Introduction: Metachromatic leukodystrophy (MLD) is a rare neurometabolic disorder caused by deficiency of arylsulfatase A (ARSA), leading to accumulation of sulfatides in the central and peripheral nervous systems, and subsequently progressive demyelination, neurodegeneration, loss of all motor and cognitive skills and early death. **Methods:** We present long-term results from an integrated analysis of 39 patients with early-onset MLD (19 late infantile, 20 early juvenile) treated with autologous *ex vivo* hematopoietic stem cell gene therapy (atidarsagene autotemcel, "arsa-cel") across two prospective clinical trials (n=30) and expanded access frameworks (n=9). Arsa-cel consists of autologous $CD34^+$ cells transduced *ex vivo* with a lentiviral vector encoding for the human *ARSA* gene. After busulfan conditioning, arsa-cel was administered intravenously. Clinical outcomes were compared with natural history (NHx) data from 49 untreated early-onset MLD patients. **Results:** The median length of follow-up was 6.76 years (range 0.64-12.19). All patients demonstrated stable multilineage engraftment of gene-corrected cells and restoration of ARSA activity in peripheral blood mononuclear cells to normal or supranormal levels by 3 months post-treatment and restoration in cerebrospinal fluid to normal levels by 3-6 months post-treatment, which were sustained throughout follow-up. The risk of experiencing severe motor impairment or death was significantly reduced in the pre-symptomatic late-infantile (PSLI, $p<0.001$), pre-symptomatic early-juvenile (PSEJ, $p=0.042$), and early-symptomatic early-juvenile (ESEJ, able to walk independently and without cognitive impairment prior to treatment, $p<0.001$) treated subgroups versus MLD subtype-matched NHx patients. Arsa-cel treatment resulted in substantial improvements in motor and cognitive outcomes as compared with NHx, particularly among patients treated before symptom onset. Over 95% (25/26) of treated PSLI and PSEJ patients retained the ability to walk at last follow-up, and most treated patients showed clinically meaningful preservation of cognitive abilities and speech. In contrast, most NHx patients experienced rapid motor and cognitive decline and loss of speech, progressing to a severely debilitated state or death. Three treated patients died, all considered unrelated to arsa-cel. There were no serious adverse events related to arsa-cel, no malignancies, and no evidence of abnormal clonal expansion or replication-competent lentivirus. The most common adverse events (AEs) were consistent with the known safety profile of busulfan or symptoms of MLD. The only arsa-cel-related AEs were 6 events of transient and low titer anti-ARSA antibodies with no impact on pharmacodynamic or clinical outcomes. **Conclusions:** With up to 12 years follow-up in the earliest treated patient and a cumulative 251 patient-years of follow-up, arsa-cel shows a favorable benefit-risk profile with clinically meaningful, sustained efficacy, preventing severe motor and cognitive impairment, preserving speech, and slowing disease progression in early-onset MLD patients.

2. *In Vivo* Generation of Both CAR T Cells and CAR NK Cells Using a CD7 Targeted Lentiviral Vector

Karla F. Mullen, Daniel Grubaugh, Kayla R. Welsh, Jeffery Foss, Julia L. A. Nguyen, Nishi Gheewala, Leticia Kuri-Cervantes, James I. Andorko, Bruce C. Schnepp, Timothy D. Culp, Philip R. Johnson

Interius BioTherapeutics, Philadelphia, PA

CAR-T cell therapy has shown remarkable clinical efficacy against various cancers, including hematologic malignancies. CAR-NK cells have shown promising results in cancer therapy, especially B-cell lymphoma, with a lower risk of GVHD, serious cytokine release syndrome (CRS) and immune effector-cell associated neurotoxic syndrome (ICANS) compared to allogenic CAR-T cells[1]. INT2104 utilizes a lentiviral vector platform that incorporates CD7-targeting to specifically transduce T cells and NK cells upon intravenous (i.v.) administration. Here we describe the ability of a single i.v. administration of INT2104 to transduce both T and NK cells *in vivo* generating functional CAR20+ cells resulting in the depletion of CD20+ B cells. *In vitro* assessments of INT2104 confirmed transduction of both CD7+ NK cells and T cells, including CD4+ and CD8+ subsets. A humanized CD34-engrafted NSG-Tg (Hu-IL15) mouse model, which constitutively expresses human interleukin-15 to enhance NK-cell development in these mice, was utilized to demonstrate effective NK cell transduction following INT2104 administration. Mice receiving a single bolus INT2104 dose of 1×10^7 transducing units by tail vein injection were compared to control mice receiving no vector. Weekly analysis of blood confirmed CD20+ B cell depletion compared to untreated control mice. At select timepoints throughout the study, the distribution and persistence of transduced CAR+ NK cells and T cells was assessed examining select tissues from euthanized animals. Beginning on Day 7 post INT2104 administration, CAR T and NK cells were detected in bone marrow, spleen, and liver. After demonstrating targeted gene delivery to T and NK cells using humanized mouse models, CAR20 vector was administered i.v. to cynomolgus macaques. Depletion of peripheral blood B cells in vector-treated NHPs was evident as early as Day 4 post administration. The complete absence of circulating B cells was maintained in one animal and analysis of secondary lymphoid organs in this animal confirmed

systemic B cell depletion at necropsy 1-year post treatment. Separately, to demonstrate that both CAR+ T cells and NK cells were generated in NHPs following i.v. administration of a CAR20 vector, two NHPs were treated with CAR20 vector and sacrificed 4 days post treatment. Immunohistochemical analyses of spleen and liver were conducted with an anti-CAR antibody and markers for T cells (CD3), NK cells (NKG2A), as well as hepatocytes (HNF4α). CAR+ cells were detected in spleen with CAR+ signal colocalizing to both CD3+ T cells (Figure 1a) and NKG2A+ NK cells (Figure 1b). No CAR+ hepatocytes were detected among the 8685 hepatocytes present in the representative liver sections analyzed to date. These data highlight the selectivity in targeting and transducing CD7+ T cells and NK cells, with no off-target transduction observed in hepatocytes. A FIH study for INT2104 is scheduled to begin in 4Q2024.

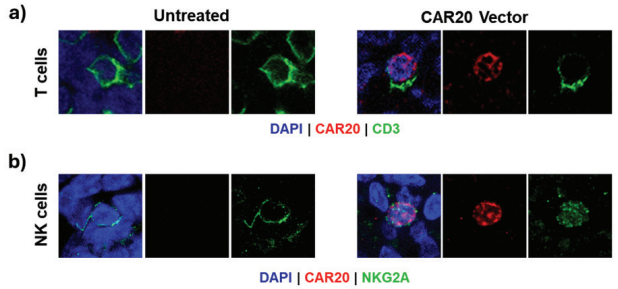

Figure 1: CD7 targeted CAR20 vector treatment in NHPs results in CAR+ T cells and NK cells. Representative CD3+ T cells (a) and NKG2a+ NK cells (b) colocalize with CAR+ signal in NHP spleen.

3. A Recombinant Human Bocavirus Vector Delivers Therapeutic Levels of CTFR to Cystic Fibrosis Primary Human Airway Cells and Transduces Airway Epithelium *In Vivo*

Jeff Moffit, Salvatore Iovino, Graham Casey, Leila Malkoc, Gillian Payne, Josh Merritt, Robert M. Kotin, Marc Abrams, Joel Schneider

Carbon Biosciences, Waltham, MA

Gene therapies for severe pulmonary diseases, including cystic fibrosis (CF) could achieve meaningful clinical outcomes if the physical and cellular barriers of airway epithelial cell transduction could be overcome. Current viral-based gene delivery approaches are also limited by genome capacity and immunogenicity. Human Bocavirus Type 1 (HBoV1) is a nonpathogenic parvovirus of genus bocaparvovirus that readily infects human airway epithelial cells repeatedly in nature and offers 20% extra genomic capacity beyond adeno-associated virus 2 (AAV2). CBN-1000 is a hybrid viral vector featuring an HBoV1 capsid engineered with conventional AAV2-vector genome elements. The hybrid vector displays exquisite lung tropism while simultaneously leveraging much of the safety, regulatory, and CMC profile of AAV vectors. In the present study we evaluated the in vivo biodistribution and functional rescue by CBN-1000 in relevant species as well as in patient-derived human airway epithelial cells from two genotypes of cystic fibrosis. Primary human airway basal cells cultured at an air-liquid interface and differentiated into mature human airway epithelial cells were transduced with CBN-1000 carrying CFTR, the gene mutated in CF. Western blot demonstrated restoration of mature CFTR protein equal to that of non-CF cultures, and electrophysiology confirmed rescue of CFTR-mediated ion current. For biodistribution studies, an 124I-labeled HBoV1 capsid was administered intratracheally resulting in similar biodistribution and clearance in both WT and CF ferrets, despite a moderate-to-severe lung disease phenotype in the transgenic animals. Furthermore, CBN-1000 was well tolerated in both NHP and ferrets at clinically relevant dose levels after pulmonary delivery, and demonstrated airway-specific gene expression. These data demonstrate that CBN-1000, a new and selective viral vector for lung delivery, can deliver large transgenes including full-length CFTR which is out-of-reach for AAV vectors. CBN-1000 addresses several of the most daunting challenges of current pulmonary gene delivery and exemplifies the potential of capsids derived from non-AAV, autonomous parvoviruses to expand the scope of gene therapy for diverse applications.

Clinical Trials Spotlight

4. Gene Therapy for Adult and Pediatric Patients with Severe Pyruvate Kinase Deficiency: Results from a Global Study of RP-L301

Pyruvate kinase deficiency (PKD) is a rare hemolytic anemia caused by *PKLR* gene mutations. Manifestations include anemia, splenomegaly and iron overload, which may be life-threatening. Current treatments are limited to chronic blood transfusions, iron chelation and splenectomy which are associated with significant side effects, or PK activators. A Phase 1 trial (NCT04105166) is evaluating lentiviral (LV)-mediated hematopoietic stem and progenitor cell (HSPC)-targeted

gene therapy (RP-L301) in splenectomized patients with severe PKD (Hb < 8g/dL and/or transfusion-dependent anemia). Following apheresis, HSPCs were transduced with LV vector and cryopreserved, in part for analysis of the drug product. Myeloablative therapeutic drug monitoring-guided busulfan was administered prior to RP-L301 IV infusion. Follow-up was 2 years to assess safety (including insertion site analysis [ISA]) and efficacy (genetic correction, transfusion requirements, anemia and hemolysis markers), followed by a long-term follow-up study. As of November 2023, two adult and two pediatric patients have received RP-L301. All achieved neutrophil engraftment by day 15. Genetic correction (PB VCN up to 2.0) was observed in all patients. The adults demonstrated sustained Hb normalization and transfusion independence up to the latest follow-up visit (36 months). Concurrent improvement in anemia and hemolysis markers (bilirubin, haptoglobin, reticulocytes, and erythropoietin) were observed. Both adult patients reported improved quality of life (increased FACT-An and SF-36 scores, with marked improvement in SF-36 energy/fatigue, physical functioning, and general health domains). The pediatric cohort (with ≤9 months of follow up), had Hb improvement relative to pre-treatment baseline. No patients required transfusions following engraftment. No serious adverse events are attributed to RP-L301. PB ISA analyses up to 36 months follow-up indicate highly polyclonal patterns; longitudinal results delineating clonal diversity will be presented. RP-L301 is a potential treatment for patients with severe PKD, including those who did not derive benefit from available therapies (including splenectomy and mitapivat). Robust and sustained efficacy up to 36 months post-treatment is demonstrated by normalized Hb (adult cohort) and clinically significant Hb increases (pediatric cohort) with both cohorts demonstrating improved hemolysis parameters, with no transfusion requirements after engraftment.

