>Mechanical properties</i>	
Peak friction angle [ $^\circ$ ]	45.3
<i>Hydraulic properties</i>	
Air-entry value [kPa]	20
Saturated permeability [m/s]	$8.3 \times 10^{-7}$
<i>Thermal properties</i>	
Thermal conductivity [W/(m K)]	6.5
Coefficient of thermal expansion [ $\mu\epsilon/^\circ\text{C}$ ]	0.55

156 *Model RC energy piles*

157 The model piles used in this study were made of the model concrete developed by Vitali *et al.*  
158 (2016) and Zhao *et al.* (2020). This model concrete can realistically capture both the thermal and  
159 mechanical properties of concrete at prototype scale and also the nonlinear quasi-brittle behaviour  
160 that is highly important for correctly modelling the flexural behaviour of laterally-loaded rein-  
161 forced concrete structures. The model concrete was a mixture of  $\beta$ -form surgical plaster, silica  
162 sand (Congleton HST95), water and copper powder (Phoenix Scientific Industries). While silica  
163 sand (particle diameter ranging from 0.06 to 0.3 mm, with  $d_{50} = 0.2$  mm) is to geometrically scale  
164 down the size of aggregate in prototype concrete (Knappett *et al.*, 2011), the addition of copper  
165 powder (diameter ranging from 0.002 to 0.1 mm) aimed to enhance the thermal properties of the  
166 mortar. Element tests conducted by Vitali *et al.* (2016) and Zhao *et al.* (2020) showed that adding  
167 6% copper powder (by volume) into the mix was able to reproduce the thermal conductivity (about  
168  $0.73 \pm 0.09$  W/(m K); mean  $\pm$  standard error of mean) of concrete, while not adversely affecting the  
169 mechanical properties of the mortar. Like concrete, the thermomechanical behaviour of the model  
170 concrete was subject to uncertainties due to material variabilities and workmanship. Statistical

1  
2  
3  
4 171 analysis performed by Knappett *et al.* (2018) showed that the model concrete exhibited a similar  
5  
6 172 coefficient of variation of mechanical strength ( $< 10\%$ ) to full-scale concrete.  
7

8 173 By using the model concrete, model piles were produced. A design moment capacity of 230  
9  
10 174 kNm was chosen to size the pile section, based on the test results of non-energy pile-reinforced  
11  
12 175 slopes reported by Al-Defae & Knappett (2014) and Jeong *et al.* (2003). The pile design followed  
13  
14 176 Eurocode 2 (EN 1992-1-1, 2004). In order to achieve the design moment, a doubly-reinforced 0.6  
15  
16 177 m x 0.6 m square pile with a length of 6 m and a steel reinforcement ratio of 2.1% was required  
17  
18 178 (see section design in Fig. 5). Longitudinal reinforcement (bars) were applied both at the back and  
19  
20 179 in the front of the pile section, with two 18 mm-diameter and four 14 mm-diameter mild steel bars  
21  
22 180 on each side. Twenty-five transverse reinforcements (stirrups/shear links) of 14 mm diameter were  
23  
24 181 also needed and they were spaced at 240 mm along the pile length.

25 182 For conducting the 24 *g*-centrifuge tests, the pile dimension was scaled down at 1:24. The  
26  
27 183 model pile section is shown in Fig. 5. Stainless steel wire (Grade 316; Ormiston Wire Ltd) was  
28  
29 184 used to produce the scaled longitudinal bars and shear links. While the longitudinal bars were  
30  
31 185 produced by steel with a yield strength of 460 MPa and a model diameter of 1.25 mm (design  
32  
33 186 requirement: 1.12 mm), the shear links were produced using steel with a yield strength of 380 MPa  
34  
35 187 and a model diameter of 0.63 mm (design requirement: 0.59 mm). All the model longitudinal bars  
36  
37 188 and shear links were coated with a thin layer of fine sand using epoxy for providing mechanical  
38  
39 189 interlocking with the mortar (Knappett *et al.*, 2011).

191 Figure 5. Structural design of pile cross section and its small-scale modelling for centrifuge testing.  
192 Note: the abbreviation “dia.” denotes diameter and HDPE stands for high-density polyethylene.

1  
2  
3  
4 194 Two U-shaped tubes were used to circulate water of different temperature in and out of the  
5  
6 195 pile using a centrifuge-mounted heat circulation system developed by Vitali *et al.* (2018). The pipe  
7  
8 196 was made of flexible silicon, which was bent to form a U-shaped tube within the pile. The pipe  
9  
10 197 had an internal diameter of 1.5 mm, a tensile strength of 10 MPa and the thermal expansion coef-  
11  
12 198 ficient between 70 and 110  $\mu\epsilon/^\circ\text{C}$ . The pipes were fixed onto the reinforcement cage (Fig. 6), which  
13  
14 199 was assembled in an aluminium formwork, into which the model concrete was mixed with 6%  
15  
16 200 copper powder (by volume) and then left to air-cure and harden for 28 days.

Figure 6. Model pile production: (a) positioning the steel reinforcement and U-shaped pipes; (b) strain-gauge installation on reinforcements; and (c) final product of the model RC pile after casting

Four-point bending tests were conducted to determine the flexural properties of the model piles. These showed that the 1:24 scale RC energy piles produced by the methods and procedures

214 above had representative prototype thermal expansion coefficient ( $15.8 \mu\epsilon/^\circ\text{C}$ ), average peak mo-  
 215 ment capacity (336 kNm) and flexural rigidity ( $33 \text{ MNm}^2$ ), expressed at prototype scale (Minto *et*  
 216 *al.*, 2016; Zhao *et al.*, 2020). The characteristic moment capacity of the pile as measured in the  
 217 bending tests was higher than the design moment capacity, reflecting both the effects of the partial  
 218 factors in the EC2 design procedure and the slight over-reinforcement due to the use of the slightly  
 219 higher diameters of the model longitudinal bars with respect to the design values.

### 221 *Test setup*

222 Following the model simplification made to the soil-pile system (Fig. 2), a large-area ( $300 \times 300$   
 223  $\times 300 \text{ mm}^3$ ) direct-shear apparatus (LDSA; Fig. 7) was developed to simulate the process of soil  
 224 translational slip and to determine the shear resistance of the pile reinforcement in the centrifuge.  
 225 The apparatus has two components. The first one is the shearing chamber, which is composed of  
 226 four detachable aluminium square boxes stacked atop each other. These can be variously bolted  
 227 together to create four potential shearing surfaces such that soil sliding at different depths can be  
 228 modelled, with the upper-part moving. All the interfaces between the boxes are covered with pol-  
 229 ytetrafluoroethylene (PTFE) for minimising interface friction. The box interface has a frictional  
 230 coefficient of 0.107. All horizontal force measurements presented in this study have been corrected  
 231 for the box interface friction. Multiple ports are made on the sides of each box for installing ther-  
 232 mocouples and high-capacity tensiometers to monitor changes in soil temperature and PWP during

236 testing. The second component of the apparatus is the motor, which is used to drive a worm shaft  
237 to apply displacement-controlled horizontal loading to the back of the shearing chamber. A load  
238 cell is used to measure the shear loading mobilised, while a pair of linear variable differential  
239 transformers (LVDTs) are installed at the front face of the box for measuring the shear displace-  
240 ment (averaging the two measurements) and to check for any rotation about the vertical axis.

