Abstract

The design of modified oligonucleotides that combine in one molecule several therapeutically beneficial properties still poses a major challenge. Recently a new type of modified mesyl phosphoramidate (or µ-) oligonucleotide was described that demonstrates high affinity to RNA, exceptional nuclease resistance, efficient recruitment of RNase H and potent inhibition of key carcinogenesis processes in vitro. Herein using a xenograft mouse tumor model it was demonstrated that miR-21-targeted µ-oligonucleotides administered in complex with folate-containing liposomes dramatically inhibit primary tumor growth via long-term downregulation of miR-21 in tumors and increase in biosynthesis of miR-21-regulated tumor suppressor proteins.

This antitumoral effect is superior to the effect of the corresponding phosphorothioate.

Peritumoral administration of µ-oligonucleotide results in its rapid distribution and efficient accumulation in the tumor. Blood biochemistry and morphometric studies of internal organs revealed no pronounced toxicity of µ-oligonucleotides. This new oligonucleotide class provides a powerful tool for antisense technology.

Significance

Sequence-specific targeting of disease-associated RNAs by new types of chemically modified antisense oligonucleotides with improved physicochemical and biological properties are still of high demand. miRNA-addressing mesyl phosphoramidate oligonucleotides represent perspective therapeutics since they reveal good bioavailability in tumor tissue, potent and long-lasting antitumor effect, high targeted specificity associated with reactivation of tumor-suppressor proteins, and physiological safety.
Antisense-based RNA targeting approaches laid the foundation for one of the powerful drug discovery platforms (1). Antisense oligonucleotides (ASOs) are short synthetic nucleic acids designed to inhibit the expression of target RNA by sequence-specific recognition.

The first generation modified ASOs are well-known phosphorothioate oligodeoxynucleotides (PS ASOs) (1, 2). Despite decades of efforts no other modification has been developed combining a number of important properties, such as high nuclease resistance, the ability to recruit RNase H and enhanced protein binding facilitating ASO uptake by the cells and accumulation in peripheral tissues (3). The PS modification currently forms the backbone of the main ASOs in clinical trials, combined with other modifications of the second or third generation, such as 2’-O-methoxyethyl (MOE), locked nucleic acid (LNA) or constrained ethyl (cEt), stabilizing duplex interactions (the gapmer oligonucleotides) (2). Despite the number of benefits one of the significant drawbacks of PS ASOs that limits its clinical utility is substantial toxicity (4–7). It was shown that toxicity of some MOE, LNA or cEt PS gapmer ASOs arises from enhanced binding to cellular proteins, resulting in RNase H1-dependent nucleolar mislocalization of paraspeckle proteins, nucleolar stress and fragmentation, upregulation of P21, and activation of caspases, leading to large-scale apoptosis (4, 5, 8).

To improve clinical performance of oligonucleotides, attempts are made to design hybrid molecules that combine in one structure several modifications. However, the preparation of mixmers complicates synthesis and increases the cost of such compounds. Design of new modified oligonucleotides that would combine in one oligomer the maximum number of therapeutic capabilities remains as relevant as ever.

Oligodeoxynucleotides containing an aromatic sulfonyl phosphoramidate group were first obtained over a decade ago but never studied as potential antisense compounds (9). Recently, we synthesized oligodeoxynucleotides with tosyl phosphoramidate group and showed that their duplex with RNA was destabilized relative to the native DNA:RNA duplex presumably due to the bulkiness of tosyl group at internucleotidic position (10). This has prompted us to investigate a
novel DNA analog that incorporates mesyl (methanesulfonyl) phosphoramidate group (μmodification), which has the smallest one-carbon side chain (Fig. 1). Oligodeoxynucleotides with a few μ-groups replacing phosphodiester (PO) group indeed showed improved RNA binding over tosyl analogs (11). Next, ASOs substituting μ-modifications for natural PO groups at every internucleotidic position were designed to inhibit oncogenic miRNAs (12), in particularly, miR-21, which is recognized as a potent oncogene and causes global dysregulation of gene expression in malignant cells (13–17). μ-Oligonucleotides demonstrated high affinity to RNA, exceptional resistance to nucleases, and potent recruitment of RNase H with increased efficiency of catalytic miRNA degradation as compared to PS ASOs. The biological potential of μ ASOs was shown in cell culture and contributes to the efficient and specific inhibition of key carcinogenic processes in vitro (12). The present investigation focuses on the study of therapeutically important characteristics of the miR-21-targeted μ ASOs as potential antitumor agents in vivo: biodistribution, specific and off-target effects, kinetics of tumor suppression and assessment of the main criteria of systemic toxicity. Herein, the enhanced in vivo potency of μ ASOs compared with PS ASOs indicates that this new oligonucleotide class represents a novel, potent tool of antisense technology.