5. Personalized Neoantigen DNA Vaccine (GNOS-PV02) and Pembrolizumab Develop Antitumor Poly-Functional Neoantigen-Specific CD4+ and CD8+ Effector T Cells in Advanced Hepatocellular Carcinoma Therapy

A personalized therapeutic cancer vaccine (PTCV) tailored against neoantigens identified in an individual's tumor may enhance responses to PD-1 inhibitors through the induction of tumor-specific immunity. Here, we present results from a single-arm Phase Ib/2a trial evaluating a DNA plasmid (GNOS-PV02) encoding up to 40 neoantigens co-administered with plasmid-encoded IL-12 (pIL12) in combination with pembrolizumab (PEMBRO) in patients (pts) with advanced HCC. Pts were eligible for study therapy upon progression or intolerance with a 1L tyrosine kinase inhibitor (TKI). The PTCV [GNOS-PV02 (1mg) and pIL12 (0.34mg)] was administered intradermally via in vivo electroporation Q3w x 4 doses, and Q9w thereafter. PEMBRO was administered at 200mg IV Q3w. The primary endpoints were safety and immunogenicity. The data cut date was August 18, 2023. Among the 36 enrolled pts who received at least one dose of treatment, there were no DLTs or treatment-related grade ≥3 events. ORR (mITT) per RECIST 1.1 was 30.6% (11/36; 9 confirmed and 2 unconfirmed) with 8.3% (3/36) of pts achieving a CR. A complete molecular response (100% ctDNA clearance) was detected in 7 pts including the 3 radiographic CRs, and 4 additional pts who continue to show durable tumor control (3PR, 1 SD). Immunological analyses confirmed the induction of neoantigen-specific T cell responses by IFNγ-ELISpot in 19/22 (86.4%) evaluable pts, and pts with a larger ELISpot response showed a trend towards longer OS. PTCV immunization resulted in a significant increase of positive epitopes in both clinically responding and non-responding patients. The expression of T cell- biomarkers - CD8A, CD8B, CCL5, CXCR6, LCK, and TIGIT was significantly increased in the responding patients. Multi-parametric cellular profiling and single-cell analysis revealed active, proliferative, and cytolytic vaccine-specific CD4+ and CD8+ effector T cells in the blood of immunized pts, with a higher

CD8-to-CD4 ratio. In 14/14 (100%) of pts with paired pre- and on-treatment blood and tumor biopsies, we identified by TCRβ bulk sequencing expanded T cell clones in the peripheral blood that also trafficked into the tumor. Our data shows that the personalized DNA-based vaccine (GNOS-PV02) in combination with pembrolizumab generates a significant poly-functional neoantigen-specific antitumor CD8+ and CD4+ T cell responses, including T cell clonal expansion and infiltration to the tumor. These features could explain the mechanism of action behind the clinical activity observed in advanced HCC patients.

6. Allogeneic NKT Cells Expressing a CD19-Specific CAR in Patients with Relapsed or Refractory B cell Malignancies: An Interim Analysis

Leonid S. Metelitsa, Amy N. Courtney, Carlos A. Ramos
Baylor College of Medicine, Houston, TX

T cells expressing CD19-specific chimeric antigen receptors (CARs) mediate high complete response rates in patients with B cell malignancies. However, autologous cell products are costly and time-consuming to produce and demonstrate variability in potency and toxicity. Monomorphic CD1d-restricted Vα24-invariant natural killer T cells (NKTs) are not alloreactive like HLA-restricted T cells and therefore can be made from allogeneic donors without risking graft-versus-host disease. We generated a bank of healthy donor NKTs that co-express a CD19-specific CAR, IL-15, and shRNA targeting beta-2-microglobulin and CD74 to downregulate HLA class I and II expression, respectively. Five lots of allogeneic CD19-CAR-NKTs have been produced for this bank with each lot averaging 14.8 ± 2.5 days in culture, yielding 1.18 - 2.27x10(10) cells per lot and an average NKT purity of 99.0% ± 1.02%. We are assessing the safety, persistence, and efficacy of this allogeneic product in ANCHOR (NCT00840853), a first-in-human phase 1 dose-escalation trial for patients with relapsed/refractory B cell non-Hodgkin's lymphoma (NHL) and relapsed acute B lymphoblastic leukemia (ALL). No dose-limiting or grade 2+ toxicities related to CAR-NKTs have been observed in patients treated on three dose levels (DLs): 1x107 (DL1), 3x107(DL2), and 1x108 (DL3) CAR-NKT cells/m2. So far, seven NHL patients have been infused on three DLs, and two ALL patients have been infused on DL1. Three NHL patients achieved an initial partial response four-to-six weeks after infusion that in two cases evolved into a complete response (CR)(patients NHL-2 and NHL-4) by three months post-infusion. Additionally, one ALL patient (ALL-1) achieved a CR with incomplete hematologic recovery. We detected expansion of CAR-NKTs in the peripheral blood of patients NHL-5 (DL2) and NHL-7 (DL3) that peaked one week after infusion, and CAR-NKTs were also found in biopsied tumor tissue from patient NHL-3 at one week and NHL-2 at five weeks post-infusion. In patient NHL-2, who achieved a CR at three months post-infusion, we detected a population of recipient NKTs that underwent a 2000-fold expansion event, with numbers peaking at six weeks post-infusion and remaining elevated through 12 weeks. Our data indicate that allogeneic CAR-NKTs are well tolerated and can mediate objective responses in relapsed/refractory NHL/ALL patients, suggesting that NKTs represent a promising platform for "off-the-shelf" cancer immunotherapy.

7. Reprogramming of the Tumor Microenvironment in Glioblastoma Multiforme by Transplantation of Genetically-Engineered Hematopoietic Stem Cells

Introduction: Glioblastoma multiforme (GBM) is an incurable, highly aggressive tumor affecting the central nervous system, with a reported median survival of only 12.7 months in the unfavorable subgroup of patients with unmethylated (u)MGMT promoter. Immunotherapy has largely failed, due to intratumor heterogeneity, low T cell infiltration and a highly immunosuppressive myeloid tumor microenvironment (TME). Methods: We are conducting a phase 1/2a study in newly diagnosed patients presenting with (u)MGMT GBM (NCT03866109) evaluating the safety and biological activity of Temferon, a hematopoietic stem cell (HSC)-based gene therapy that induces local release of alpha-interferon (IFNα) from tumor-infiltrating macrophages. We performed scRNAseq and scTCRseq analysis of second surgery GBM tumors from n=5 patients enrolled in the Temferon study (post gene therapy) and n=6 control patients treated according to best standard-of-care to evaluate Temferon's effect on immune cell reprogramming. Findings were validated on an extended control group encompassing >100 GBM patients from publicly available scRNAseq datasets. Results: As of June 30th, 2023, 21 uMGMT GBM patients in 7 cohorts received 4 incremental doses of Temferon (0.5-3.0x10^6/kg). With a median follow-up of 29 months, all patients show long-term engraftment of genetically engineered cells, with no dose-limiting toxicities. The interim survival rate at 2 years is 28% (5 out of 18 patients; 3 patients excluded due to FU<12 months), which is higher than what is reported in the literature (15%). One patient is alive for >3 years after diagnosis, without further therapy. Genetically engineered cells were locally detected within the tumor lesion at levels >3% in 2/5 patients, and tumors showed increased IFNα-induced gene expression compared to the pre-treatment sample. These data indicate the recruitment of Temferon progeny into the TME, where they locally release IFNα. scRNAseq allowed unbiased identification of multiple subclusters within myeloid, lymphoid, tumor and stroma cell compartments. Most of these clusters showed strong up-regulation of IFNα and inflammatory responses. Tumors from Temferon patients were characterized by an increase in M1-like and a

decrease in M2-like macrophages. Of note, this population shift was particularly evident when comparing a stable with a progressive tumor lesion biopsied contemporaneously in 1 GBM patient, reproducing findings from a GBM mouse model (PMID: 35857642). Concomitant with myeloid cell reprogramming, it is striking that Temferon patients had more CD8 effector cells that were enriched with signatures of antitumor neoantigen-reactive T cells, a novel finding that challenges the prevailing dogma that GBM is an immune wasteland. Conclusion: Temferon, a first-in-class gene therapy targeting the myeloid TME in GBM patients is safe and biologically active at the tumor site favoring anti-tumor immunity. Preliminary survival data are promising, but longer follow-up is needed.

8. Long Term Safety and Integration Site Analysis Over a Large Cohort of Patients Treated with T Cells Modified by Lentiviral or Gammaretroviral Gene Addition

Frederic D. Bushman[1], Joseph Fraietta[1,2], Amy Marshall[2], Jan Joseph Melenhorst[3], Aoife M. Roche[1], John K. Everett[1], Sonja Zolnoski[1], Walter Rogal[2], Cory Czuczman[2], The CART Therapy Team[2], Carl H. June[2,4], Elizabeth Hexner[2], Julie Jadlowsky[2]

[1]Microbiology, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA,[2]Center for Cellular Immunotherapies, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA,[3]Cleveland Clinic Lerner College of Medicine, Cleveland, OH,[4]Pathology and Laboratory Medicine, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA

CART therapy has benefitted tens of thousands of cancer patients, but recent data has raised concerns about safety following observations of secondary T cell malignancies after treatment. Long-term follow-up (LTFU) is mandated for recipients of many gene therapies, and is intended to identify delayed toxicities and clarify mechanisms of cell product persistence. Here we summarize LTFU for 780 patients, including longitudinal tracking for 182 patients via integration site sequence analysis to quantify behavior of transduced cell clones. We analyzed 780 patients treated in modified T cell trials at the University of Pennsylvania between 2001 and 2023. With 1323 patient years of follow up, 21 (2.69%) of patients had a second primary malignancy. Tumor types included myelodysplastic syndrome (2) and acute myeloid leukemia (3); diffuse large B cell lymphoma (1), anaplastic large cell lymphoma (1), skin cancer (1 basal cell, 1 squamous cell, 1 melanoma); prostate (2), lung (3), neuroendocrine (1), thymoma (1) and uncategorized neoplasms (3). Median onset time was 1.86 years (range 51 days - 8.7 years). One case of anaplastic large cell lymphoma of the stomach was observed 344 days after infusion and was considered unrelated to CAR T cells with no detectable CAR product in lesional tissue. There were no instances of T cell malignancies related to the product reported. Integration site sequence analysis allowed characterization of possible insertional mutagenesis and quantification of clone sizes. Gene addition by both lentiviral and gammaretroviral vectors was analyzed. Comparison of these data to measures of vector copy number per cell clarified the extent of expansion of gene modified T cells within the full blood cell population. One extreme example, reported previously, involved integration within the TET2 gene and sharp clonal expansion, so that at the peak the TET2 clone comprised ~27% of all blood cells, both gene modified and unmodified. This case was distinctive in that the subject was already mutant in the other TET2 allele, helping explain the strong response. While notable for the expansion and dominance, this was a non-transformed clonal population of T cells that subsequently contracted. Further analysis of the remaining subjects showed that even modestly expanded clones were rare. Other than the previously described TET2 patient, maximum clone sizes, taking account of both gene modified and unmodified cells, averaged 0.16% over all samples analyzed to date, with a maximum of 1.3 %. Modest effects of integration on cell growth could be detected—there was increased frequency of integration in specific genes after T cell infusion, and cells with integration in specific genes were associated with longer persistence and modest clonal expansion. However, in our data, no example of vector insertion was associated with transformation or clinically concerning clonal skewing. In summary, we observed no examples of pathogenic insertional mutagenesis.