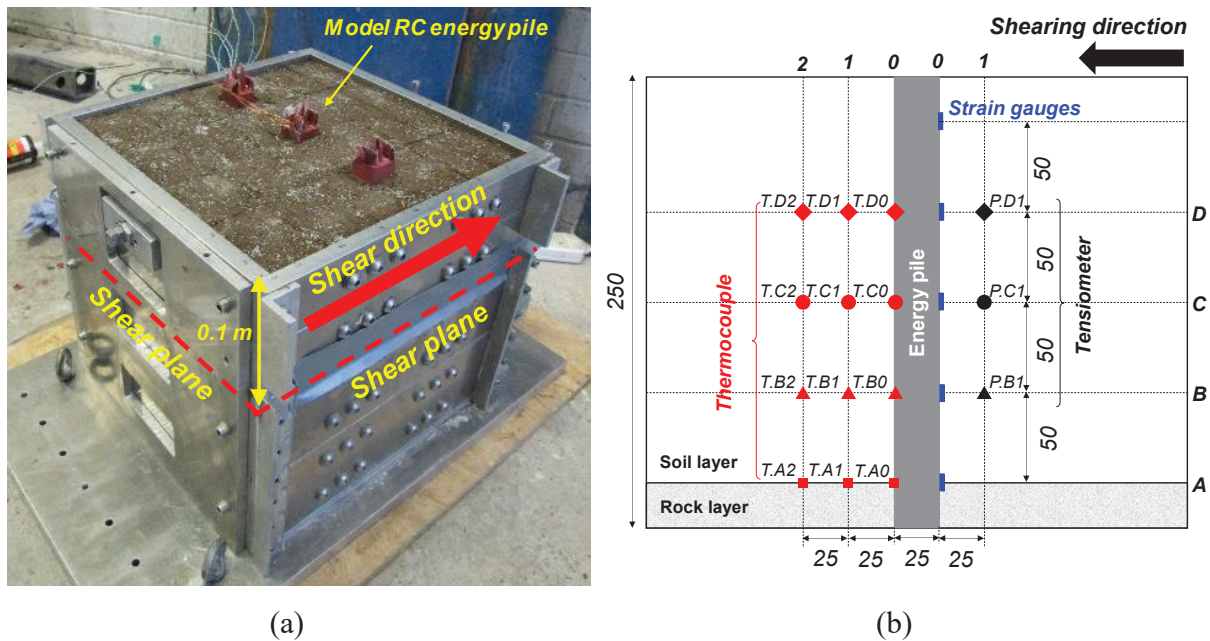

241 Figure 8 shows the overview and schematic diagram of the model setup of the centrifuge  
242 test. At the bottom of the LDSA, a 25 mm thick solid aluminium plate was placed with machined  
243 square slots to simulate the bedrock in the field and allow the piles to be socketed. Before soil  
244 compaction, three dummy piles with identical dimensions to the model RC piles but made of solid  
245 aluminium were socketed into the plate to a depth of  $1D$ . All the vertical surfaces of these piles  
246 were sleeved with polypropylene plastic sheets so that the post soil compaction extraction process  
247 would introduce minimal disturbance to the surrounding soil. The centre-to-centre spacing be-  
248 tween these piles was  $4D$ . Installing the dummy piles at this stage aimed to prevent damage to the  
249 RC piles during soil compaction. Thereafter, soil thoroughly mixed to a uniform water content of  
250 18.5% (by mass) was compacted into the LDSA by the moist tamping method. The soil compaction  
251 was divided into nine layers of equal height of 25 mm, targeting a uniform dry density profile of  
252  $1.58 \text{ g/cm}^3$ . The targeted dry density and water content (by mass) corresponded to an initial degree  
253 of saturation of the soil of 70%. After soil compaction, the dummy piles were extracted from the  
254 soil carefully and the model package was completed by socketing the three model RC piles into  
255 the bottom plate. This pile installation method may be representative to the case of cast-in-situ RC  
256 piles in practice.

### 257 258 *Instrumentation*

259 The central model pile and surrounding soil in each test was instrumented to monitor its thermo-  
260 mechanical behaviour during each centrifuge test. As shown in Fig. 8, three vertical arrays of four  
261 thermocouples at different depths were installed on the pile surface and also at  $1D$  and  $2D$  away  
262 from the pile surface within the soil, to monitor soil temperature changes induced by the model  
263 RC energy pile, both vertically and horizontally. Another array of five pairs of strain gauges (steel-  
264 foil; model no.: CAE-06-062UW-350; Micro-Measurements Ltd.) were installed to the same cen-  
265 tral model pile, four of which had approximately the same elevations as the thermocouples, for

1  
 2  
 3  
 4 266 monitoring mobilised bending moment during testing. The fifth pair of the strain gauges was in-  
 5  
 6 267 stalled in shallower pile depth of 25 mm (see the figure). Each strain gauge was affixed to a 0.3  
 7  
 8 268 mm-thick steel tab using a temperature resistant adhesive and the assembly was attached to two  
 9  
 10 269 adjacent longitudinal bars (Fig. 6), mimicking the installation method adopted in full-scale RC  
 11  
 12 270 piles in the field. Each pair of strain gauges was wired through half-bridge connections to allow  
 13  
 14 271 bending moment measurement without parasitic axial loads or thermal effects. By mounting one  
 15  
 16 272 gauge along the principal axis of strain (i.e., axial direction) and the other gauge in the same di-  
 17  
 18 273 rection but on the opposite side of the model, temperature effects on the strain gauge responses  
 19  
 20 274 can be eliminated (National Instruments, 2016).

21 275 In addition, a vertical array of three miniature high-capacity tensiometers (HCTs; model no.  
 22  
 23 276 EPB-PW-7BS; StrainSense Ltd.) were installed to measure soil PWP change. Each HCT had a 3-  
 24  
 25 277 bar ceramic stone, which can measure a range of PWP from -300 to 700 kPa. Prior to installation,  
 26  
 27 278 each HCT was saturated following the rigorous procedures adopted by Zhou *et al.* (2006). Toll et  
 28  
 29 279 al. (2013) have shown that temperature has minimal influence on the linear calibration factor (i.e.,  
 30  
 31 280 gradient of PWP and voltage; kPa/ $\mu$ V) of the HCTs.