RESULTS

Structure of chemically modified ASOs

In this work, 22-mer oligodeoxynucleotides complementary to mature miR-21 (18) and containing μ- or PS-modifications of all internucleotide bonds, termed as μ-miR-21-ON and PS-miR-21-ON, respectively, were studied (for sequences and structures see Fig. 1; Materials and Methods). As a control fully modified μ- or PS-scrambled oligodeoxynucleotides (μ-ScrON and PS-Scr-ON) of the same length with a sequence that has no homology in mammalian genome were used.
Kinetics of miRNA downregulation in vitro by µ and PS ASOs

To develop the optimal regimen of antisense therapy with µ ASOs in vivo, the kinetics of miRNAs silencing by µ ASOs (100 nM) was investigated in melanoma B16 cells that combines the main malignant features – aggressiveness, rapid proliferation, and high metastatic potential. Lipofectamine2000TM mediated transfection of B16 cells with µ-miR-21-ON causes 6 days lasting decrease in the miR-21 level with maximum downregulation observed at 72 h (SI Appendix, Fig. S1). Similar kinetics of miRNA downregulation was also evidenced for µ ASOs targeted to oncogenic miRNAs miR-155 and miR-17: the lowest level of miRNAs accounted for 80-90% decrease was reached by 72 h and was preserved up to 144 h (SI Appendix, Fig. S1). It should be emphasized that no unspecific downregulation of other miRNAs, for instance, miR155 and miR-17 was observed after cell treatment with µ-miR-21-ON (SI Appendix, Fig. S1). In turn, PS-miR-21-ON promoted no more than 2-fold decrease in the level of miR-21 observed by 48 h with the total duration of inhibition being less than 72 h (SI Appendix, Fig. S1).

Biodistribution of µ and PS ASOs in tumor-bearing mice

To study biodistribution and therapeutic potential of µ ASOs, a xenograft model of human epidermoid carcinoma KB-8-5 cells in immunodeficient SCID mice was chosen. The use of this model permits to assess a direct antitumor effect and minimize the interference of the immunity engagement in response to oligonucleotide therapy. To study biodistribution and conduct an initial analysis of pharmacokinetic parameters of the developed oligonucleotides, KB-8-5 tumor-bearing SCID mice were peritumorally or intravenously injected with 40 μg of µ- or PS- Cy5.5-modified oligonucleotides. Folatecontaining cationic liposomes F shown to efficiently deliver siRNA to KB-8-5 tumors characterized by high abundance of folate receptors were used as a delivery vehicle (19).

Data analysis showed that after peritumoral administration both oligonucleotides accumulated mainly in the kidneys and tumor tissue (Fig. 2). The content of µ ASO and PS ASO
in the kidneys after 4 h was 71% and 36% of the total amounts of the therapeutics retained in the
body (Fig. 2B). Four hours after peritumoral administration the relative content of oligonucleotides
in the tumor was 23% for μ ASO and 63% for PS ASO. By 24 h, the excretion of μ ASO slowed
and its relative content in the tumor increased to 48% (Fig. 2B). The content of
PS ASO in tumor tissue by 24 h decreases to 48% with more active accumulation in the kidneys.
As can be seen from the fluorescence imaging of mouse internal organs, most of PS ASOs
remained anchored in the area of administration, while the μ- oligonucleotide was distributed
throughout the body, providing high accumulation in the tumor tissue (Fig. 2A).

After intravenous administration the main fraction of both μ and PS ASOs is localized in
the kidneys and liver of animals. The content of μ and PS ASOs in the kidneys after 24 h was 90%
and 77%, respectively, and 16% of PS ASO accumulated in the liver (Fig. 2A and B).
Accumulation of oligonucleotides in tumor tissue after intravenous administration was poor: by 24
h the relative content of both oligonucleotides did not exceed 2% (Fig. 2B). According to the
obtained data peritumoral injections were used to study the antitumor potential of μ ASOs in
vivo.