9. Safety and Efficacy of AB-1002 Gene Therapy in Patients with Advanced Heart Failure: Results from an Ongoing Phase 1 Clinical Trial

Luke Roberts[1], Timothy Henry[2], Eugene Chung[2], Monica Alvisi[1], Ferzin Sethna[1], David Murray[3], Jay Traverse[4], Lothar Roessig[1], Tugba Ozkan[1], Stacy Webb[1], Monika Mittal[1], Leigh Ervin[1], Kaitlyn Walker[1], Hesham Sadek[5], Sheila Mikhail[6], Kobra Haghighi[7], Canwen Jiang[1], R. Jude Samulski[6], Evangelia G. Kranias[7], Anna Tretiakova[1], Roger Hajjar[8]

[1]Asklepios BioPharmaceutical, Inc, Durham, NC,[2]Christ Hospital, Cincinnati, OH,[3]University of Wisconsin, Madison, WI,[4]The Minneapolis Heart Institute, Minneapolis, MN,[5]UT Southwestern Medical Center, Dallas, TX,[6]Asklepios BioPharmaceutical, Inc., Durham, NC,[7]University of Cincinnati, Cincinnati, OH,[8]Massachusetts General Brigham, Cambridge, MA

Congestive heart failure (CHF) is a progressive disease in need of innovative therapies. A key characteristic of failing hearts is abnormal intracellular Ca^{2+} handling and increased protein phosphatase 1 activity (PP1). Inhibition of PP1 by a constitutively active inhibitor-1 (I-1c) has been shown to enhance cardiac function in pre-clinical models of heart failure. We developed a novel cardiotropic and liver de-targeted capsid, AAV2i8, designed to overcome poor transduction in cardiac tissue. In a Phase 1 clinical trial the AAV2i8 capsid delivered a constitutively active I-1c protein to cardiac tissue via a single intracoronary infusion of AB-1002 (AAV2i8.I-1c). Eligible patients were >18yrs with non-ischemic cardiomyopathy, New York Heart Association (NYHA) class III with Left Ventricular Ejection Fraction (LVEF) of ≥15% to ≤35%. Efficacy measures included changes from baseline to month 12 in NYHA classification, Peak VO_2, 6-minute walk test (6MWT), LVEF and Minnesota Living with Heart Failure Questionnaire (MLHFQ). Safety and tolerability were assessed by collection of AEs and SAEs, laboratory tests, vital signs and ECGs. Eleven patients have received either 3.25E13 (Cohort 1; n=6) or 1.08E14 (Cohort 2; n=5) viral genomes (vg) of AB-1002. Three patients in cohort 1 have completed at least 36 months follow up and a further three have completed 3

months follow up. Three patients in cohort 2 have completed at least 30-months observation, and one completed 24 months of observation. Patients were aged between 53 and 76yrs, with 9 males and 2 females. Mean LVEF at baseline was 30.33% (SD 3.88; cohort 1) and 23.28% (SD 5.92; cohort 2). The first 3 participants in Cohort 1, showed clinically meaningful improvements in LVEF, NYHA Class, MLHFQ, Peak VO_2 and 6MWT at 12 months. Of the 3 remaining patients in cohort 1, two have shown initial improvement in NYHA Class, 6MWT and MLHFQ score at 3 months post administration. Among participants in Cohort 2, four of the 5 patients enrolled could be evaluated. Two of 4 patients showed improvements in MLHFQ and NYHA score, and all 4 showed improvements in LVEF at 12 months, compared to baseline. Peak VO2 declined in three but improved in one at 12 months while 6MWT declined in one patient, worsened in one, and was stable in two at 12 months. In support of this encouraging early clinical efficacy signal, left ventricular cardiac tissue was obtained from 1 patient in cohort 2 who underwent left ventricular assist device (LVAD) placement 13 months post-intracoronary gene transfer. AB-1002 demonstrated high myocardial transduction efficiency at 1.19 vg per cardiomyocyte and phosphorylation levels of phospholamban similar to normal hearts. To date AB-1002 has been well tolerated. Over the total follow up time available, 4 of 6 patients experienced 25 treatment emergent adverse events (TEAEs) and 5 patients experienced 56 TEAEs in cohorts 1 and 2 respectively, most of which were mild or moderate in severity. There was 1 fatal event in cohort 2 not considered related to investigational product. We believe our Phase 1 clinical trial demonstrates that AB-1002 is well-tolerated and results in positive efficacy outcomes in patients with non-ischemic HF. Further development of AB-1002 will be conducted in a phase 2 trial of up to 150 patients, GenePHIT, which is currently ongoing.

10. Intracochlear Administration of DB-OTO Gene Therapy in Pediatric Patients with Profound Hearing Loss Due to Otoferlin Mutations: The CHORD Phase 1/2 Open-Label Trial

Lawrence Lustig[1], Manohar Bance[2], Akira Ishiyama[3], Robert Nash[4], Ruben Polo[5], Angel Ramos[6], Manuel Jesus Manrique Rodriguez[7], Jay T Rubinstein[8], Tera Quigley[9], Jason Riggs[9], Eduardo Corrales[9], Jeffery Anderson[9], Vassili Valayannopoulos[9]

[1]Department of Otolaryngology - Head & Neck Surgery, Columbia University Medical Center, New York, NY,[2]Cambridge University, Cambridge, United Kingdom,[3]UCLA, Los Angeles, CA,[4]Great Ormond Street Hospital, London, United Kingdom,[5]Hospital Universitario Ramon y Cajal, Madrid, Spain,[6]Las Palmas University, Las Palmas Gran Canaria, Spain,[7]Clinica Universidad de Navarra, Pamplona, Spain,[8]University of Washington, Seattle, WA,[9]Regeneron Pharmaceuticals, New York, NY

Introduction: Biallelic otoferlin gene (*OTOF*) mutations commonly result in auditory neuropathy characterized by severe-to-profound sensorineural hearing loss. In these patients, the auditory brainstem response (ABR) is absent or severely reduced contrasting with normal outer hair cell function. *OTOF* gene replacement may provide instatement of high-quality, physiological hearing and be a more effective and durable treatment than cochlear implants. DB-OTO is a dual adeno-associated virus (AAV1) vector designed for intracochlear delivery of a full-length copy of the human *OTOF* gene under the control of the Myo15 hair-cell specific promoter. In this first-in-human clinical trial with DB-OTO (CHORD, NCT05788536), the safety, tolerability and preliminary efficacy of DB-OTO is being evaluated in pediatric patients with profound hearing loss caused by *OTOF* mutations. **Methods**: CHORD is a global, phase 1/2 trial of DB-OTO enrolling pediatric patients with biallelic pathogenic *OTOF* variants, profound hearing loss, presence of otoacoustic emissions or cochlear microphonic if >2 years. In Part A, the initial unilateral dose escalation phase of the study, DB-OTO is being administered by intracochlear injection using a typical facial recess approach through the round window. A 10-month-old female received a single intracochlear injection of 7.2×10^{12} vector genomes of DB-OTO unilaterally with a cochlear implant placed in the contralateral ear. At baseline the patient had no detectable hearing by behavioral pure tone audiogram (PTA) nor ABR. **Results**: Through week 12 after treatment, no dose-limiting toxicities and no DB-OTO related adverse events (AEs) were reported, including absence of vestibular manifestations. Hearing recovery was detected at 4 weeks post-treatment, with average behavioral PTA thresholds improving to 55 dB in the best frequencies (2, 4 and 8 kHz) at 12 weeks posttreatment. Hearing recovery measured by ABR showed a positive wave V amplitude through week 12 (thresholds of 40-80 dB, no response at 100 dB at baseline) in the DB-OTO treated ear, while no improvement was observed in the untreated ear. According to parental reports, as indicated by the LittlEARS auditory questionnaire, an improvement in the patient's global auditory skill development was also observed at week 12. Parents reported also more natural vocalizations when the patient was not wearing the cochlear implant on the other ear, indicating improved hearing acuity on the DBOTO-treated ear. Additional data from this and other enrolled patients will be presented. **Conclusions**: In this first-in-human gene therapy trial of DB-OTO, an overall positive tolerability profile was reported, with no AEs related to DB-OTO treatment reported. Audiometric data showed improvement in hearing from baseline corroborated by early auditory skills testing and parental reporting. These encouraging results prompt further investigation in other patients with profound hearing loss due to *OTOF* mutations.

New Technologies for Gene Targeting and Gene Correction

11. Efficacy and Integration of a Non-Viral *ABCA4* Transposon in Treating Stargardt Disease: Evidence from Mice and Primate Studies

Michelle E. LeBlanc, Chuanqi Peng, Shashank Shukla, Mitchell R. Kopacz, Kelsey A. Rush, Jungyeon Hwang, Michael J. Crowley, Subhadeep Dutta, Hugues Bernard, Ria Vashishth, Jonathan T. Lu, Sandeep Nema, Joseph J. Higgins, Joseph J. Senn

SalioGen Therapeutics, Lexington, MA

Introduction: Stargardt disease (STGD1) is a genetic disorder causing progressive central blindness. Novel integrative non-viral gene therapy applications overcome the limitations of low immunogenicity and durability. In addition, other advantages specific to STGD1 include the potential to deliver the large (6.8 kb) ATP Binding Cassette Subfamily A Member 4 (*ABCA4*) gene to correct the numerous *ABCA4* mutations in patients. The dysfunctional ABCA4 transporter causes STGD1 by altering the transfer of all-trans-retinal (ATR) and the accumulation of diretinoid-pyridinium-ethanolamine (A2E) and retinal dimer conjugates. In *Abca4*$^{-/-}$ and *Rdh8*$^{-/-}$ double knock-out (dKO) mice, A2E accumulation is accelerated compared to *Abca4*$^{-/-}$ single KO mice because the deficient all-trans-retinol dehydrogenase enzyme (Rdh8) augments the ATR defects. As such, we performed subretinal injections of an optimized lipid nanoparticle (LNP) to deliver an mRNA encoding a novel bioengineered transposase derived from the mammal, *Myotis lucifugus* (*bMLT*), and a DNA expressing full-length human *ABCA4* (*fl-ABCA4*) under the control of a constitutive promoter. This transposition process, called Gene Coding technology, was also tested in non-human primates (NHPs) to confirm interspecies translation. **Methods:** We co-encapsulated *bMLT* mRNA and *fl-ABCA4* cDNA in LNPs to evaluate dosing, tolerability, and subretinal administration (1uL per eye) in three groups of *dKO* mice at postnatal day 14 to 17: vehicle alone (n=2) and treated groups with low dose (LD) (n=4) and high dose (HD) (n=6). The three *dKO* groups were compared to wild-type (WT) mice (n=9) by serial fundoscopy, optical coherence tomography (OCT) both within and outside the treated retinal area, and histological sectioning. In 10-week-old mice, terminal A2E measurements were analyzed in the three *dKO* groups and age-matched WT mice at 50 days after subretinal injection using a reversed phase chromatography (RP-HPLC) method with analyte detection at a wavelength of 430 nanometers. To assess ABCA4 expression and genomic integration, we administered the same DNA/RNA co-encapsulated LNP by subretinal injection in African Green monkeys (n=2). Immunohistochemical (IHC) studies co-staining for ABCA4 and Arrestin-3, digital droplet polymerase chain reaction (ddPCR), and quantitative reverse transcription (RTqPCR) were used to show *ABCA4* integration and photoreceptor localization. **Results:** There were no detectable differences in retinal thickness by OCT outside the treated area in 10-week-old *dKO* mice compared to WT mice. Within the treated area, LD and HD treated *dKO* mouse groups showed no differences in OCT retinal layer measurements compared to the untreated controls, implying good tolerability. Untreated *dKO* mice showed a significant ($p<0.0001$) increase in A2E levels compared to age-matched WT mice. At 50 days post LNP injection, *dKO* HD treated mice showed a 40% reduction in A2E compared to untreated controls ($p=0.03$). NHP retinal IHC staining showed ABCA4 protein co-localization with the cone photoreceptor marker, Arrestin-3, and evidence of integration by ddPCR. **Conclusions:** Fifty days after treatment, *dKO* mice exhibited a reduction in A2E levels compared to untreated *dKO* mice suggesting correction of the Stargardt phenotype. NHP studies confirmed expression of *ABCA4* in photoreceptors and the interspecies translatability of Gene Coding technology. This non-viral integrative gene therapy represents a potentially promising, one-time treatment for STGD1.