56 282 Figure 8. (a) Overview and (b) elevation view of the centrifuge model setup of the LDSA, together

 58 283 with the instrumentation plan (all dimensions are in mm)

59 284

1  
2  
3  
4 285 *Test procedures*

5  
6 286 The test procedures of all centrifuge tests broadly consisted of three consecutive steps, namely: (i)  
7  
8 287 centrifuge spin-up; (ii) pile continuous heating; and (iii) direct shearing. In Step (i), the model  
9  
10 288 package of each test was spun up to 24 *g*. Step (ii) only applied to Tests 3 and 4, where all three  
11  
12 289 model RC energy piles were heated internally by maintaining an average inlet temperature (i.e.,  
13  
14 290 measured in the water immediately before entering the piles) at 42.5 °C for 90 – 120 days (proto-  
15  
16 291 type scale). This inlet temperature was typical of energy pile operation (e.g., Ng *et al.*, 2015; Stew-  
17  
18 292 art & McCartney, 2014). The adopted heating duration aimed to provide sufficient time to heat up  
19  
20 293 the model RC pile so that the changes in pile surface temperature are representative of values  
21  
22 294 normally recorded in the field (Loveridge & Powrie, 2013). Step (iii) applied to all four tests. In  
23  
24 295 this step, constant-water-content shearing was carried out at 2.4 m depth (prototype), mimicking a  
25  
26 296 translational slip. The shearing rate was controlled at  $8.75 \times 10^{-8}$  m/s (prototype), which is catego-  
27  
28 297 rised as a “very slow” landslide (Dixon & Spriggs, 2007). Test 3 aimed to model soil failure during  
29  
30 298 the “operation” mode of the system (refer to Fig. 1) upon heat storage in summer or heat extraction  
31  
32 299 for road de-icing in winter. In both cases, the energy piles are expected to be hotter than the sur-  
33  
34 300 rounding soil and actively heating; hence, in this test, the model piles were heated continuously  
35  
36 301 during shearing. Test 4, on the contrary, modelled soil failure during the “shutdown” mode of the  
37  
38 302 system under milder climate conditions, e.g. after a previous period of use but when heat is neither  
39

### 13 310 **FINITE ELEMENT BACK-ANALYSIS**

15 311 To interpret the complex water-vapour-heat transport process involved in the heating of the un-  
16  
17 312 saturated soil by the energy pile rows, three-dimensional (3-D) **finite element** (FE) simulations  
18  
19 313 were carried out to back-analyse the responses of soil temperature and PWP during the 90-day pile  
20  
21 314 heating. The governing equations presented by Leung *et al.* (2020) were adopted. To describe the  
22  
23 315 water liquid and vapour transport, the **Richards equation (which is a combination of Darcy's law**  
24  
25 316 **and continuity principle)** was used:

$$27 \quad 317 \quad \frac{\partial \theta(T, \psi)}{\partial t} + \frac{\partial \theta_V(T, \psi)}{\partial t} = \nabla[(K_L(T, \psi) + K_V(T, \psi))\left(\frac{1}{\gamma_w} \nabla \psi + \nabla z\right) + (K_{LT}(T, \psi) + K_{VT}(T, \psi))\nabla T] \quad (2)$$

29  
30 318 where  $T$  is soil temperature;  $\psi$  is matric suction;  $\theta(T, \psi)$  and  $\theta_V(T, \psi)$  are volumetric liquid water  
31  
32 319 content and volumetric water vapor content, respectively;  $K_L(T, \psi)$  is the hydraulic conductivity  
33  
34 320 of liquid water with respect to  $\psi$  change;  $K_V(T, \psi)$  is the hydraulic conductivity of the water vapor  
35  
36 321 with respect to  $\psi$  change;  $\gamma_w$  is unit weight of liquid water;  $K_{LT}(T, \psi)$  is the hydraulic conductivity  
37  
38 322 of liquid water with respect to  $T$  change; and  $K_{VT}(T, \psi)$  is the hydraulic conductivity of water va-  
39  
40 323 por with respect to  $T$  change. On the other hand, the equations derived by Philip and de Vries  
41  
42 324 (1957) were adopted to simulate heat transport:

$$44 \quad 325 \quad C_s(\theta) \frac{\partial T}{\partial t} + L_0 \frac{\partial \theta_V}{\partial t} = \nabla[\lambda(\theta)\nabla T] - C_L q_L \nabla T - C_V \nabla(q_V T) - L_0 \nabla q_V \quad (3)$$

46  
47 326 where  $C_s(\theta)$ ,  $C_L$  and  $C_V$  are the volumetric heat capacities of soil, liquid water and water vapor,  
48  
49 327 respectively;  $\lambda(\theta)$  is a moisture-dependent thermal conductivity function (Chung & Horton, 1987);  
50  
51 328  $q_L$  and  $q_V$  are fluxes of liquid water and vapor, respectively; and  $L_0$  is latent heat of vaporisation  
52  
53 329 of liquid water. The coupling between Eqs (2) and (3) was made via the psychometric law:

$$55 \quad 330 \quad H_r = \exp\left(\frac{\psi M}{\rho_w R T}\right) \quad (4)$$

56  
57  
58 331 where  $H_r$  is relative humidity;  $\rho_w$  is water density;  $M$  is molecular weight of water; and  $R$  is the  
59  
60 332 universal gas constant (8.314 J/(K mol)). The mathematical formulation is similar to that reported

333 by Leung *et al.* (2020) but expressed in the 3-D condition for the problem of interest in this study.  
 334 These equations were implemented into a **finite element** multi-physics platform, COMSOL v5.4.  
 335 The soil hydraulic and thermal properties input to solve Eqs (2) – (4) are given in Table 3.

336 The geometry of the **finite element** mesh and the thermal and hydraulic boundary conditions  
 337 were identical to what was tested at prototype scale (Fig. 9, following Fig. 2). At the soil surface,  
 338 a constant ambient temperature of 23.1 °C and a relative humidity of 50% were specified and the  
 339 evaporation rate was determined by the equation proposed by Wilson *et al.* (1997). Heat exchange  
 340 across all sides was permitted by specifying the following equation:

$$341 \quad Q_h = h(T - T_a) \tag{5}$$

342 where  $Q_h$  is the heat flux;  $T$  and  $T_a$  are the soil temperature and ambient temperature, respectively;  
 343 and  $h$  is heat exchange coefficient, which was taken as 6.06 J/(m<sup>2</sup> s K) (Liu, 2017).  
 344

345 **Table 3.** Input parameters of soil’s hydraulic and thermal properties

Parameters		Value
Water density [kg/m <sup>3</sup> ]		1000
Molecular weight of water [kg/mol]		0.018015
Universal gas constant [J/mol K]		8.314
VG parameters for fitting the drying water re- tention curve	Saturated volumetric water content [-]	0.32
	Residual volumetric water content [-]	0
	$a$ [kPa <sup>-1</sup> ]	0.00062
	$n$ [-]	1.09
	$m$ [-]	36.2
<b>Hydraulic conductivity of saturated soil at 20 °C [m/s]</b>		<b><math>8.3 \times 10^{-7}</math></b>
Surface tension at 25 °C [kg/s <sup>2</sup> ]		0.07189
<sup>1</sup> Soil thermal conductivity	$b_1$ [-]	0.228
	$b_2$ [-]	-2.406
	$b_3$ [-]	4.909

346 <sup>1</sup>the soil thermal conductivity was modelled as a function of soil volumetric water content (Chung & Horton,  
 347 1987) and the parameters are for silica soil taken from Chung & Horton (1987).  
 348

349 Test 3, which involved pile heating in the centrifuge test, was back-analysed. The simulation  
 350 focused on the responses of soil temperature and PWP after reaching 24 *g* but before being subject  
 351 to shearing. The initial soil temperature and PWP were specified based on the measurements made  
 352 in the centrifuge test at 24 *g*. In this simulation, pile heating was modelled by specifying the dis-  
 353 tribution of pile surface temperature measured from the centrifuge test on the pile surface boundary.