Confocal microscopy images of tumor node cryosections confirmed the accumulation of μ
and PS oligonucleotides in tumor tissue (Fig. 2C, SI Appendix, Fig. S2). According to the results
of confocal microscopy, both oligonucleotides localize in the intercellular space as well as in the
cytoplasm and nucleus of tumor cells 24 h after injection.

**Tumor growth retardation in vivo by miR-21-targeted μ and PS ASOs**

The antitumor potential of μ ASOs was studied using a xenograft KB-8-5/SCID model.
miR-21 inhibitory effect of μ ASO in KB-8-5 tumor cells was preliminarily confirmed in vitro by
stem-loop PCR (SI Appendix, Fig. S3). At day 12 when primary tumor node was formed, 10 μg of
μ or PS ASOs in complex with cationic liposomes F were peritumorally administered to animals.
In total, 4 injections were given at three-day intervals (Fig. 3A). This treatment regimen was used
based on the data on stability of the oligonucleotides in serum, kinetics of miRNA downregulation and biodistribution. Control groups received unloaded liposomes F, or OptiMEM culture medium.

Analysis of kinetics of tumor growth revealed that PS-miR-21-ON despite significant accumulation in tumor tissue did not promote any statistically reliable retardation of tumor growth and its effect was statistically insignificant in comparison with control PS-Scr-ON and unloaded liposomes F (Fig. 3B). In turn, μ-miR-21-ON provided 8-fold reduction of tumor volume compared to control, 5-fold compared to PS-miR-21-ON and 4-fold compared to μ-ScrON (Fig. 3B). Moreover, application of μ-miR-21-ON contributed to considerable increase in the tumor doubling time that in average was 2-fold longer than in other groups (Fig. 3C). Comparison of tumor weights showed that the average tumor weight in μ-miR-21-ON-injected group is up to 12-fold less than in control and about 6-fold less compared to μ-Scr-ON (Fig. 3D). In contrast, tumor weight in groups injected with PS ASOs was only 2-fold less than in the control with no reliable differences between PS-miR-21-ON and PS-Scr-ON (Fig. 3D).

To confirm that antitumor effect of μ-miR-21-ON was miR-21-mediated, the levels of miR-21 and its direct protein targets PTEN and PDCD4 in tumor tissue were evaluated at the end of the experiment. μ-miR-21-ON administration caused 50% decrease in the miR-21 level compared to control (Fig. 4A), while PS-miR-21-ON administration reduced the level of miR-21 only by 25% (Fig. 4A). It is noteworthy that the observed effect of μ-miR-21-ON was specific: no detectable downregulation of other miRNAs, such as miR-155 and miR-17 in tumor tissue was observed (Fig. 4B).

After inhibition of oncogenic miR-21 the activation of biosynthesis of tumor suppressor proteins, among which PTEN and PDCD4 represent the most well-established targets might be expected (20, 21). Indeed, the level of these proteins was significantly enhanced after μ-miR-21ON treatment: 1.5-fold for PDCD4 and 3.5-fold for PTEN compared to control, while μ-Scr-ON, PS-miR-21-ON and PS-Scr-ON had no detectable impact on the expression of these proteins (Fig. 4C and D).
Histological analysis of tumors KB-8-5 after treatment with miR-21-targeted μ and PS ASOs

Microscopic examination of KB-8-5 carcinomas showed that tumor tissue is represented by polymorphic epidermal cancer cells with acidophilic cytoplasm, large nucleus with 2-3 hyperchromic nucleoli and high mitotic rate (Fig. 5). Necrotic changes and inflammatory infiltration, represented predominantly by lymphocytes with a small number of neutrophils and macrophages located at the border of unaltered tumor tissue and necrosis, were found in the tumors of all groups (SI Appendix, Table S1). However, in the group treated by μ-miR-21-ON areas of necrosis and inflammation were much smaller than in other groups (SI Appendix, Table S1). The smaller size of the primary tumor node in this group and its trophic and blood supply may have significant influence on these parameters.