12. RNA-Based Gene Writer and Lipid Nanoparticle (LNP) Delivery Enables Generation of Functional Chimeric Antigen Receptor (CAR) T Cells with *In Vitro* and *In Vivo* Anti-Tumor Activity and T Cell-Specific Genome Engineering *In Vivo*

Kartika Venugopal, Michael Magee, Alberto De Iaco, Jason Rodriguez, James Rottman, Donghui Li, Giulia Schiroli, Yu Cao, Rebecca Levy, Travis Schute, Mohit Gupta, Christina Ferren, Michael Monte, Jane Wang, Bill Querbes, Cecilia Cotta-Ramusino, Madhusudan V. Peshwa, Michael C. Holmes

Tessera Therapeutics, Somerville, MA

Autologous Chimeric Antigen Receptor (CAR) T-cell therapies have added an effective tool to the treatment options for relapsed and refractory leukemias and lymphomas. However, significant challenges limit patient access to these therapies, including eligibility, cost, scalability, and manufacturing. These limitations highlight the critical unmet need for effective same day treatment options. We are combining our Gene Writing and delivery platforms to enable T cell specific genome engineering, in an effort to reduce the challenges associated with conventional autologous CAR-T approaches. RNA Gene Writers are designed to introduce a broad range of alterations to the genome, from writing in a transgene, inserting an exon, or introducing single nucleotide changes, providing an attractive toolkit for sophisticated cell engineering. RNA Gene Writers are inspired by the biology of non-LTR retrotransposons, a class of mobile genetic elements that can edit the genome through target-primed reverse transcription, or TPRT. RNA Gene Writers are designed to be delivered as all-RNA composition, which is intended to facilitate in vivo delivery by lipid nanoparticles, or LNP. LNP-RNA delivery of RNA Gene Writers resulted in the integration and expression of green fluorescent protein (GFP) transgenes in >70% of primary human T cells in vitro. We achieved successful LNP delivery of RNA to T cells in vivo in both mouse and non-human primate (NHP) models, with approximately 80% and 40% GFP reporter expression observed, respectively. We demonstrated that LNP delivery of one of our RNA Gene Writers achieved the integration and CAR expression in an average of ~21% of primary human T cells in vitro. We did not observe detriment to cell viability or proliferative capacity in these CAR-T generated cells, and robust tumor cell killing was also observed in vitro. Moreover, RNA Gene Writer derived CAR-T cells demonstrated antigen specific tumor clearance in vivo when introduced into mouse xenograft models. We also demonstrated an average of ~6% GFP reporter expression in T cells after in vivo administration of LNP-RNA delivery into a humanized mouse model, potentially opening up the possibility of using RNA Gene Writers for in vivo CAR-T treatment. In addition, the modularity of our RNA Gene Writers delivered in an LNP potentially allows for multiplex editing to co-introduce multiple genetic changes in a single step using all-RNA compositions. In preclinical studies, we achieved >90% knockout of the TRAC and B2M genes, individually, in T cells, that when multiplexed led to ~88% of T cells with knockout of both TRAC and B2M. We also demonstrated T cells containing 3 edits, including TRAC and B2M knockout, and either GFP or CAR writing, showing that rewriting and writing can be multiplexed. Further, we

observed approximately 30% B2M knockout by rewriting following in vivo administration in a humanized mouse model. We believe our RNA Gene Writers are uniquely positioned to drive a broad range of genetic alterations, including multiplex editing, and the ability to deliver RNA Gene Writers as all-RNA compositions packaged in a LNP potentially offers greater simplicity and flexibility compared to conventional lentiviral based CAR-T therapies.

13. Language Models Generate Novel Genome Editors from Scratch

Jeffrey A. Ruffolo, Stephen Nayfach, Aadyot Bhatnagar, Joseph Gallagher, Joel Beazer, Jennifer Yip, Riffat Hussain, Jordan Russ, Alexander J. Meeske, Peter Cameron, Ali Madani

Profluent Bio, Berkeley, CA

Gene editing has the potential to cure disease yet requires complex molecular machinery for precise manipulation of cellular genetic material. Editors derived from microbial CRISPR systems, while powerful, often face tradeoffs in key attributes like size, activity, and immunogenicity when used in non-native environments. AI-based protein engineering is a powerful alternative that has the potential to bypass evolutionary constraints and generate proteins with optimal properties. Here, we present the first programmable gene editor designed 'from scratch' using artificial intelligence models. Our models were trained on massive-scale biological diversity, including a dataset of over one million CRISPR operons systematically identified from 26 terabases of assembled genomes and meta-genomes. Our models generate thousands of diverse CRISPR-associated proteins never before seen in nature, including highly functional Type II nucleases that are >400 mutations away from any known natural protein. We also used AI models to generate fully synthetic single-guide RNAs that were compatible with their cognate gene editors and boosted activity. Our most performant AI-generated editor, which we denote OpenCas, exhibited up to 95% editing efficiency across a variety of cell types, has a low off-target rate, is compatible with base editing, and is predicted to have reduced immunogenicity. We intend to release OpenCas to the public in order to democratize the ethical usage of gene editing across research and commercial applications. Collectively, our results demonstrate the power of AI to build customized gene editing proteins and will be a foundation for AI-based protein engineering in the future.

14. Retron Mediated Exon-Sized Genome Insertion Using an All- RNA System

Kyong-Rim Kieffer-Kwon, Jacob Layer, Zhongxia Yi, Socheata Ly, Elise Keston-Smith, Shailesh Gurung, Elizabeth Narayanan, Sierra Harken, Abril Fleitas, Aisha A. Aljanahi, Dawn Ciulla, Matthew Pandelakis, Hari Jayaram, Vlad Presnyak, Inna Shcherbakova

ReNAgade Therapeutics, Cambridge, MA

While exogenous DNA has been instrumental in advancing precise genome editing technology, effective delivery of donor DNA remains a substantial hurdle in therapeutic applications. DNA is frequently packaged in viral vectors, which presents challenges such as non-specificity, liver toxicity, immunogenicity, and high manufacturing costs. There is a need for a non-viral "all-RNA" gene editing modality that enables *in vivo* targeted insertions and potential re-dosing. Retrons, which hail from bacterial retroelements involved in bacteriophage defense, are minimally two-component RNA systems comprising a non-coding RNA (ncRNA) and an associated reverse transcriptase (RT) which together can be harnessed to create ssDNA templates required for targeted insertion when coupled with a CRISPR nuclease or nickase. We have screened and optimized retrons that show vastly improved editing efficiency of exon-sized gene insertions in cell lines and primary cells. Starting with an *in silico* retron prediction algorithm we identified >7000 novel retrons. After screening a phylogenetically diverse subset of hundreds of these for precise insertion activity we identified >50 retrons with up to a 45-fold better performance than our Eco1 benchmark. We have utilized a combination of retron RT engineering, ncRNA minimization, chemical modification, and homology-dependent repair manipulation to improve retron-mediated target insertion. Retron system optimization using *in silico* modeling-based RT engineering achieved 2-fold higher 305 base pair insertion. These combinations of ncRNA engineering and retron system optimization has led to ~40% editing efficiency in hematopoietic stem cells and T cells. Together, our initial data demonstrates retron capabilities to produce repair templates for exon-sized insertions using an all-RNA system in mammalian cells.

15. Reduction in Triglycerides through a Novel Ultracompact CRISPR System: Efficacy in Mouse Models and NHP Studies

Lucas B. Harrington, Janice Chen

Mammoth Biosciences, Brisbane, CA

In the last decade, CRISPR-based therapies have made tremendous progress in cell therapy applications and selected diseases that can be targeted in the liver. However, correcting the vast majority of genetic diseases outside the liver has remained challenging due to the large size of the original CRISPR systems, such as Cas9 and Cas12a. Ultracompact CRISPR systems present an opportunity to overcome the challenge of *in vivo* delivery, enabling single-AAV delivery of genome editors, including next-gen editing techniques such as epigenetic editing, reverse transcriptase editing, and base editing. Although many compact CRISPR systems have been described, their application to therapeutic targets has been limited due to challenges in matching the efficacy of larger systems. Here, we describe the discovery of a novel ultracompact CRISPR platform and show it is a potent genome editor *in vivo* in mouse and nonhuman primate models. Through high-throughput screening of natural variants, extensive protein engineering, and guide optimization, we optimize this platform for robust editing with both AAV and LNP delivery. This ultracompact CRISPR system was effectively used to target the APOC3 gene, a key player in triglyceride metabolism, offering promising therapeutic potential for durable treatment of severe hypertriglyceridemia. *In vivo* studies in humanized mouse models demonstrated an 80% reduction in triglyceride levels. Complementing these findings, our nonhuman primate studies further confirmed significant genetic editing of APOC3 with no major safety concerns observed. In addition, we provide an update on leveraging these ultracompact CRISPR systems for single AAV delivery of epigenetic editing for muscular dystrophy. These results underscore

the potential of ultracompact CRISPR systems for precise and efficient gene editing applications in diverse conditions and to enable single-aav compatible next-gen editing approaches such as epigenetic editing.

16. Selective Repression of C9ORF72 Repeat Expansion-Containing Sense and Antisense Transcripts in an ALS Mouse Model

Amrutha Pattamatta[1], Mohammad Samie[2], Awdhoot Godbole[3], Chen Ting-Wen[1], Anagha Sawant[1], Susan Ping[4], Alexandra Srnka[1], Siobhan Ford[4], Lujain Al-Sowaimel[1], Ricardos Tabet[4], Robert Bell[1], Lisa R. Keyes[5], Sheila Rao-Dayton[5], Rob Moccia[3], Claudia H. Huichalaf[4], David Shivak[6], Bryan Zeitler[2], Amy Pooler[2], Christine Bulawa[1]

[1]Previous affiliation, Pfizer Inc, Cambridge, MA,[2]Sangamo Therapeutics, Inc., Richmond, CA,[3]Pfizer Inc, Cambridge, MA,[4]Genomic Medicine, Alexion AstraZeneca Rare Disease, Cambridge, MA,[5]Genomic Medicine, Alexion AstraZeneca Rare Disease, Durham, NC,[6]Previous affiliation, Sangamo Therapeutics Inc, Richmond, CA

Amyotrophic lateral sclerosis (ALS) is a progressive disease characterized by degeneration of motor neurons in the brain and spinal cord, leading to paralysis and early death. The most frequent genetic cause of ALS is the expansion of the hexanucleotide GGGGCC (G4C2) repeats in the first intron of C9ORF72 gene. Healthy individuals carry up to 30 hexanucleotides repeats, but expansions of this region to hundreds or even thousands cause familial ALS and frontotemporal dementia. There are several mechanisms that may contribute to the disease progression as a result of this expansion. G4C2 repeats undergo bidirectional transcription generating sense and antisense expansion containing RNA and RNA foci as well as repeat-derived peptide translation products, suggesting a pathological, gain-of-function mechanism. To decrease the levels of expansion-containing transcripts in cells, while maintaining expression of healthy C9ORF72 mRNA levels, we previously identified an engineered transcription factor comprised of a zinc finger protein (ZFP) specifically targeting the G4C2 repeat region fused to a DNA-binding repressor protein (KRAB), named ZF-R. We showed >90% reduction of both sense and antisense G4C2 containing transcripts in patient-derived fibroblasts and motor neurons from patient-derived iPSCs carrying 1200 G4C2 repeats with minimal detectable off-target activity as measured by global transcriptomics analyses. To evaluate the potential use of this approach therapeutically, we studied the effect of ZF-R in neonate and adult $C9^{500}$-BAC transgenic mice. ZF-R was delivered via ICV in neonates, and 5 weeks post injection animals were euthanized for molecular analysis. Using this approach, we reached ~70-80 % reduction of expanded repeat RNA (sense and antisense) in the cortex, associated with 40% of C9ORF72 protein reduction. We also observed ~50% decrease in sense and antisense RNA foci in the same brain region. The repression of sense and antisense containing RNA in the cortex was not associated with any changes in the molecular markers of neuroinflammation or neuronal loss. For the adult study, five month old $C9^{500}$-BAC mice were injected via ICV with the same construct. Five months post injection animals were euthanized, and molecular analysis was performed. Similar to the neonate study, we found a strong reduction of expanded repeats and also ~60% decrease in Dipeptide repeats (DPR) proteins in the Cornu Ammonis (CA) of hippocampus. Overall, these findings strongly support the use of ZF-Rs for the treatment of familial ALS.