1  
2  
3  
4 354 Note that Test 4 (which also involved pile heating) was not separately modelled because the test  
5  
6 355 condition and procedures before the shearing stage were identical to Test 3. To investigate the  
7  
8 356 effects of pile heating on soil PWP changes, two additional simulations were conducted. One sim-  
9  
10 357 ulation considered pile heating but ignored vapour transport and water-vapour exchange, while the  
11  
12 358 other ignored pile heating.

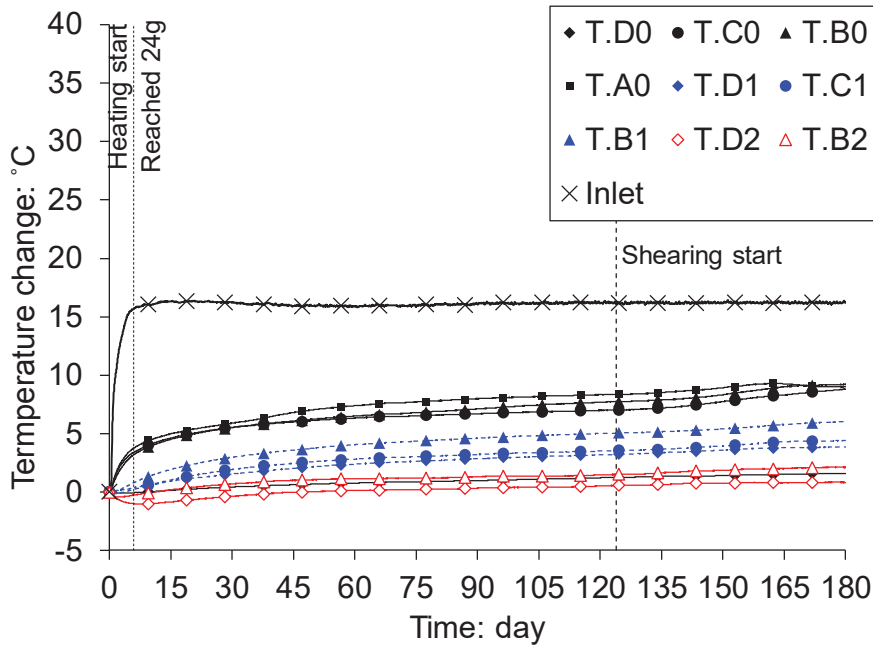

359  
360 Figure 9. **Finite element** mesh and boundary conditions adopted in the numerical back-analysis.

## 362 RESULTS AND DISCUSSION

### 363 *Heat transfer mechanisms and temperature field*

364 Fig. 10 shows the measured variations of temperature change with time at different positions of  
365 the system in Tests 3 and 4. During heat transfer, some of the heat energy was absorbed by the  
366 model concrete due to its thermal mass and resistance, and thus not all of the heat energy was  
367 transported to the pile surface. Indeed, at the pile surface, the increase in temperature was 6 – 8 °C  
368 in both tests. For Test 3 when pile heating was maintained during the shearing stage (i.e., opera-  
369 tional mode), the pile surface temperature continued to rise by a small amount until an increase in  
370 surface temperature of almost 10 °C was observed by the end of the test (Fig. 10(a)). These meas-  
371 urements were input in all the exterior surfaces of the three piles in the **finite element** mesh shown

(a)

(b)

Figure 10. Temperature-time histories at the pile surface and the soil in (a) Test 3; and (b) Test 4.

As the pile heat was dissipated to the surrounding soil, the soil temperature at both 1D and 2D away from the pile centre in both tests was increased (Figs 10 and 11). However, the amount of temperature rise in the soil (up to 5 °C) was less significant than that in the pile, primarily because the silt had a lower thermal conductivity and higher heat compacity. It can be seen from

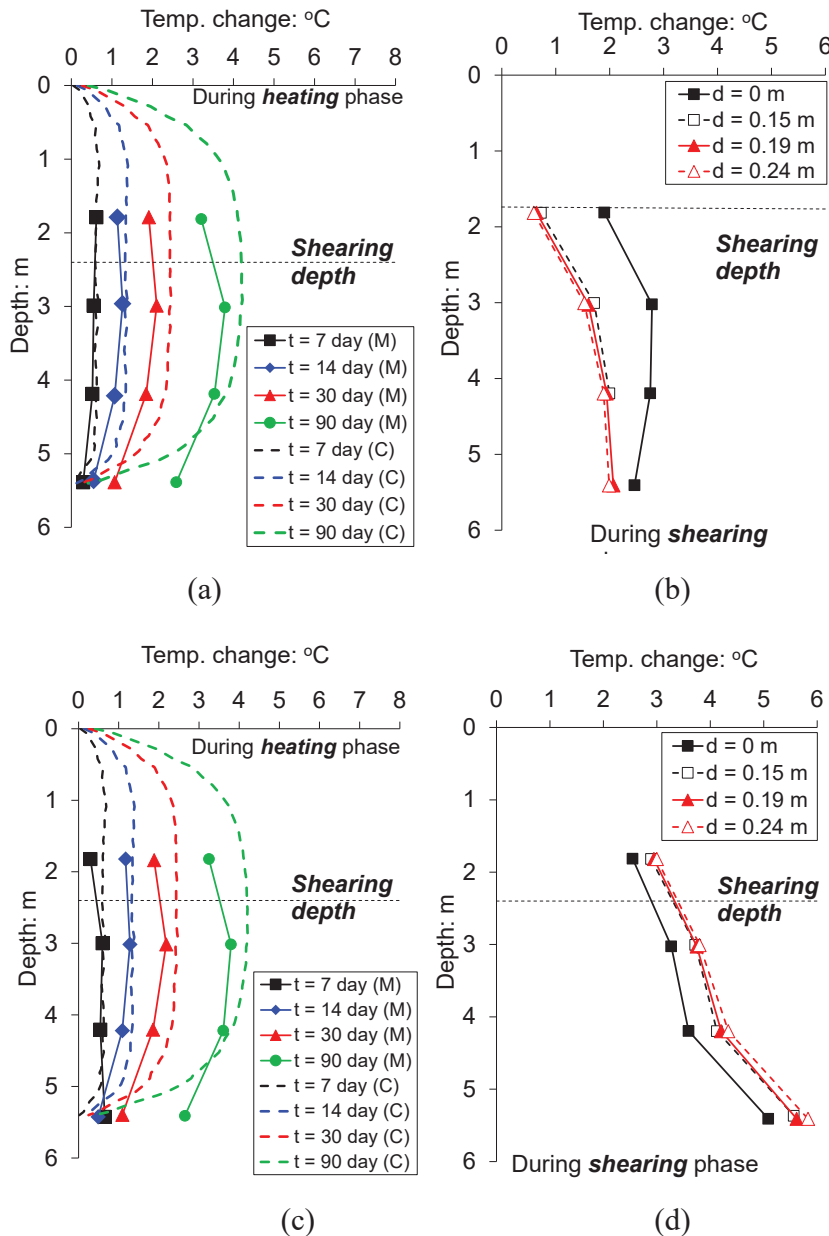

Figure 11. Vertical profiles of soil temperature 1D away from the pile surface at different elapsed time during the heating phase in (a) Test 3 and (c) Test 4, and at different shear displacements (d) during the shearing phase in (b) Test 3 and (d) Test 4. 'M' and 'C' in the legend mean measured and computed results, respectively. Note that the computed results apply to both Tests 3 and 4.