Histological analysis showed that tumor tissue of μ-miR-21-ON-treated mice is characterized by 4-fold reduced mitotic activity as compared to the control group and 2-fold reduced as compared to groups treated with μ-Scr-ON and PS-miR-21-ON (Fig. 5A and B). Morphometric analysis of caspase-3 immunohistochemical images demonstrated that non-treated KB-8-5 tumor tissue has small number of apoptotic cells (Fig. 5C and D). μ-miR-21-ON treatment led to 12.8-fold increase in the number of caspase-3 positive cells as compared with the control group (p=0.0001; Fig. 5D). Administration of oligonucleotides regardless of target specificity and modification type led to an increase in the number of apoptotic cells in tumor tissue, but the average number of apoptotic cells in μ-miR-21-ON treated group was 1.5-fold higher compared to groups of mice injected with other oligonucleotides. However, due to the increase in the scatter of experimental data statistically significant differences between the number of caspase-3 positive cells were observed only after the treatment with μ-miR-21-ON and PS-Scr (p=0.0005; Fig. 5D).
Toxicity of oligonucleotides

Biochemical blood tests showed that μ ASOs exhibited no toxic effect on the liver and kidneys of mice. No statistically significant differences in blood indicators, such as ALT, ALK, total protein, creatinine and BUN, between the groups (including healthy mice) were found (SI Appendix, Table S2).

The development of KB-8-5 tumor pe se has distinguishable toxic effect on the liver manifested in increase in destructive changes (dystrophy + necrosis) up to 35% from the entire liver parenchyma (SI Appendix, Fig. S4 and Table S3). Administration of ASOs caused no additional detrimental effect on the liver. Moreover, in the groups treated with μ-miR-21-ON or PS-miR-21-ON, a significantly reduced percentage of destructive changes in the liver parenchyma is observed, which reflects a therapeutic effect. Tumor development as well as applied therapy did not affect the regenerative properties of the liver: no changes in numerical density of binuclear hepatocytes were observed (SI Appendix, Table S3).

Morphometric analysis of kidneys showed that upon tumor development the normal kidney tissue reduced to about 75% (SI Appendix, Table S4). In the group treated with PS ASOs some increase in destructive changes in the kidney tissue was observed – 25-27% (compared to 23-24% in other experimental groups), manifested in dystrophy of the epithelium of the proximal tubules (SI Appendix, Fig. S4 and Table S4). Despite the predominant localization of both μ and PS ASOs in the kidney, signs of dystrophy are most pronounced only in the groups injected with PS ASOs.

DISCUSSION

Over the history of development of nucleic acid therapeutics, more than two dozen modifications of internucleotidic bonds in oligonucleotides have been proposed, in which the phosphodiester backbone was replaced by different variants of phosphorothioates, methylphosphonates, phosphoramidates, phosphotriesters, phosphorodithioates or derivatives with guanidinium groups or S-methylthiourea motifs (22–24). Among the proposed modifications, the
most successful are phosphorothioates. Although this chemical substitution is endowed with a number of beneficial properties, the presence of serious shortcomings (4, 5, 25–27), has led to a search for new improved modifications. In this regard the μ-modification has a number of important favorable properties including exceptional resistance to nucleases, high affinity for the RNA targets and faster RNA degradation by RNase H compared to PS ASOs (12).

The listed biological characteristics of μ ASOs are directly reflected in the duration of functioning within the cell and the strength of silencing effect. The visible effect of μ ASOs lasts for at least 6 days achieving 80-95% downregulation of miRNA level, while PS ASOs caused only a two-fold decrease and it expired after 1 day. The main in vitro and in vivo characteristics of μ-oligonucleotides in comparison with phosphorothioate analogues are summarized in Table 1.

An important difference between μ and PS ASO is the ability of phosphorothioates to penetrate inside the cells in a carrier-free mode (28, 29). In the study of antitumor activity of μmiR-21-ON in vivo both oligomers were enclosed in folate-containing lipoplexes in order to equalize the conditions of their delivery to tumor cells. The biodistribution data showed that μ ASO rapidly spread throughout the body, ensuring efficient accumulation in tumors, while phosphorothioate oligonucleotides are characterized by anchoring in the area of administration and lower penetration efficiency into the tumor tissue. At 24 h post injection both μ- and PSASO were almost equally distributed between tumor and kidney (Fig. 2).