17. Systematic Discovery, In Vivo Delivery, and DNA Repair Mechanism of Single-Strand Annealing Protein for Precision Integration of Large DNA Sequences

Le Cong[1], Di Yin[2], Guangxue Xu[3], Yuanhao Jerry Qu[1], Chengkun Wang[1], Xiaotong Wang[2], William Arthur Johnson[4], Gabriel Filsinger[2], Tim Wannier[5], George M. Church[6], Lai Yee Phoon[7], Boya Gao[7], Li Lan[7]

[1]Pathology, Genetics, Stanford University, Stanford, CA,[2]Stanford University, Stanford, CA,[3]Stanford University, Palo Alto, CA,[4]Stanford University Laboratory for Cell & Gene Medicine - Palo Alto, CA, Stanford, CA,[5]WildMicrobes, NA, CA,[6]Harvard Medical School, Boston, MA,[7]Duke University, Durham, NC

The challenge of accurately inserting large DNA sequences is a significant limitation in current genome editing tools, particularly for in vivo gene therapy applications. Our project explores the potential of microbial recombination systems, focusing on phage-encoded Exonuclease and Single-Strand Annealing Proteins (Exo-SSAPs), for efficient, cleavage-free gene editing in mammalian cells. Building on prior work demonstrating large DNA integration via SSAPs directed by catalytically inactive dCas9, we investigated a large range of microbial recombination systems, identifying over 26,000 recombination systems originating from both prokaryotic and eukaryotic sources. Via this systematic survey, we identified top candidates with three-fold efficiency compared to reported SSAP editors. This improved system is shown to be compatible with in vivo delivery using AAV vectors, successfully integrating knock-in sequences in primary mouse cells. Further, we explored Exo-SSAP mediated integration and DNA repair mechanisms in human cells, particularly with dCas9 genome targeting to avoid activation of double-stranded break (DSB) repair pathways. Our genetic and chemical perturbation results revealed that the Mismatch Repair pathway (MMR) proteins could play a pivotal role in the Exo-SSAP mediated DNA insertion. Specifically, by targeting MMR enzymes, we could further enhance the efficiency of Exo-SSAP integration in human cells, indicating room for future improvements. Overall, our study highlights the significant potential of microbial recombination systems for large DNA sequence integration in human cells. The mechanistic part indicates that mismatch repair proteins could be a previously under-appreciated mechanism that influences DNA integration when DSB is absent during the editing process. These results open new avenues for understanding and applying large DNA insertion in gene therapy, setting the stage for in vivo therapeutic applications.

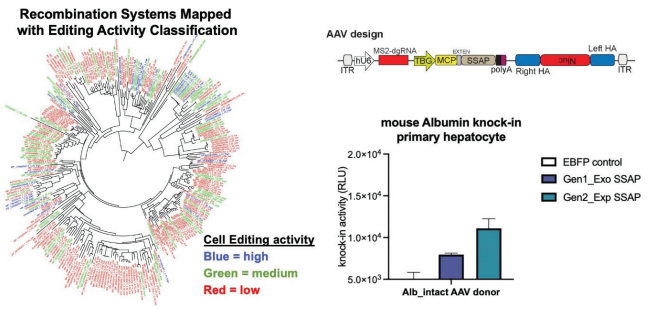

Figure. Left: mining of over 26,000 Exo-SSAP systems reveal differential cellular activities distributed across evolutionary tree. Right, proof-of-concept demonstration of large insertion (800bp) in primary hepatocyte using improved Exo-SSAP system.

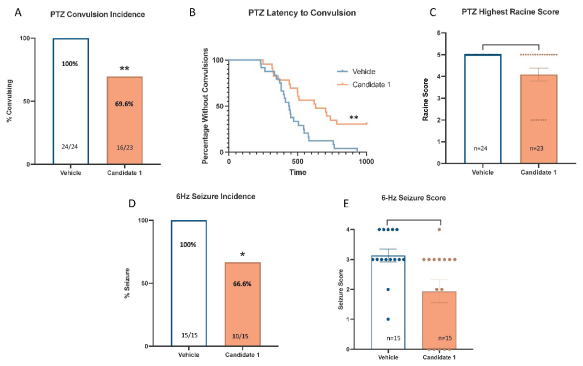
AAV Vectors - Preclinical and Proof-of-Concept: Therapy Focus

18. Breaking Ground in CMT1B Treatment: AAV9-Mediated Dual RNAi and Gene Replacement Therapy Targeting Schwann Cells Improves Myelination and Peripheral Nerve Function in Mice

Daniella Munezero[1], Jingting Zhu[1], Arun Paripati[1], Russell Chuah[1], Lauren Taylor[1], Afrooz Rashnonejad[1,2]

[1]Center for Gene Therapy, Abigail Wexner Research Institute, Nationwide Children's Hospital, Columbus, OH,[2]Department of Pediatrics, The Ohio State University, Columbus, OH

Charcot-Marie-Tooth (CMT) encompasses a diverse group of hereditary sensory and motor neuropathies resulting in progressive disability and pain. Lacking a cure for these debilitating diseases, current patient care strategies involve symptom management, surgery, rehabilitation, and occupational therapy. CMT1B, a demyelinating subtype, is associated with over 200 different mutations in *Myelin Protein Zero* (*MPZ*) gene. Most mutations in *MPZ* gene are autosomal dominant and exhibit toxic gain-of-function effects, resulting in the aggregation of mutant MPZ protein within Schwann cells (SCs) followed by endoplasmic reticulum (ER) stress, defective myelination, reduced nerve conduction, failure of peripheral nerve and subsequent muscle wasting and weakness. Creating a single, comprehensive therapy for CMT1B is challenging due to the diverse mutations throughout the MPZ gene. In response, we developed a novel, universal AAV gene therapy approach termed AAV9-KDAR (**K**nock**D**own **A**nd **R**eplacement). This strategy involves knocking down mutated MPZ using RNAi to reduce the aggregate burden in SCs, and concurrently replacing it with a functional RNAi-resistant MPZ (rMPZ) gene provided by the same vector to promote re-myelination. Given that MPZ constitutes over 50% of proteins in the myelin sheath, its replacement is essential for enhancing myelination. Twelve micro-RNAs targeting MPZ gene (miMPZ) were designed and cloned. To identify lead miRNAs capable of targeting both mutant and wild-type MPZ (mut/wtMPZ) mRNA without affecting rMPZ expression, we co-transfected HEK293 cells with mut/wtMPZ plasmids, rMPZ, and each miMPZ, followed by luciferase assays, western blot, and qRT-PCR analyses. Then, the effects of AAV-based MPZ knockdown, rMPZ replacement, and MPZ-KDAR were investigated separately in an ex-vivo model of severe early-onset CMT1B-R98C's DRG/ SCs co-cultures. Reduction of mutant MPZ, decreased ER stress, and increased myelination were assessed using IF staining, western blot, and qRT-PCR. Off-target effects of miMPZ were investigated by RNA-seq analysis in human Schwann cells. Next, we tested the in vivo efficacy of AAV9-KDAR therapy at two-time points: pre and early onset of CMT1B disease. We administered 2.5E+11 or 5E+11 vg of AAV9-miMPZ-rMPZ via intracerebroventricular or intrathecal injections on neonatal and adult CMT1B-R98C mice, respectively. Molecular, behavioral, and electrophysiological assays were performed at 6 months post-injection. Lead miMPZs successfully reduced mut/wtMPZ levels by > 85-fold in both ex vivo and in vivo models without affecting rMPZ expression. Interestingly, silencing MPZ alone worsened demyelination symptoms, and replacement of MPZ alone was insufficient to reverse ER stress and restore myelination. In contrast, CMT1B-DRG/SCs co-cultures treated with KDAR approach exhibited enhanced myelination, increased numbers of MBP + internodes, and reduced ER stress biomarkers. Similarly, we detected a significant reduction in mut/wtMPZ and a 60-fold increase in rMPZ expression in treated sciatic nerves accompanied by improvement in treadmill and rotarod motor performance by 50% , as well as CMAP and NCV electrophysiological outcomes in treated pre- and post-onset CMT1B-R98C mice compared to untreated controls. Furthermore, no significant off-target effects were detected by RNA-seq analysis on lead miRNA-treated human SCs. This study marks a groundbreaking development in gene therapy for CMT1B, providing proof of concept for treating CMT1B through AAV9-KDAR approach. Nonetheless, additional research is imperative to optimize AAV doses, enhance efficacy, and assess in vivo safety thoroughly.



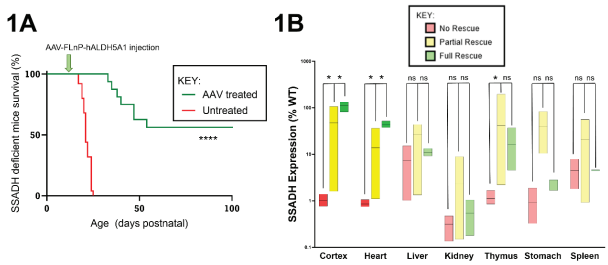
19. GABA Selective AAV-Mediated Gene Therapy Provides Durable Seizure Protection in Multiple Refractory Epilepsy Models

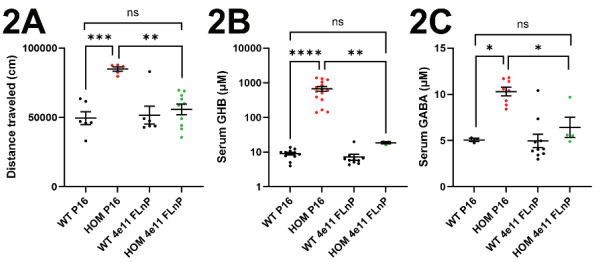
Brooke Babineau, Sheila Sears, Jennifer Su, Chao Tai, Keiko Takahashi, Adriana Gonzalez-Sandoval, Annie Tanenhaus, Pingping Jia, Rangoli Aeran, Tselmeg Amarlkhagva, Ming Chen, Dixon Hoffelt, Jason Le, Keith Place, Sammy Liang, Mark Elegue, Suresh Poda, Stephanie Tagliatela

Encoded Therapeutics, South San Francisco, CA

Rationale: Epilepsy affects approximately 1% of the population, equating to 3 million individuals in the U.S. Nearly a third of epilepsy cases fail to respond to first- and second-line treatment, leaving patients with persistent and potentially disabling seizures. Antiseizure medications often exhibit a 'honeymoon period' of initial efficacy that diminishes over time and are associated with significant side effects, including organ toxicity, drowsiness, dizziness, and cognitive impacts. Consequently, there is an urgent unmet need for novel treatments to address refractory epilepsies. Genetic targeting of GABAergic neurons to enhance inhibition in an activity-dependent manner has the potential to restore excitatory-inhibitory balance in the brain and

reduce seizure burden. **Methods:** Using Encoded's vector engineering platform, we identified regulatory elements capable of driving cell-selective transgene expression within GABAergic inhibitory neurons. We coupled these GABA-selective AAV expression cassettes with effector genes with known roles in regulating neuronal excitability and/or neurotransmission. Candidates or vehicle were administered to wild-type mice via intracerebroventricular (ICV) injection on postnatal day 1 and seizure protection was evaluated 7-8 weeks later after chemical or electrical induction. In the 6-Hz model of focal seizures and refractory epilepsy, mice were administered an electric shock to induce seizures and protection was measured within 30 seconds of electrical stimulus. In the Pentylenetetrazole (PTZ) model for tonic-clonic seizures, mice were given a subcutaneous injection of PTZ to induce seizures and protection was measured over 30 minutes. **Results & Conclusions:** The top candidate (Candidate 1) showed promising results in the 6-Hz and PTZ models, reducing both seizure incidence and severity. In the PTZ assay, Candidate 1 also prolonged the latency to first convulsive seizure. Our novel AAV-mediated GABA-selective gene therapy approach demonstrated *in vivo* efficacy across multiple epilepsy models, supporting its potential to provide durable seizure reduction in genetically heterogenous epilepsy populations. **Figure 1.** Efficacy of gene therapy Candidate 1 in the PTZ and 6Hz electroshock seizure assay: PND1 ICV delivery of Candidate 1 significantly reduced seizure incidence (Panel A; p=0.0156, Wilson Signed Rank Test), increased latency to first tonic-clonic convulsion (panel B; p=0.0025, Mantel-Cox test), and reduced seizure severity score (Panel C; p=0.039, Mann-Whitney) in the PTZ assay at 7 weeks of age. Additionally, PND1 delivery of Candidate 1 in the 6Hz assay at 8 weeks of age resulted in a significant reduction in both seizure incidence (Panel D; p=0.0143, Chi-square) and seizure severity (Panel E; p=0.0128, Mann-Whitney) when compared with vehicle controls.