393 Fig. 11 that as the heating phase progressed in both tests, the soil temperature profile at  $1D$  away  
394 from the pile centre became more parabolic in shape. This profile shape was consistently found in  
395 the FE simulation. The computed contours of soil temperature at sections A-A and B-B are given  
396 in Fig. 12. The soil near the top and bottom of the block was cooler than that in between. This was  
397 because of evaporation of near surface moisture, which was a cooling process that counteracted  
398 the pile heating effect, as well as heat exchange with the atmosphere. The heat transfer from the  
399 pile to the surrounding soil was less effective near the pile toe due to (i) the end-effect where the  
400 two U-shaped tubes curved away from the pile surface and the cover depth was hence greater and  
401 (ii) heat transfer to the aluminium base plate of the LDSA and eventually the thermal mass of the  
402 model container of the centrifuge. This heat exchange at the bottom boundary was captured by the  
403 FE analysis. The temperature contour shows that there was thermal interaction between the neigh-  
404 bouring piles (spaced  $4D$  centre-to-centre) as indicated by the overlapping of the influence zone  
405 of temperature. As the shutdown operation mode was activated and the heat supply to the piles  
406 was stopped in Test 4 (Figs 10 and 11), there was associated reduction of soil temperature but the  
407 magnitude of temperature drop was less significant than that in the piles because of thermal inertia  
408 within the silt.

409  
410 Figure 12. Computed temperature contours of Test 3: (a) Section A-A; (b) Section B-B.

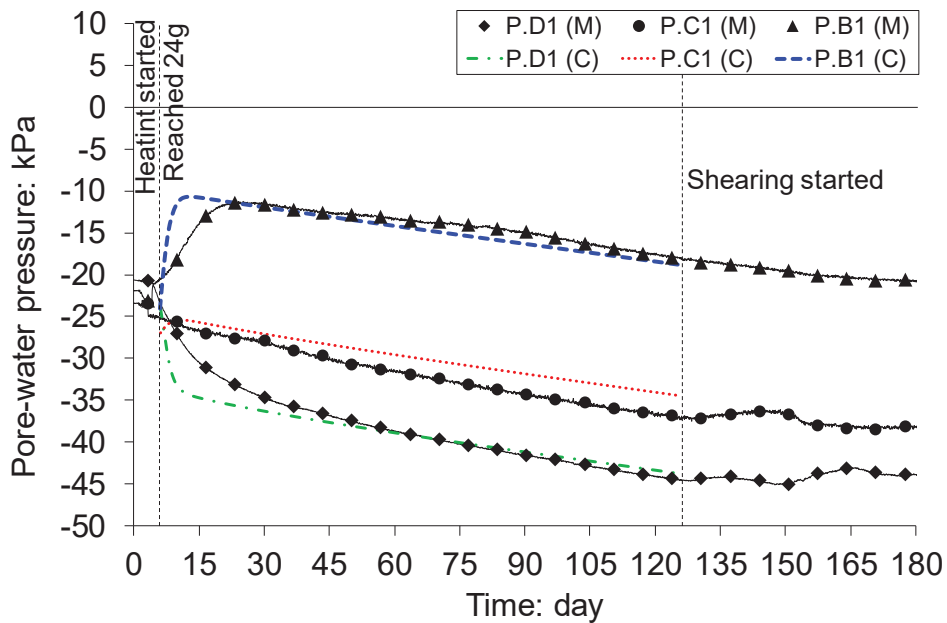

411  
412 *Pore water pressure field*

413 Figures 13(a) and 14(a) show the measured time histories and vertical distribution of PWP meas-  
414 ured at  $1D$  away from the pile centre for Test 2 using the conventional piles. When  $24 g$  was  
415 reached and maintained, there was a consistent reduction of PWP because of the dissipation of the

1  
 2  
 3  
 4 416 excess PWP during the rising- $g$  level stage and gravity-driven downward water flow. Before shear-  
 5  
 6 417 ing, the PWP ranged between -5 to -10 kPa. During shearing, there were continuous reductions of  
 7  
 8 418 PWP by approximately 10 kPa and the PWP appeared to converge to an approximately constant  
 9  
 10 419 value of -19 kPa.

420  
421 (a)

422  
423 (b)

424 Figure 13. Pore water pressure-time histories at  $1D$  from the pile surface; (a) Test 2; (b) Test 3.

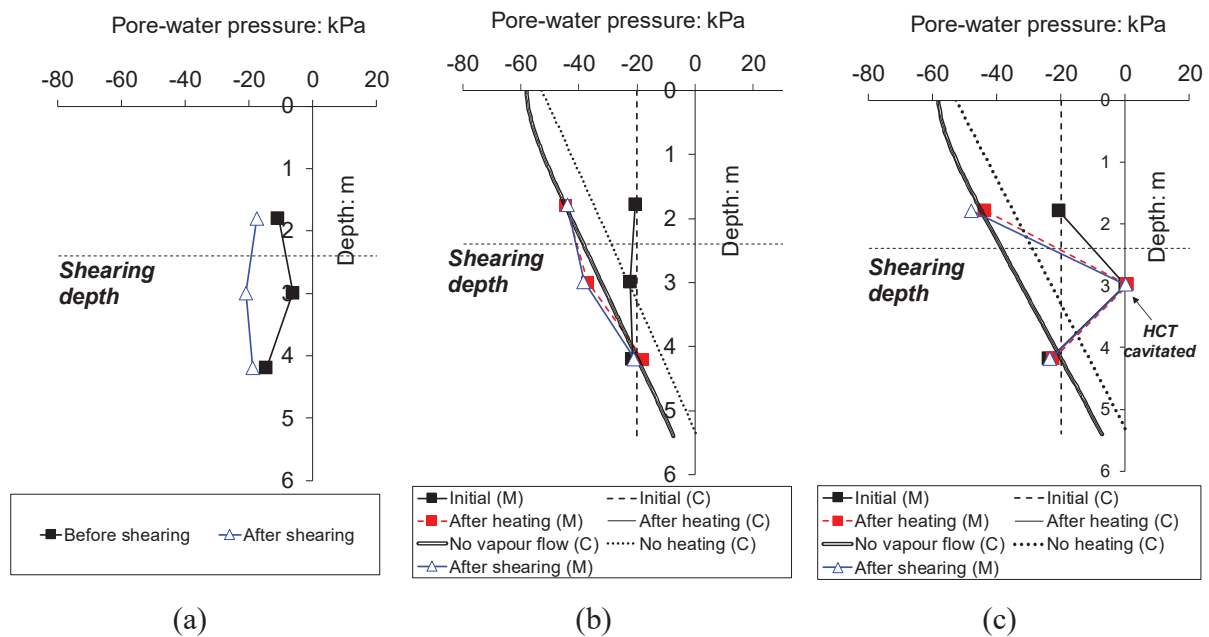

Figure 14. Vertical profiles of pore water pressure (at  $1D$  away from the pile surface) obtained during the heating and shearing phases for (a) Test 2; (b) Test 3; and (c) Test 4. Note: M and C in the bracket stands for measured and computed, respectively. In Figs (b) and (c), the computed lines for 'After heating' and 'No vapour flow' overlap.