The study of antitumor potential showed that μ-miR-21-ON provides drastic retardation of tumor growth, up to 90% 3 days after the first injection, which lasted up to 30 days until the end of the experiment. The antitumor effect of μ-miR-21-ON was accompanied by a significant decrease in mitotic activity and stimulation of pro-apoptotic, but not necrotic behavior of tumor cells. μ-miR-21-ON administrated to mice specifically decreased miR-21 level in tumor observed even a week after the last injection, that was not the case for PS-miR-21-ON therapy. Moreover, during this period μ-miR-21-ON-mediated increase in expression of tumor-suppressor proteins such, as PTEN and PDCD4, is maintained. These data demonstrate specific and potent
therapeutic effect of µ-miR-21-ON, whereas the effect of PS-miR-21-ON is not so pronounced and unspecific. Earlier it was noticed that, efficient uptake of PS ASOs by cells does not always result in pharmacologically functional intracellular pathway and therapeutic activity (30, 31).

According to the results of in vivo experiments, it seems that µ-Scr-ON is exerting some effects on tumor cells. The obtained data show that administration of oligonucleotides of any type, regardless of target specificity, leads to a moderate non-targeted effect and an increase in the scatter of experimental parameters within the group. It should be emphasized that there were no statistically significant differences between the effects of µ-Scr-ON, PS-Scr-ON as well as PS-miR-21-ON. Moreover, our experiments have shown that no decrease in the level of miR-21, miR-17 or miR-155 was detected in response to µ-Scr-ON, thus additionally indicating the nontargeted systemic response to oligonucleotide administration. It cannot be excluded that this nontargeted effect can be not only of negative nature, resulting from general cytotoxicity, but also have a positive character, providing an immunomodulatory or immunostimulating effect, leading to tumor regression.

The use of targeted folate-equipped cationic liposomes allowed not only to balance the delivery of µ and PS ASO into the tumor, but also to reduce the dose of the administered compounds, as well as mitigate their possible toxicity. For instance, in vivo administration of PS ASOs in a carrier-free mode requires doses 20 mg/kg for the inhibition of tumor growth (32). Application of targeted delivery systems provides the decrease in PS ASOs dose to 2 mg/kg (10 µg/mice), which is sufficient for their effective accumulation in tumor tissue (33). The study of blood biochemistry showed that neither the presence of a tumor, nor the therapy performed, have an effect on the level of liver and kidney enzymes. Moreover, it has been shown that the effect of both µ- and PS ASOs on the tumor process apparently reduces the total destructive changes in the liver tissue.

The other side of the ability of phosphorothioates to circulate in the body for a long time is the off-target effects associated with non-specific interactions. The use of µ-oligonucleotides with
higher therapeutic performance formulated in cationic liposomes or other nanoparticles or conjugated to some chemical moieties that interact with cell specific receptors for effective tissue delivery, seems to be safer and advantageous. In this direction, the use of N-acetylgalactosamine (GalNAc) moiety, providing interaction with asialoglycoprotein receptors, conjugated to antisense oligonucleotide was shown to greatly expand the therapeutic opportunities of ASOs (34–36). Conjugation of GalNAc ligand to gapmer PS ASOs attenuates toxicity and promotes penetration into cells by a productive endocytic pathway that leads to a 30-fold increase in therapeutic potency and at least a 40-fold decrease in the dosage of PS ASOs (35, 37).

The high performance of antisense therapy in vivo is determined to a large extent by the appropriate RNA target choice. Selected in the study miR-21 represents a crucial regulator of plethora of cellular processes, such as proliferation, differentiation, apoptosis, migration, etc. (38–41). As a result, inhibition of aberrant hyperactivity of miR-21 in tumor tissue leads to global changes in cellular signaling pathways and promotes manifold reinforcement of tumor suppressor protein synthesis such as PTEN, PDCD4, RhoB, LATS1, MGMT and TP53, exerting potent anti-tumor action on several carcinogenesis processes simultaneously (42, 43).

In conclusion, the designed oligonucleotides are worth attention as they are new highly effective uniformly modified DNA analogs that do not require additional modifications and substitutions, which synthesis is easily acceptable in solid-phase platform. The biological antitumor potential of µ ASOs targeted to highly oncogenic miR-21 is successfully realized in vivo, leading to a drastic retardation of tumor growth in mice, contributing to the effective and specific inhibition of key carcinogenesis processes – reduction of tumor cell mitotic activity and induction of apoptotic cell death. Thus, mesyl phosphoramidate oligonucleotides are a novel potent tool of antisense technology and, in certain cases, an attractive alternative to phosphorothioate ASOs.