20. Curable Hyperactive Behaviors and Serum Biomarkers upon Gene Replacement Therapy in Succinic Semialdehyde Dehydrogenase Deficiency in Mice

Henry Lee[1], Gabrielle McGinty[1], Amanda Liebhardt[1], Bjoern Welzel[1], Alex Zhang[1], Clifford Woolf[1], Guangping Gao[2], Alexander Rotenberg[1]

[1]Neurology, Boston Children's Hospital, Boston, MA,[2]UMass Chan Medical School, Worcester, MA

Introduction: Succinic semialdehyde dehydrogenase deficiency (SSADHD) is a rare metabolic neurodevelopmental disorder due to loss of function mutations of *ALDH5A1* gene. SSADH is essential for degradation of the inhibitory neurotransmitter γ-aminobutyric acid (GABA). In SSADHD, pathologic accumulation of GABA and its metabolite γ-hydroxybutyrate (GHB) results in early life encephalopathy with autism, refractory epilepsy, and high mortality rate from seizures. Targeted drug treatments for SSADHD are ineffective. Gene replacement therapy is a potential cure for SSADHD but is unavailable. As a step toward clinical translation of SSADH gene replacement, we developed and tested the therapeutic efficacy of a novel vector encompassing a human *ALDH5A1* full length native promoter (FLnP) tethered with a human *ALDH5A1* coding sequence, namely AAV-FLnP-hALDH5A1, and tested its efficacy using SSADH deficient mice. **Methods:** We packaged AAV-FLnP-hALDH5A1 into PHP.eB capsid and injected into homozygous (HOM) SSADH deficient mice and wild-type (WT) littermates via intraperitoneal (IP) injection at high dose (~6-8x10^{13} gc/kg) at P14 symptomatic stage. Survival was recorded and tracked until P100. Automated native exploratory behavioral tracking was performed using a high resolution ventral view camera at P100. Whole blood, brain tissues, and internal organs were collected at P100 for serum metabolites and protein analyses. **Results:** AAV-FLnP-hALDH5A1 administration resulted in significant increase in survival at P100 (55%) compared to 0% (p=0.0002, Fisher Exact Test) in untreated HOM mice (1A). Western blot data revealed that SSADH was restored to 70-95% WT levels in the brain of treated mutants, and up to 50% in other vital organs (1B). Importantly, the level of restored SSADH in brain and myocardium correlated with HOM mice survival. At a behavioral level, we found hyperactive behavior (distance travelled) before treatment (WT=495±46m, HOM=848±16m, p=0.0043, Mann-Whitney test) is reversible upon AAV-FLnP-hALDH5A1 treatment (WT+AAV=517±64m, HOM+AAV=557±38m, p=0.4278, Mann-Whitney test) (2A). These behavioral results corroborate serum biomarkers GHB and GABA demonstrating phenotypic reversibility upon AAV-FLnP-hALDH5A1 treatment: GHB (in μM) - WT=8.99±0.80, untreated HOM=672.17±108.99, AAV-treated HOM=18.60±1.32 (p=0.00001, One-way ANOVA) (2B); GABA (in μM) - WT=5.07±0.17, untreated HOM=10.31±0.47, AAV-treated HOM=6.43±1.10 (p=0.0003, One-way ANOVA) (2C). **Conclusions:** We demonstrated hyperactive behaviors and disease-associated serum biomarkers in SSADH deficient mice are reversible upon treatment of AAV-FLnP-hALDH5A1 at symptomatic stage. AAV-FLnP-hALDH5A1 therapeutic effects directly correlate with the amount of restored SSADH in brain and myocardium, providing insights into tissue targeting, delivery route, AAV serotype selection, and relevant biomarker for eventual clinical translation of our findings into a first-in-class therapy for SSADHD.

21. From Darkness to Light: *CIB2* Gene Delivery Rescues Age-Related Macular Degeneration-Like Phenotype in a Preclinical Model

Sehar Riaz[1,2], Saumil Sethna[3], Saima Riazuddin[1], Zubair M. Ahmed[3]

[1]Otorhinolaryngology Head & Neck Surgery, University of Maryland, School of Medicine, Baltimore, MD,[2]Center of Excellence in Molecular Biology, University of the Punjab, Lahore, Pakistan,[3]Department of Otorhinolaryngology - Head & Neck Surgery,, University of Maryland, School of Medicine, Baltimore, MD

Worldwide, nearly 200 million people suffer from irreversible vision impairment due to age-related macular degeneration (AMD), a multifactorial neurodegenerative disorder. Prior studies have identified risk alleles in over 30 genes associated with AMD. However, the exact mechanism behind AMD remains largely elusive. AMD comes in two flavors: neovascular (wet-AMD) and slower, irreversible dry-AMD. Recently, the FDA has approved two drugs targeting complement pathways to treat geographic atrophy (GA), the most advanced stage of dry-AMD. Previously, we reported that deficiency of calcium and integrin binding protein 2 (CIB2), specifically in the RPE, leads to progressive vision impairment and dry-AMD-like phenotype in mice. We also showed that *CIB2* regulates autophagy in RPE via the mTORC1 signaling pathway. Herein, we packaged h*CIB2* in two different Adeno-associated virus (AAV) serotypes (AAV-Anc80L65 and AAV2.7m8), along with a control GFP-expressing vector, and performed gene augmentation studies in *Cib2* mutant mice via subretinal delivery. Interestingly, *hCIB2* subretinal delivery in mutant mice, at 1 month of age, using either capsid rescued the visual function as ascertained by electroretinograms (ERG), which persisted until 9 months (the latest timepoint tested) post-injection. We also found improved photopic visual acuity and contrast sensitivity levels in *hCIB2*-injected mice. Transmission electron microscopy (TEM) studies revealed a reduction of sub-RPE deposits while immunolabeling followed by confocal imaging demonstrated significantly reduced levels of drusen proteins such as Apolipoprotein E, beta-amyloid, C3, and C5B-9, and lipids such as unesterified cholesterol in *hCIB2* injected mice, indicating improved autophagy, which was confirmed through immunoblotting of LC3-II and p62/SQSTM1 levels. Finally, significantly reduced levels of pS6K and p4E-BP1, suggesting that the delivery of *hCIB2* results in the downregulation of mTORC1 and, consequently, an upregulation of autophagy. Taken together, these findings support the notion that AAV-mediated *CIB2* delivery could be a promising therapy for individuals suffering from dry-AMD and other mTORC1 hyperactivity-associated disorders and warrants further safety and efficacy studies in larger species.

22. Prevention of High-Risk Allogeneic Corneal Transplant Rejection by AAV-Mediated Transfer of Novel Anti-Inflammatory Immunomodulator

Tomoko Hasegawa[1], Brian C. Gilger[2,3], Sutton B. Roger[3,4], Jacquelyn Bower[1,5], Chengwen Li[3,6,7], Matthew L. Hirsch[1,3,6]

[1]Department of Ophthalmology, University of North Carolina at Chapel Hill, Chapel Hill, NC,[2]Department of Clinical Sciences, North Carolina State University, Raleigh, NC,[3]Bedrock Therapeutics, Raleigh, NC,[4]Department of Cell Physiology and Molecular Biophysics, Texas Tech University Health Sciences Center, Lubbock, TX,[5]Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill, Chapel Hill, NC,[6]Gene Therapy Center, University of North Carolina at Chapel Hill, Chapel Hill, NC,[7]Department of Pediatrics, University of North Carolina at Chapel Hill, Chapel Hill, NC

Corneal blindness affects over 5 million individuals globally, with over 180,000 allogeneic corneal transplantation (CT) performed worldwide annually. However, high-risk CT encounter a challenge as almost all grafts are rejected within 10 years, despite the current standard of care. In this study, adeno-associated virus (AAV) ex vivo gene therapy was investigated to establish immune tolerance in the corneal allograft to prevent graft rejection. Human leukocyte antigen G (HLA-G) is present in ocular tissues and contributes to immune privilege by inhibition of immune cells as well as by preventing neovascularization. Optimal HLA-G function relies on beta 2 microglobulin (B2M) association and then binding to another HLA-G/B2M heterodimer generating a 4 protein complex, the formation of which has been deemed rate-limiting. Although our previous work demonstrates that AAV-HLA-G gene addition treats uveitis, ocular graft versus host disease, corneal neovascularization and fibrosis, concerns remain as to the sequestration of host B2M altering tissue homeostasis. Therefore, a novel protein, termed single chain immunomodulator (scIM), was engineered that mimics the structural conformation of the 4 protein HLA-G/B2M complex. Investigations in cell lines demonstrate that scIM is a stable protein that exists intracellular and is also secreted. To investigate function, AAV8-scIM was administered via subconjunctival injection to a murine model prior to an alkali-induced corneal burn. One-week post-injury, AAV8-scIM treated animals demonstrated a significant reduction in corneal vascularization and decreased fibrosis compared to untreated controls. Next, ex vivo AAV8 gene delivery to rabbit corneal allografts was optimized which resulted in tissue retention of 3.0e6 vg following a 15 min tissue incubation with AAV8-scIM. To generate a high-risk CT rejection model, 4 sutures were placed in the recipient rabbit cornea 14 days before CT using vehicle or AAV8-scIM treated corneal allografts. Ocular inflammation and central corneal thickness steadily increased for both groups 14 days post-surgery, at which point the data diverted, with the vehicle group steadily increasing for both metrics while the scIM treated corneas returned to baseline levels over a 42 day period. Based on rejection index, 5/6 vehicle treated corneas were rejected while all of the AAV8-scIM allografts

were remarkably well tolerated with minimal vascularization and central corneal clarity. Histological analysis of rabbit central corneas revealed many CD3 positive infiltrating T cells in control group eyes while none were observed in scIM treated group. Consistent with the clinical analyses, neovascularization and fibrosis at the central cornea was obviously observed in control group eyes but not in scIM treated group. Biodistribution studies demonstrated viral genomes were restricted to the corneas that underwent CT with no induction of AAV8 neutralizing antibodies. The collective data demonstrate that scIM gene therapy prevents corneal neovascularization, reduces trauma-induced corneal fibrosis, and prevents allogeneic CT rejection in a high risk large animal model warranting further investigations to prevent allogeneic organ rejection in humans.

23. Neonatal AAV9 Gene Therapy Prevents Hepatic Mitochondrial Dysfunction in a Mouse Model of DGUOK Deficiency

Nandaki Keshavan[1], Simon Waddington[2], Rajvinder Karda[2], Shamima Rahman[1]

[1]Genetics and Genomic Medicine Programme, University College London, London, United Kingdom,[2]University College London, London, United Kingdom

Background and Aims: The mitochondrial DNA depletion syndromes are severe debilitating monogenic disorders of childhood. Mutation of the gene encoding deoxyguanosine kinase (*DGUOK*) is one cause, presenting with an infantile-onset hepatocerebral phenotype leading to death by 2 years. There are no curative treatments. Liver transplantation is unsatisfactory because it does not reverse or prevent the development of neurological disease. Effective disease-modifying treatments are urgently needed. We aimed to establish proof-of-principle for a neonatal intravenous (IV) AAV9 gene therapy approach to treating a mouse model of DGUOK deficiency that has recently been shown to recapitulate the human hepatocerebral disease phenotype. **Methods:** AAV9-CAG-*hDGUOK* vectors were generated and injected intravenously to *Dguok* KO mice at P1 for efficacy studies. A dose escalation of 8e13 vg/kg, 8e14 vg/kg and 8e15 vg/kg was undertaken to determine the minimum effective dose. **Results:** Excellent long-lasting liver transduction was demonstrated at both the 8e13 vg/kg and 8e14 vg/kg doses as indicated by high hepatocellular targeting (>99% transduction in vector copy number studies), and reconstitution of *DGUOK* RNA expression to endogenous levels. Immunohistochemical findings suggested that transduced hepatocytes in knock-out animals had a repopulation advantage over untransduced cells. Efficacy was clearly demonstrated by prevention of liver mtDNA depletion (Figure 1a), complete rescue of liver transaminitis to wild-type levels (Figure 1b), a dose-dependent improvement in survival (Figure 1c) and rescue of liver Complex I, III and IV activities (Figure 2a-c). Administration of 8e15 vg/kg, however, resulted in early mortality (Figure 1c).