The PWP responses, with time and with depth, of Test 3 using energy piles are depicted in Figs 13(b) and 14(b), respectively. During the first five days of pile heating, there was a substantial decrease in PWP at shallower soil depth (i.e. P.D1) with time and yet a further increase in PWP at deeper depth (i.e. P.B1), consistently found from both the measurements and simulations. This was because the initial PWP distribution was uniform with a value of -20 kPa; due to gravity, water at shallow depths (where the total head was relatively high) seeped downward. After the water redistribution during these five days, the PWP at all depths subsequently reduced with time, apparently following the same rate. The measured and computed PWP profiles after heating depicted in Fig. 14(b) both showed that the PWP distributed hydrostatically with a gradient close to the unit weight of water (i.e.  $10 \text{ kN/m}^3$ ). The computed PWP profiles for the two hypothetical cases, (i) without pile heating and (ii) without vapour flow (but with pile heating), are superimposed in the figure. In both cases, similar hydrostatic PWP distribution was found but the magnitude of PWP in case (i) was higher (i.e. less negative) whereas that in case (ii) showed no practical difference. The comparisons highlight that the primary effect of pile heating in Test 3 was an increase in soil

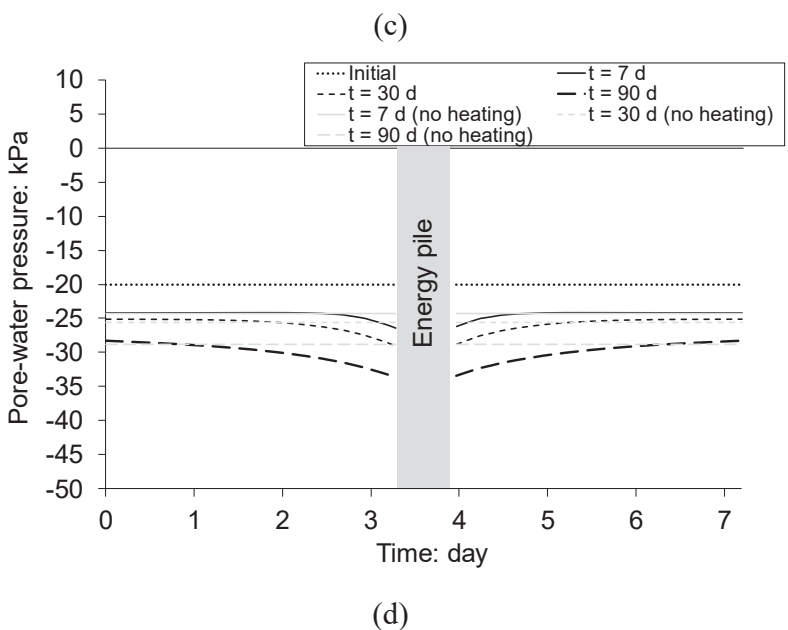

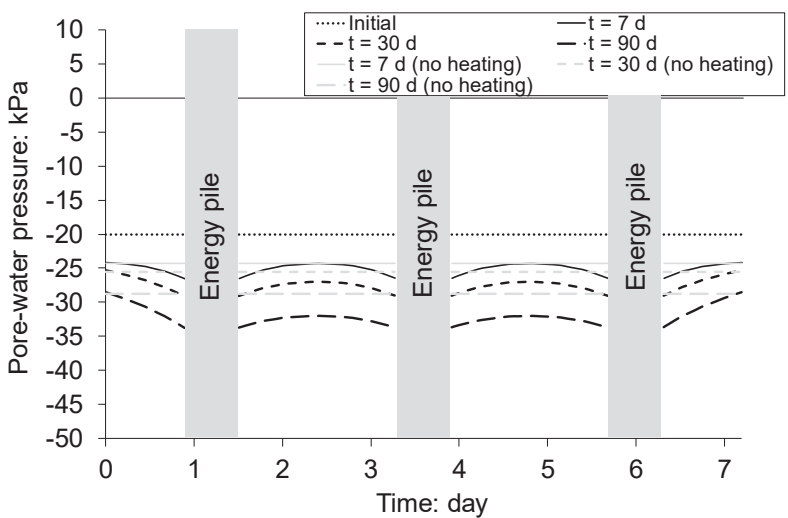

1  
2  
3  
4 444 hydraulic conductivity due to the heat-induced reduction of water viscosity (via the term  $K_{LT}(T, \psi)$   
5 in Eq. (2)). The gravity-induced downward water flow was thus accelerated by the pile heating.  
6 445 The effects of vapour transport and water-vapour exchange appeared to have only marginal influ-  
7 446 ences on the observed PWP changes. A similar phenomenon was identified in Test 4 (Fig. 14(c)).  
8 447

9  
10 448 Figures 15(a) and (b) show the computed PWP contours for Test 3 after pile heating, while  
11 449 Figures 15(c) and (d) depict the changes of horizontal PWP profiles due to pile heating across the  
12 450 shearing plane at 2.4 m depth. There was an evident drop of PWP near the pile surface as discussed  
13 451 earlier. Due to the thermal interaction between the piles (spaced  $4D$  centre-to-centre; section A-  
14 452 A), the PWP between the two piles (e.g.  $2D$  away from the pile centre) was lower than that also at  
15 453  $2D$  away from the pile centre at section B-B. Since the effects of vapour transport and vapour-  
16 454 water exchange were minimal in this system, vapour condensation, and hence any associated in-  
17 455 crease in PWP (like those identified by Baser et al. 2018), in the far field was negligible.  
18 456

#### 19 457 *Lateral response of energy pile rows*

20 458 Figure 16 shows the shear load-displacement curves obtained from all centrifuge tests. The curve  
21 459 obtained from the conventional small-size direct shear apparatus is also shown for comparison,  
22 460 after applying the appropriate scaling laws. The total vertical stress applied in this test was the  
23 461 same as that expected along the sliding plane of the LDSA. While there was a similar initial stiff-  
24 462 ness between the two unreinforced cases, the silt tested in the LDSA displayed a distinct peak  
25 463 followed by a more prominent post-peak softening response. These differences were attributed to  
26 464 the silt tested in the LDSA being drier (due to water redistribution during centrifuge spin-up) than  
27 465 that in the small shear apparatus, resulting in a higher suction and peak strength. When the silt was  
28 466 reinforced by the conventional pile row (Test 2), the system response was noticeably stiffer and  
29 467 stronger than both the unreinforced cases. The ultimate load at large displacement was 15% to  
30 468 35% higher. When the energy RC pile row was used and was operational during shearing (Test 3),  
31 469 the pile heating reduced both the initial stiffness and the peak shear load considerably compared  
32 470 to Test 2. Yet the ultimate load (at large displacement) appeared to converge to the same value as  
33 471 that obtained from the conventional RC pile case and the soil-energy pile system was more ductile  
34 472 (i.e., the difference between the peak and residual load were reduced). When the energy RC pile  
35 473 row had been shut-down before shearing (Test 4), the initial stiffness of the soil- energy pile system  
36 474 was similar to that observed in Test 3, yet the peak load was higher. The ultimate load, similarly,

480 Figure 15. Computed PWP contour of Test 3: (a) Section A-A; (b) Section B-B and computed  
481 horizontal PWP distribution at the shearing depth of 2.4 m (c) Section A-A; (d) Section B-B