MATERIALS AND METHODS
Oligonucleotides

Mesyl phosphoramidate (μ) oligonucleotides were assembled by automated solid-phase synthesis from commercial 5’-dimethoxytrityl (DMTr) β-cyanoethyl N,N-diisopropyl 3’-phosphoramidites and Controlled Pore Glass supports by substituting Staudinger reaction with methanesulfonyl azide (0.5 M in acetonitrile, 30 min at ambient temperature) for aqueous iodine oxidation in each cycle of nucleotide incorporation as described previously (11). After the completion of the synthesis, oligonucleotides were cleaved from the polymer support and deprotected by standard ammonia treatment. Phosphorothioate (PS) oligodeoxynucleotides were prepared by sulfurization with Sulfurizing Reagent II (3-(((dimethylaminomethyliden)amino)-3H-1,2,4dithiazol-3-thione) from (Glen Research, USA) following manufacturer’s protocol. Analysis and purification of μ-oligonucleotides were performed by electrophoresis in 20% denaturing PAGE. The bands in the gels were visualized by UV shadowing, excised, and oligonucleotides were eluted with 0.3 M NaClO4, desalted on NAP-25 column by elution with deionized water, and freeze-dried. To obtain Cy5.5-labeled oligonucleotides, the respective 3’-aminoalkyl mesyl phosphoramidate and phosphorothioate oligonucleotides assembled on 3’-Amino-modifier C7 CPG (Glen Research, USA) were acylated with Cy5.5 N-hydroxysuccinimide ester (Lumiprobe, Russia) and purified as described above.

The following oligonucleotides were prepared for the study (symbols μ and s designate mesyl phosphoramidate and phosphorothioate internucleotidic groups, respectively):

μ-miR-21-ON 5’-TμCμAμCμAμTμAμGμTμCμGμTμAμTμAμAμGμCμTμA

Transfection of tumor cells with ASOs

Transfection of mouse B16 melanoma cells (obtained from the Cell Culture Bank of the Blokhin National Medical Oncology Research Center, Moscow, Russia) was performed by using
Lipofectamine2000™ (Invitrogen, USA) according to the manufacturer’s protocol as described previously (12). The cells were incubated at 37 °C in a humidified atmosphere with 5% CO₂ for 4 h. Then the medium then was replaced with DMEM containing 10% FBS and 1% antibiotic antimycotic solution (10,000 μg/mL streptomycin, 10,000 IU/mL penicillin, and 25 μg/mL amphotericin), and the cells were further cultivated for 144 h.

**Preparation of the complexes of cationic liposomes and oligonucleotides**

Prior to use in *in vivo* studies, the cationic folate-containing liposome F (19) and modified oligonucleotide were mixed to form lipoplexes in a serum-free Opti-MEM by vigorous mixing of equal volumes of liposomes and respective ASO solutions in Opti-MEM taken at 100 μg/ml concentration. Lipoplexes were prepared at N/P ratio 4/1, where N/P is a ratio between nitrogen atoms of polycationic lipid and lipid helper in liposomes and phosphorus atoms of oligonucleotides. The resulting mixtures were incubated for 20 min at room temperature and used for *in vivo* treatment.

**Mice**

Male 10-12 week-old SCID mice were kept with a natural light regime on a standard diet for laboratory animals [GOST (State Standard) R 5025892] in compliance with the international recommendations of the European Convention for the Protection of vertebrate animals used for experimental studies (1997), as well as the rules of laboratory practice in the performance of preclinical studies in the Russian State Standards (R 51000.3–96 and 51000.4–96). The experimental protocol (#53) was approved by the Committee on the Ethics of Animal Experiments with the Institute of Cytology and Genetics SB RAS).