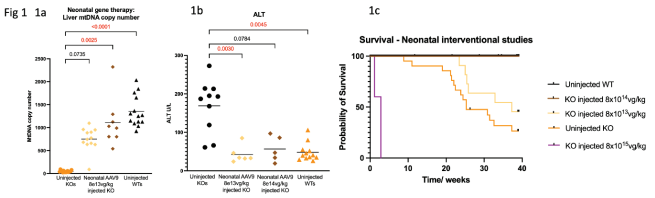


Figure 1 Liver mtDNA copy number, ALT and survival in gene therapy treated and control groups. The numbers above the brackets represent p values (Kruskal-Wallis test with multiple comparisons. p values <0.05 are considered statistically significant and are indicated in red).

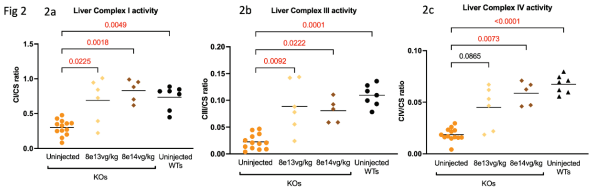

Figure 2 Liver Complex I, III and IV activities as a ratio to citrate synthase activity in gene therapy treated and control groups. The numbers above the brackets represent p values (Kruskal-Wallis test with multiple comparisons. p values <0.05 are considered statistically significant and are indicated in red)

Conclusions: Intravenous neonatal AAV9 gene therapy doses up to 8e14 vg/kg prevented liver mitochondrial dysfunction. This study suggests that AAV9-based gene therapy is a viable gene therapy approach to treating liver manifestations of DGUOK deficiency.

24. AAV9 Delivered Artificial microRNAs Effectively Improves GFAP Pathology and Motor Impairment in an Alexander Disease Rat Model

Wassamon Boonying, Guangping Gao, Jun Xie

Horae Gene Therapy Center, University of Massachusetts Chan Medical School, Worcester, MA

Alexander disease (AxD) is a type of rare neurodegenerative disease known as leukodystrophies. AxD is caused by dominant gain-of-function mutations in the glial fibrillary acidic protein (*GFAP*) gene and occurs in approximately one in one million births. The disease is progressive and fatal, ranging from infancy to adulthood. GFAP is mainly present in astrocytes of the central nervous system (CNS) and plays an important role in controlling myelination. Mutations in *GFAP* result in the overproduction and accumulation of the mutant form of GFAP, which causes the formation of Rosenthal fibers, the histopathological hallmark of AxD throughout the CNS. Currently, there is no therapy available to treat AxD. Thus, silencing mutant *GFAP* could be an attractive therapeutic approach. We have previously developed a scAAV9 vector (scAAV9-GfaABC1D-amiR-*GFAP*) expressing an artificial microRNA (amiR) to target the conserved *GFAP* sequences among mice, rats, NHPs and humans. The amiR expression directed by the native promoter of the human *GFAP* gene (GfaABC1D) was able to downregulate *GFAP* gene expression and effectively reduce Rosenthal fibers in the AxD mouse brains. However, the mouse model does not show the apparent leukodystrophy and the severity of the human disease phenotypes. Thus, we tested our scAAV9-GfaABC1D-amiR-*GFAP* in an AxD rat model which recapitulates the whole spectrum of severe features of the AxD syndrome, including high amounts of GFAP accumulation, widespread Rosenthal fibers

formation throughout the brain and spinal cord, myelin deficits, motor impairment, failure to thrive and increased mortality. We injected scAAV9-GfaABC1D-amiR-*GFAP* into three-week-old AxD rats (*Gfap*$^{+/R237H}$) by intravenous administration at a dose of 2.0 x e14 genome copies/kg. We found that the treated AxD rats started gaining body weight from three weeks post-injection compared to the untreated AxD rats. Four weeks later, the treated *AxD* rats showed significant improvements in the rotarod, grip strength and performance in the horizontal ladder test when compared to the untreated animals. In addition, histopathologic analysis showed significant reductions of Rosenthal fibers in whole brain of treated *AxD* rats. Reduced hyperintense signals (i.e. signs of brain edema) on T2 MRI imaging were observed in the treated AxD rat brains as well. Western blot revealed that GFAP protein levels were reduced after four weeks post-injection. Furthermore, the treated AxD rats continue to show improved performances in motor function tests at 12- and 36-weeks post-injection. Taken together, our data indicates that astrocyte-restricted gene silencing is a promising strategy for efficient and sustainable treatment of AxD and potentially other gain-of-function diseases that affect astrocytes. G.G. and J.X. are corresponding authors.

AAV Manufacturing I

25. Production of Different AAV Serotypes Using a Novel Plant-Based Viral Vector Manufacturing Platform

Pranav Dinesh Mathur, Qingqing Xie, Kevin Wong, Terri Grider, Finley Burns, Katarina Dumar, Matthew Schafer, Connors Jake, Daniel Gibbs

Cirsium Biosciences, San Diego, CA

Introduction: The manufacturing gap in Gene Therapies is emerging as the primary bottleneck in the field. The expensive production of AAV vectors in mammalian or insect cells results in prohibitively high costs for approved AAV-based gene therapies. With single doses priced in the millions of dollars, these crucial treatments are inaccessible to many patients. In addition, with more than 3000 pre-clinical and clinical cell and gene therapies currently under development, and with the existing scale-up process taking anywhere from 9-18 months, manufacturing facilities are finding it harder to keep up with the growing demand. While the concept of producing biologics in plants has existed for decades, with several plant-based biologics demonstrating effectiveness and gaining regulatory approval, manufacturing viral vectors in these systems had not been previously attempted. Here we report for the first time, successful production of highly potent AAVs using whole plants as modular bioreactors. Methods: Using a transient plant-based expression methodology, we delivered the necessary components for making AAV2 or AAV9-CMV-GFP viruses (Rep, Cap, GOI and helper genes) to *Nicotiana Benthamiana* plants. In this method, plants were infiltrated using *Agrobacterium* containing engineered plasmids of interest. Five days later, harvested leaf matter was homogenized, and AAV was purified from the lysate using post-clarification downstream methods identical to conventional AAV purification. This involved TFF for crude lysate concentration, followed by affinity capture and Iodixanol gradient purification to enrich full AAVs. In parallel, we transfected adherent HEK293 cells with plasmids containing Rep, Cap, GOI and helper genes to produce AAV2 or AAV9-CMV-GFP. Cells and media were harvested and mammalian-AAV-CMV-GFP was purified using the identical downstream protocol that was used to purify the plant-AAV-CMV-GFP virus. Next, we characterized and compared the mammalian and plant produced AAV-CMV-GFP using dPCR, ELISA, TEM, SDS page, Sterility testing, Endotoxin and Mycoplasma testing to name a few. Further, we tested the infectivity of plant-AAV-CMV-GFP against the mammalian-AAV-CMV-GFP in-vitro, ex-vivo and in-vivo. Results: We found that Plant produced AAVs purified with similar recovery percentages to that of the HEK293T derived AAV, suggesting that the existing downstream methods for AAV purification works well for the plant derived AAVs. Plant-AAV-CMV-GFP demonstrated VP1, VP2 and VP3 banding ratios and purity by SDS-PAGE similar to the mammalian-AAV-CMV-GFP vector, and both sources produced ~90% full capsids post purification, as observed by TEM and ELISA. We were able to obtain ~1e14vgs from 1Kg biomass of plant and from 1L of mammalian culture. Both AAVs were free of any contaminants, mycoplasma and had lower than FDA recommended Endotoxin levels. When compared in vitro, ex vivo, and in vivo, both plant and mammalian AAVs showed potent infectivity and comparable tropism. Conclusion: Here we report for the first-time, transient production of two different AAV serotypes using plants as modular bioreactors. Manufacturing AAVs by this method drastically (>10-fold) reduces the cost of goods compared to the traditional mammalian-based systems. Further, this method significantly reduces the scale up time and because individual plants act as a single reproducible unit of production, this method is highly reliable during the scale up process. This unique upstream method of AAV production in plants still provides identical downstream purification options as used for current mammalian-AAV production methods, making this technology easy to adapt by any existing AAV manufacturing facilities. We believe that our manufacturing method can solve some major challenges that the field of Cell and Gene therapy is currently facing.

26. A Novel Proviral Plasmid Reduces Cross-Packaging and ITR Promoter Activity in AAV Vector Preparations

Noah Taylor, Matthew John Guggenbiller, Pranali Mistry, Scott Q. Harper

Center for Gene Therapy, Nationwide Children's Hospital, Columbus, OH

Background: AAV preps largely contain correctly packaged genomes, with the intended ITR-flanked, therapeutic gene expression cassette inserted within the AAV capsid. However, achieving 100% AAV genome purity is challenging. A recent survey suggested AAV preps contain ~3.5% packaged DNA contaminants (N=30; range <1 - 13%), mostly derived from mispackaging of proviral plasmid backbone sequences instead of the intended payload. Thus, AAV contaminants can include sequences required to propagate plasmids in bacteria, such as antibiotic resistance genes and bacterial sequences with immunostimulatory CpGs and/or potential open reading frames (ORFs). Such AAV contaminants are often referred to as cross-packaged material. Potential risks of cross-packaged bacterial sequences in AAV vectors were highlighted in a recent study in non-human primates, where AAV contaminants were toxic to monkey brain (PMID: 34663988). Toxicity was linked to ITR-driven expression of transcripts arising

from cross-packaged bacterial sequences in the plasmid backbone and *not* the intended payload. These results suggested that improved production methods are needed to (1) increase correctly packaged AAV payloads, and (2) decrease ITR-driven transcription of cross-packaged material to avoid expressing potentially toxic bacterial sequences. Methods: *Interfering with ITR-driven transcription.* We generated a dual luciferase reporter plasmid containing promoterless *Renilla* or Firefly luciferase cDNAs outside each ITR (i.e. in the plasmid backbone). We then inserted insulator sequences in the plasmid backbone between the ITR and luciferase genes or flanking the ITR on both sides, and assessed ITR-driven gene expression via dual luciferase assay. *Reducing cross-packaging.* We designed a novel AAV proviral plasmid for vector production. We inserted 3 modifications into a basic scAAV proviral plasmid containing an AAV2 ITR-flanked miRNA payload and stuffer sequence, and plasmid backbone containing a Kanamycin resistance gene and bacterial origin of replication (5.6 kb total size). Specifically, we (1) flanked ITRs with insulator sequences to decouple ITR-driven transcription from adjacent ORFs; (2) inserted large human intronic sequences in the plasmid backbone adjacent to the ITRs (11.1 kb total size), so that any cross-packaged material would more likely contain human, and not bacterial DNA; (3) mutated all ATG start codons in the human intronic sequences to ensure that protein translation could not be initiated from any remaining cross-packaged plasmid backbone sequences. We then used this plasmid to generate 7 different AAV serotypes, and assessed vector titer, gene expression, and presence of cross-packaged material. Results: Insulators reduced *Renilla* and firefly luciferase activity by 55% (insulators in plasmid backbone only) or 90% (ITR-flanking insulators), supporting this design may be useful for inhibiting ITR promoter activity. Average percentage of cross-packaged material was 1.35% using our first-generation scAAV proviral plasmid, while our optimized scAAV proviral plasmid significantly reduced cross-packaging by half (0.65% avg), with improvements for every serotype tested (1, 2, 5, 6, 9, rh10, rh74). The new plasmid had no impact on viral titers or expression from correctly packaged genomes. Conclusions: We achieved the goals of our study by reducing cross-packaged DNA in AAV preps, and decoupling ITR promoter activity from adjacent DNA sequences, thereby reducing the potential for expression of deleterious ORFs. This plasmid could be used to improve yield of correctly packaged AAV genomes and reduce the potential for toxic gene expression from remaining cross-packaged material.