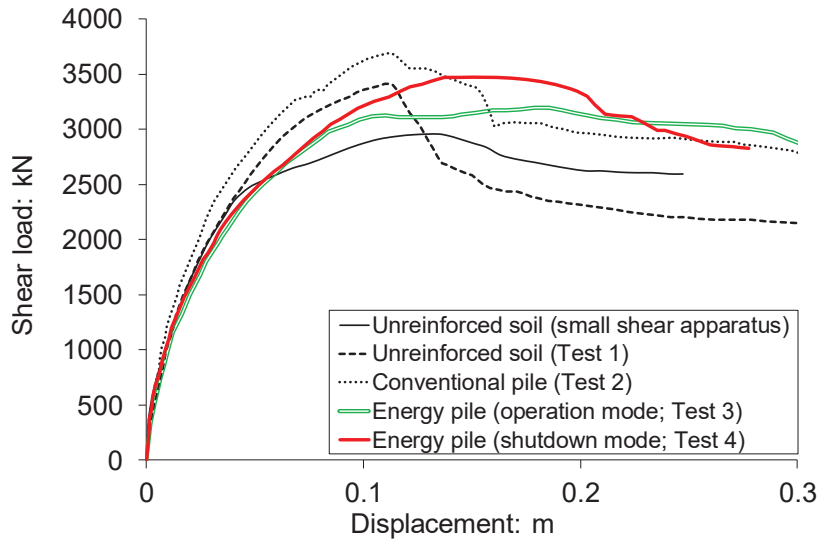

Figure 16. Measured shear load-displacement curves for the unsaturated silt with and without reinforcing by a discrete row of three conventional piles and energy piles

As the silt was heated by the energy pile row, there were two major mechanisms that would be expected to have occurred yet counteract each other. The first one was potential increases in the peak shear strength and stiffness of the unsaturated silt due to the heat-induced increase in matric suction (see Fig. 14). The second mechanism is related to thermal softening, a thermomechanical phenomenon that describes the retraction of yield loci of the soil due to temperature increase. Uchaipichat & Khalili (2009) who conducted triaxial suction- and temperature-controlled drained compression tests showed that the peak deviatoric stress of their compacted silt (similar to the one tested in the present study) reduced when the shearing took place at elevated temperatures. The temperature-induced reduction of peak deviator stress was greater when the initial suction of the silt was higher. At large strain, the deviator stress-strain curves obtained from different temperatures converged to the same single curve, regardless of the confining pressure and matric suction considered. Between these two mechanisms, the centrifuge observed shear behaviour of the soil-energy pile system in Fig. 15 appears to tend to follow the second mechanism.

The implications of these observations are that an energy pile row will act like a conventional reinforcement scheme when the heat transfer systems are inactive. During or shortly after use, there may be greater deformations observed in the slope if the external stressors take it close to

failure. However, if these are sufficient to cause the soil mass to slip, the reinforcement will prevent a sudden brittle failure (sudden large slip) and provide similar resistance to slip as a conventional pile stabilisation scheme (without the thermal functionality) in the post-failure regime.

Figure 16 shows the bending moment profiles of the central model piles instrumented in Tests 2, 3 and 4, showing snapshots at different levels of shear displacement. Note that the pile head was allowed to move freely, so moment at the pile head was set to zero. Positive bending moments correspond to tension on the back side of the pile. When the shearing took place at 2.4 m depth and reached 0.15 m displacement in the case of conventional pile (Test 2), significant moments were mobilised at the back of the bottom part of the pile in the stable soil (i.e., in the soil mass below the shearing plane), whereas much smaller moments were induced in the unstable soil above the plane. When shearing to 0.19 m, the peak moments found in the stable soil grew significantly, yet little further growth was observed in reaching 0.24 m displacement. During the entire shearing process, the moment measured near the shearing plane was close to zero, which is expected because the shear force there was maximum due to the applied lateral pressure from the moving soil. Two peak bending moments may be identified in Test 2, one smaller one in the slipping soil and another larger one in the stable soil. In particular, the bottom-most peak moment was

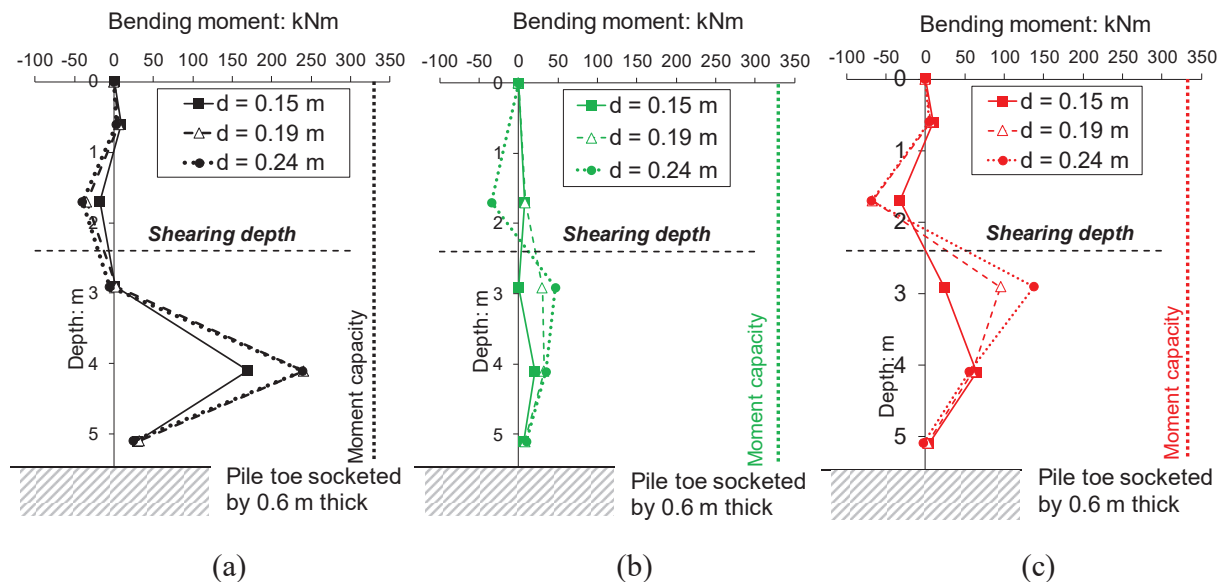

Figure 17. Mobilised bending moment profiles at different shear displacements ( $d$ ) of 0.15, 0.19 and 0.24 m for the case of (a) conventional pile (Test 2); (b) energy pile in operation mode (Test 3); (c) energy pile in shutdown mode (Test 4). Moment capacity of 336 kNm was determined by the four-point bending tests from Zhao *et al.* (2020).

526 close to the characteristic structural capacity of the model RC pile (Zhao *et al.*, 2020). Indeed, clear  
527 tension cracks were identified at the similar depth of the exhumed pile. Based on the shape of the  
528 moment profiles, “soil flow” might have taken place, as suggested by Poulos (1995). In this fail-  
529 ure mode, the soil mass above the shearing plane might flow around the upper portion of the piles,  
530 fully mobilising the soil strength in the stable mass before the pile flexural strength in the stable  
531 strata below the plane can be exceeded (Viggiani, 1981; Kanagasabai *et al.*, 2011).