**In vivo biodistribution studies**

*In vivo* real-time fluorescence imaging was used to evaluate the distribution of Cy5.5-labeled μmiR-21-ON and PS-miR-21-ON in KB-8-5 tumor-bearing SCID mice. The In-vivo MS FX PRO
Imaging System (Carestream, USA) was used to obtain X-rays and, concurrently, near-infrared fluorescence (NIRF) images (Cy5.5: excitation 620 nm, emission 700 nm). Mice (n=3 per each group) were injected intravenously (200 μl) or peritumorally (100 μl) with 40 μg per mouse of Cy5.5-labeled μ-miR-21-ON or PS-miR-21-ON precomplexed with liposomes F. Animals were anesthetized with Isoflurane and placed on a heating tray (37 °C). The fluorescence (10 s exposure) and X-ray (15 s exposure) scans were performed at 4 and 24 h post injection. At the end of the experiment, mice were sacrificed and lungs, heart, liver, spleen, kidneys, and tumor were collected and fluorescence intensity of each organ was detected. Two parameters reflecting the efficiency of Cy5.5-labeled oligonucleotides accumulation in the organs were used for comparison: organ fluorescence intensity, measured in relative fluorescent units (RFU), and the percentage of organ fluorescence intensity relative to the total fluorescent intensity of all organs. Images were batch exported as 16-bit tiffs, and overlays were completed in Adobe Photoshop CS3 (v 10.0).

**Confocal microscopy**

After imaging, tumors were immediately mixed with Tissue-Tek O.C.T. (Sakura) and frozen in liquid nitrogen. The samples were kept at −70°C until processing. Sections 7 μm thick were cut in a Microm HM 505N cryostat (Microm) at −21°C. The cryosections of tumor tissues were stained with DAPI and phalloidin-TRITC according to the standard protocol and mounted in ProLong Gold Antifade Mountant (Life Technologies). Finally, the cryosections were observed using an LSM 780 confocal fluorescent microscope (Carl Zeiss) at 20×magnification using bandpass (BP) 420 – 480 nm, BP 505 – 530 nm, and long-pass (LP) 560 nm optical filters.

Microscopic analysis was carried out at the Multiple-access Center for Microscopy of Biological Subjects (Institute of Cytology and Genetics SB RAS, Novosibirsk, Russia).
Antitumor studies in vivo

Human epidermoid carcinoma KB-8-5 tumors were initiated in SCID mice by subcutaneous injection of KB-8-5 cells (generously provided by Prof. M. Gottesman NIH, USA), 10^6 in 0.1 ml in sterile saline buffer, into left flank. At day 12 after transplantation, when tumors began to be palpable, mice were divided into six groups according to further treatment (n=7 mice per group): (1) control (Opti-MEM); (2) F (unloaded folate-containing liposomes F); (3) µ-miR-21-ON; (4) µ-Scr-ON, (5) PS-miR-21-ON and (6) PS-Scr-ON. Oligonucleotides precomplexed with liposomes F at N/P ratio 4/1 were peritumorally injected at a concentration 10 µg per mice every four days. Four injections were made in total. The dose was calculated according to the data on efficiency of nucleic acids delivery using folate-containing liposomes (19) to ensure an intratumorlal concentration of at least 100 nM, which provides an efficient decrease in miR-21 level (12) (see also SI Appendix, Fig. S1). The tumor volumes were measured every 3 days using calipers in investigator-blinded fashion. Tumor volumes were calculated as V = (π/6 × length × width × height). At day 30 animals were sacrificed, tumors and internal organs including livers and kidneys were collected and fixed in 10% neutral-buffered formalin (BioVitrum, Russia) for further histological analysis. A quarter of each tumor node was collected to isolate total RNA and to prepare lysates for western blot analysis. Tumor doubling time (DT) was estimated as: DT = (t – t₀) × ln 2/(ln V – ln V₀), where (t – t₀) indicates the length of time between two measurements of tumor size and V₀ and V denote the tumor volume at two points of the measurement (44).

qPCR

After treatment with oligonucleotides, total RNA was isolated using TRIzol Reagent (Invitrogen, USA) according to the manufacturer’s protocol. After in vitro transfection of mouse B16 melanoma cells total RNA was extracted from tumor cells at time points 24, 48, 72, 96 and 144 h. After in vivo therapy RNA from human epidermoid carcinoma KB-8-5 tumor tissue was isolated at day 30 by homogenization of tumor samples in TRIzol. The level of miRNAs in B16 cells or KB-8-5 tumors was measured using stem-loop qPCR technology (45, 46). cDNA synthesis was carried out
using SuperScript III reverse transcriptase (SSIII RT, Invitrogen, USA) as previously described (47, 48). The RT and PCR primers used in the study are listed in Table S5. PCR amplification was carried out using BioMaster HS-qPCR SYBR Blue mix (Biolabmix, Russia) according to the manufacturer’s protocol. The obtained qPCR data were analyzed by standard Bio-Rad iQ5 v.2.0 software. For each sample, the threshold cycle (Ct) was determined. Quantitative assessment of the level of transcripts representation and relative miRNA expression was performed by comparing the Ct values for miRNA and U6 snRNA used as a reference.

**Western Blot analysis**

To prepare cell lysates from KB-8-5 tumors, tumor tissue specimens were homogenized in RIPA buffer (Thermo Scientific, USA) using an electric homogenizer followed by centrifugation at +4 °C (12 000 rpm, 20 min). Collected cell lysates were separated in 12.5% SDS-PAGE and transferred to a PVDF membrane using a semi-dry transfer. Western Blot analysis was performed as described earlier (47, 48) using primary antibodies against PTEN (ab154812, Abcam, UK, 1:800), PDCD4 (ab79405, Abcam, UK, 1:1000) GAPDH (ab9485, Abcam, UK, 1:2000) and secondary HRP-conjugated goat anti-rabbit antibodies (ab6721, Abcam, UK).

**Histology**

For histological analysis, the specimens of fixed tumors, kidneys and livers from each animal were dehydrated in ascending ethanols and xylols and embedded in HISTOMIX paraffin (BioVitrum, Russia). Paraffin sections (5 μm) were sliced on a Microm HM 355S microtome (Thermo Fisher Scientific, USA) and stained with hematoxylin and eosin, microscopically examined and scanned. Tumor sections for immunohistochemical (IHC) studies (3-4 μm) were de-paraffinated and rehydrated; antigen retrieval was carried out after exposure in a microwave oven at 700 W. The samples were incubated with the caspase-3 (ab2302, Abcam, USA) specific antibodies according to the manufacture’s protocol. Next, the sections were incubated with secondary HRP-conjugated antibodies (Spring Bioscience detection system, USA), exposed to
DAB substrate, and stained with Mayer’s hematoxylin. Images were obtained using Axiostar Plus microscope equipped with AxioCam MRc5 digital camera (Zeiss, Germany) at 100× and 400× magnifications. Twenty random fields were studied in each specimen, comprising 140 fields for each group of mice.

Morphometric analysis of tumor, liver and kidney sections was performed by point counting, using a counting grid which consists of 100 testing points in a testing area equal to 3.2×10^6 μm^2. Ten to fifteen random fields were studied in each specimen, comprising 70-100 fields for each group of mice in total during morphometric analyses of liver and kidney and twenty-fifty random fields were studied in each specimen, comprising 140-350 fields for each group of mice in total during morphometric analyses of tumors. Morphometric analysis of tumor tissue included evaluation of the volume densities (Vv, %) of unaltered tumor tissue, lymphoid infiltration, necrosis, total destructive changes (lymphoid infiltration + necrosis) and numerical density (Nv) of mitoses and caspase-3 positive cells in tumor tissue. The ratio of unaltered tumor tissue to mutilated tumor tissue was estimated.

The volume density (Vv, %) representing the volume fraction of tissue occupied by this compartment was determined from the points lying over this structure and calculated using the following formula: Vv = (Pstructure/Ptest) × 100%, where Pstructure denotes the number of points over the structure and Ptest denotes the total number of test points, in this case 100. The numerical density (Nv) indicating the number of particles in the unit tissue volume was evaluated as a number of particles in the square unit, 3.2×10^6 μm^2 in this case.

Statistics

The data obtained were statistically processed using one-way ANOVA and post-hoc Tukey test (p ≤ 0.05). The statistics package STATISTICA version 10.0 was used for this analysis.
ACKNOWLEDGMENTS

This work was funded by Russian Science Foundation (Grant #19-74-30011), the Russian State funded budget project of ICBFM SB RAS # AAAA-A17-117020210024-8 and the Russian Foundation for Basic Research (grants Nos. 18-515-05007 and 18-515-57006). The authors thank Dr. B.P. Chelobanov for synthesis of Cy5.5 labeled oligonucleotides.

The volume density (Vv) represents the volume fraction of tissue occupied by this compartment. The numerical density (Nv) indicates the number of morphological structures in the unit tissue volume. Vv, % ×100. Nv ×400. *, †, ‡, § statistically significant differences from healthy mice, control, F, µ-Scr and PS-Scr, respectively (p < 0.05).