532         Similar bending moment profiles were identified from the energy piles tested in Tests 3 and  
533 4, implying that “soil flow mode” might have also occurred in these cases. Yet, the magnitude of  
534 the peak bending moments in the stable strata was much smaller than that mobilised in the con-  
535 ventional pile tested in Test 2. Correspondingly, no prominent tension cracks were observed in  
536 both the central model piles tested. The depth below the shear plane at which the moment peaked  
537 appeared to be shifted to a higher elevation. These observed changes suggested stress redistribution  
538 between the soil and the energy piles due to the changes in soil behaviour upon pile heating. The  
539 reduced loading on the energy piles at similar soil deformations is consistent with the overall lower  
540 stiffness of the combined soil-pile system observed in Fig. 16. According to theoretical analyses  
541 of soil plastic flow proposed by Ito & Matsui (1975) and Poulos (1995), at a given pile spacing,  
542 piles would attract less lateral force and less bending moment when the surrounding soil is weaker,  
543 in this case, because of thermal softening by the pile heating. Although horizontal load may be  
544 induced in the pile due to its thermal expansion under lateral restraint by the soil, such an increase  
545 is deemed to be negligible due to the relatively small coefficient of thermal expansion of the model  
546 RC pile ( $15.8 \mu\epsilon/^\circ\text{C}$ ) and hence small thermal strain (compared to the soil strain during shearing).

547         These observations suggest that use of a stabilising RC pile row for additional energy transfer  
548 functionality will not attract additional flexural stress to the piles during soil displacement and  
549 therefore will not adversely affect the structural integrity of the piles under in-service conditions.  
550 However, caution should be exercised in case of excessive slope movement (i.e. the piles being  
551 loaded to the ultimate limit state), which might introduce tension cracks to the RC pile section and  
552 result in potential leakage of the heat-circulating fluid from the embedded pipes, affecting the heat  
553 exchange functionality and the subsequent serviceability of the damaged system.

4 **557 CONCLUDING REMARKS**

5  
6 558 This study has evaluated the concept of using a discretely spaced energy RC pile row in slope  
7  
8 559 stabilisation schemes to increase soil matric suction, reduce excessive temperatures on bituminous  
9  
10 560 roadways in summer and provide a de-icing solution as an alternative to gritting in winter. The key  
11  
12 561 focus has been on identifying how such use would affect the primary geomechanical stabilisation  
13  
14 562 function of the pile row. To achieve this, centrifuge model tests were conducted to measure the  
15  
16 563 shearing behaviour of unsaturated silt with and without reinforcement by conventional piles and  
17  
18 564 energy piles. **Finite element** coupled vapour-water-heat transport analysis was performed to further  
19  
20 565 understand the effects of pile heating on the responses of temperature and PWP of the soil.

21 566         Continuous heating by three closely-spaced energy piles (i.e. during operation of the energy  
22  
23 567 recovery/storage system in summer or winter) caused reduction of **pore water** pressure (increases  
24  
25 568 in soil matric suction), particularly near to the soil surface, because of enhanced gravity-driven  
26  
27 569 water flow as a result of an increase in soil hydraulic conductivity when the water viscosity reduced  
28  
29 570 due to pile heating. Although the heat-induced increase in suction might have potentially increased  
30  
31 571 the shear strength of soil in the vicinity of the energy piles, unexpectedly this mechanism did not  
32  
33 572 lead to any increase in the maximum shear capacity of the soil-energy pile system. Indeed, peak  
34  
35 573 reinforcement provided by the energy piles was lower than that observed by the conventional piles.  
36  
37 574 However, at large shear displacements, the additional resistance provided by the energy piles was  
38  
39 575 similar to that provided by the conventional piles yet significantly above the strength of the unre-  
40  
41 576 inforced soil. The shearing response of the energy pile row was more ductile than the conventional  
42  
43 577 pile case. The exact underlying mechanism behind this unexpected behaviour is unclear at this  
44  
45 578 stage, but based on existing limited knowledge of the thermo-hydro-mechanical behaviour of un-  
46  
47 579 saturated soil, it is reasonable to hypothesise that the observed reduction of shear capacity due to  
48  
49 580 the pile heating was associated with soil thermal softening, with this mechanism having over-  
50  
51 581 whelmed any beneficial effects associated with suction-induced increase in shear strength. Shear-  
52  
53 582 ing the pile-reinforced unsaturated soil mobilised pile bending moment. For the given soil type  
54  
55 583 and model RC pile design considered in this study, pile heating reduced the amount of pile moment  
56  
57 584 mobilised at all depths, possibly because of the reduction of soil strength upon thermal softening.

58  
59 585         The findings of this study suggest that the piles modified with additional energy transfer  
60  
61 586 functionality would prevent soil from a sudden brittle failure and provide similar ultimate re-  
62  
63 587 sistance to slip as a conventional pile stabilisation scheme (without the thermal functionality) in  
64  
65

1  
2  
3  
4 588 the post-failure regime. Use of a stabilising energy pile row will not attract additional flexural  
5  
6 589 stress to the piles due to the thermal operation and therefore will not adversely affect the structural  
7  
8 590 integrity of the piles during soil displacement. This suggests that the concept of using an energy  
9  
10 591 pile row within road embankments to mitigate some of the extreme weather effects associated with  
11  
12 592 climate change (i.e. reduction in road surface temperatures in summer and road de-icing in winter)  
13  
14 593 could be utilised alongside a primary role in mitigating large deformations associated with ground  
15  
16 594 slip, and warrants further study.

**Notations**

$a$	A fitting parameter of the van Genuchten (1980)'s equation
$c'$	Cohesion
$C_s(\theta)$	Volumetric heat capacities of soil
$C_L$	Volumetric heat capacities of liquid water
$C_V$	Volumetric heat capacities of water vapour
$\gamma_w$	Unit weight of liquid water
$h$	Heat exchange coefficient
$H_r$	Relative humidity
$K_L(T, \psi)$	Hydraulic conductivity of liquid water with respect to $\psi$ change
$K_V(T, \psi)$	Hydraulic conductivity of the water vapor with respect to $\psi$ change
$K_{LT}(T, \psi)$	Hydraulic conductivity of liquid water with respect to $T$ change
$K_{VT}(T, \varphi)$	Hydraulic conductivity of water vapor with respect to $T$ change
$L_0$	Latent heat of vaporisation of liquid water
$\lambda(\theta)$	Moisture-dependent thermal conductivity function
$M$	Molecular weight of water
$m$	A fitting parameter of the van Genuchten (1980)'s equation
$n$	A fitting parameter of the van Genuchten (1980)'s equation
$\phi'$	Friction angle
$q_L$	Fluxes of liquid water
$q_V$	Fluxes vapor
$Q_h$	Heat flux
$\theta_s$	Saturated volumetric water content
$\theta_r$	Residual volumetric water content
$\theta(T, \psi)$	Volumetric liquid water content
$\theta_V(T, \psi)$	Volumetric water vapor content
$R$	Universal gas constant
$\rho_w$	Water density
$S$	Matric suction
$s_e$	Air-entry value
$\sigma$	Total normal stress
$T$	Soil temperature
$T_a$	Ambient temperature
$u_a$	Pore air pressure
$u_w$	Pore water pressure
$\chi$	Effective stress parameter
$\psi$	Matric suction