27. Removal of Empty and Partial AAV Capsids Using Cu Ions and Oversaturated Loading on Multicolumn AEX Chromatography

Ohnmar Khanal, Vijesh Kumar, Mi Jin

Technical Development, Downstream, and Drug Product Development, Spark Therapeutics, Philadelphia, PA

A common platform adeno-associated virus (AAV) purification process comprising filtration and two-step chromatography operations is costly and can impact product quality and efficacy. A current challenge in the downstream purification of recombinant Adeno-associated virus is the separation of transgene-containing capsids from empty and undesired capsid variants. Anion exchange chromatography (AEX) resin is often used below its saturated binding capacity to separate empty and full AAV particles on a single column. However, the outcome of the traditional single-column operation can be impacted by variability in load composition, sensitivity to buffer composition, and fractionation strategies. Furthermore, the removal of empty and partial capsids with a high yield is rarely demonstrated in literature. This talk will present three-stage separation strategies for two rAAV constructs and show how to overcome the yield/purity trade-off. The first is the selection of resin chemistry (Poros XQ, Poros HS, Poros I) with a concoction of kosmotropic agents such as ammonium sulfate or sodium sulfate to promote capsid stability at low ionic strength. Metal ions (Cu, Mg, Ca) were used to promote desired capsid selectivity. Using Cu ions improved the resolution between empty and full capsid separation and helped remove other product-related impurities. The second is selecting an appropriate resin/media structure and geometry to exclude AAV from smaller resin pores such as Poros XQ, minimizing dispersion and improving resolution. Monolith and membrane chromatography showed better peak resolution than traditional resin based on favorable transport behavior. The third is the transition from single column to multiple columns in series with a loading of 1.5x the resin saturation capacity to allow for > 40% reduction of partial capsids and > 95% removal of empty capsids. Using these strategies, we provide the best modality to achieve maximum empty and partial capsid removal with a yield > 80%.

28. Novel Mechanism to Increase rAAV Yield through Blocking rAAV Transduction of the Manufacturing Hek293 Cells During rAAV Production

Xiaofei E[1], Anmol Kotian[2], Isabella Pajevic[2], Bisma Ajaz[2], Jennifer Marlowe[1], Sharon McGonigle[1]

[1]R & D, Solid Biosciences, Charlestown, Boston, MA,[2]A & D, Solid Biosciences, Charlestown, Boston, MA

Recombinant adeno-associated virus (rAAV)-mediated gene therapy is a promising gene delivery strategy that allows for broad clinical application. With recent clinical success, there is rising demand for improved rAAV production processes to increase yield, enhance quality, and reduce costs. In this study, we first demonstrated that extracellular rAAV being produced in HEK293 cells by transient transfection can transduce the manufacturing cells. Protein expression from two different rAAV-delivered transgenes was detected in lysates from HEK293 cells sampled at various timepoints during rAAV production. Supernatant transfer experiments further confirmed that extracellular rAAV does transduce HEK293 cells during rAAV production. From this observation, it follows that a lower rAAV yield will result from loss of rAAV to transduction of HEK293 cells. We then explored whether inhibitors of endocytosis could block AAV transduction of the production HEK293 cells. Two small molecule inhibitors of endocytosis (compounds A and B) were identified for their ability to limit this transduction. When added to HEK293 cells during rAAV production, both compounds resulted in a significant reduction in rAAV transduction as measured by transgene protein expression. Reduced transduction translated into increased rAAV yield of 2-3-fold, presumably since this rAAV was no longer being lost to transduction and returned to the media supernatant. The impact of compound A treatment on rAAV yield and quality was further characterized. The optimal timing of addition to HEK293 cells was identified with an observed ~3-fold increase in rAAV yield, as compared to low or no effect when administered at earlier or later timepoints. A dose-

responsive effect on rAAV yield was observed for the compound with no impact on HEK293 cell viability or growth. Following iodixanol purification of rAAV produced in the presence or absence of compound A, the viruses were assessed in various quality assays, where compound A-produced rAAV yielded similar or marginally improved quality attributes. Significantly, rAAV produced in the presence of compound A showed consistently higher transgene expression in a cell-based assay. Increased yield through transduction inhibition by Compound A has been extensively studied with rAAV-SLB101 (a novel capsid with AAV9 backbone) production; moreover, a similar effect has also been observed during rAAV rh74 manufacture. These data highlight that loss of rAAV to transduction during manufacture does occur and is significant. Addition of endocytosis inhibitors limits this transduction and consequently improves rAAV yield and quality via this previously unreported mechanism. Studies are underway to better understand how broadly applicable this novel finding may be across various rAAV manufacturing processes and platforms.

29. Enhancing Product Quality: Utilizing Salt-Tolerant Anion Exchange Chromatography in Flow-Through Mode as a Polishing Step for Advanced Process-Related Impurity Removal

Johanna Weizenegger, Regina Staffler, Julia Trommer, Sinisa Petrik, Matthias Boscher, Johanna Wagner, Jared Babic, Beatriz Laurena Carnio, Anita Heinlein, Christine Zach, Sebastian Ritter, Matthias Gora, Tobias Kloetzler, Alexandra Schoberth, Ahmed Youssef, Karl Heller, Markus Hoerer, Melanie Langhauser

Ascend, Planegg, Germany

Recombinant adeno-associated virus (rAAV) is among the most widely used viral vectors for gene therapy. However, vector manufacturing remains a challenge to demand for **high quality AAV vectors**. In our modular AAV **platform purification process** as polishing step for further unpacked impurity removal an **Anion Exchange Chromatography (AEX) in Flow-Through (FT) mode** can be applied after affinity capture chromatography. Since higher salt concentrations during the affinity chromatography elution reduced the aggregation level for some AAV serotypes, this study explores the applicability of a salt tolerant serotype independent AEX step in FT mode. Usually, an AEX step is performed at low salt concentrations to receive unpacked impurity removal. Therefore, the goal of this study was to assess the effectiveness of AEX membranes and resins to remove impurities despite a higher level of conductivity. We performed a comprehensive screening study with **four AEX resins/membranes at varying conductivities**, assessing their performance in terms of recovery and the removal of aggregation, host cell proteins (HCPs) and non-packed DNA. To challenge the purification capacities and to determine impurity removal factors, the load material was spiked with a mixture of HCPs and non-packed DNA. The step recoveries were not affected by the conductivity of the load material, but differences were observed between the tested AEX resins/membranes. Across all conditions, regardless of the resin/ membrane or salt concentration used, non-packed DNA was consistently reduced below the detection limit of the applied analytical method. Moreover, all conditions proved effective aggregate removal as determined by DLS. The most notable difference among the tested resins/ membranes was observed for the HCP removal. Two out of four tested AEX exhibited a remarkable efficacy with one of them demonstrating a consistent performance across a wide range of salt concentrations, showcasing its robustness. The second AEX resin displayed a salt-dependent trend, where higher conductivities correlated with a decreased ability to remove aggregates. However, given that the impurity level in spiked samples was significantly higher than in our standard Downstream Process, the removal capacity was sufficient. Despite an excellent performance in aggregate and non-packed DNA removal for all tested resins and membranes, we selected one specific AEX resin for our modular platform process due to its most desirable properties with respect to step recovery, HCP removal and scalability. **This serotype independent AEX step in FT mode improves product quality and can be applied under high-conductivity conditions if needed.** High product quality and safety is at the core of our research and platform offering. This AEX step can be used to deliver high quality AAVs. It is an optional process step which can be implemented based on client needs.

30. Optimizing Affinity Chromatography Purification for Enhanced Quality and Stability of Adeno-Associated Viral Vectors (rAAVv)

Thuy Linh Do, Zeynep Çukurçeşme, Susanne Konrad, Thomas Bissinger, Chris Williams

Gene Therapy Technical Research & Development, Roche, Penzberg, Germany

The production and purification of Adeno-associated viral vectors (rAAVv) is a complex process that requires simultaneously careful consideration of numerous factors to ensure optimal yield, purity, potency and stability. Specifically, during the Affinity Chromatography purification step, there are potential product quality risks such as loss of viral vector particles, contamination, non-specific binding of impurities, and potential impact on the integrity and potency of the final product. To ensure comprehensive management of product quality risks, it is important to holistically examine the entire Affinity Elution/ Neutralization phase, taking into account factors such as buffer pH, buffering components, stabilizers, pooling parameters, and the timing of neutralization. To determine the optimal elution conditions, a comprehensive investigation was conducted. Initially, a negative linear gradient using an acidic buffer solution was employed to determine the range of elution pH. The elution profile revealed a suitable pH range for subsequent experiments. Subsequently, affinity chromatography purification of rAAVv with the elution buffer solutions from more mild to more acidic pHs was performed to assess the impact of different elution pH values on the yield and purity of the eluted product. To further explore the stability of rAAVv under optimal elution conditions, an acidic hold time study was conducted. The eluted rAAVv product was held at two pH levels for various periods, ranging from 0 up to 16 hours before neutralization. The stability study aimed to evaluate changes in yield, purity, aggregation, and potency over time. The results demonstrated that selection of the most appropriate elution pH can confer superior rAAVv stability in terms of yield and purity, even over extended periods. Here correlations were observed by product loss and the formation of aggregated particles. We also observed a time-dependent formation of post-translational modifications which, if left uncontrolled, may contribute to variability in product quality

and performance. These findings have significant implications for the development of rAAVv purification processes in gene therapy applications. Optimizing elution pH, particularly by employing the newly identified pH range for elution, can improve the yield, purity, and stability of rAAVv vectors. By carefully selecting elution conditions, it is possible to obtain high-quality rAAVv vectors while minimizing the detrimental effects of low pH on the capsid structure. In summary, this study offers valuable insights into the influence of elution buffer components and neutralization timing on the stability of rAAVv during affinity chromatography purification. These findings are significant for the development of strategies aimed at improving the efficiency and quality of rAAVv purification processes, thereby supporting the progress of gene therapy applications. Further research is necessary to investigate additional factors that may impact rAAVv stability and to further optimize the purification process.

31. Not Created Equal: Impact of Deamidation on Capsid Heterogeneity and Anion Exchange Chromatography (AEX) Performance

Oxford Biomedica (US) LLC, Bedford, MA

Post-translational modification of Adeno-Associated Virus (AAV) capsid proteins is becoming a focus in the gene therapy process and analytical development space. In particular, deamidation of capsid protein VP1 specific residues including N57 has been linked to a loss of potency in vivo. Temperature, pH, and storage time have been identified as key factors causing this phenomenon. As a result, controlling strategies in the upstream and downstream processes should be studied and defined at the early stage of process development to limit onset of deamidation in order to minimize product related impurities and loss of vector functionality. Besides process control to prevent deamidation, here we also discuss our approach to removing deamidated AAV capsids in the downstream process. We hypothesize that extrusion of VP1 and deamidation of N57 are related and result in capsid heterogeneity of empty, partial, and full capsids which significantly influences the Anion Exchange Chromatography (AEX) process' ability to remove empty capsids and deliver functional AAV. Currently, charge driven separation techniques do not provide adequate resolution required to differentiate between deamidated and non-deamidated capsid species. Here we highlight our novel approaches that can be employed in the AEX process to tackle this complex challenge in removing not only empty capsids but also deamidated intact capsids.

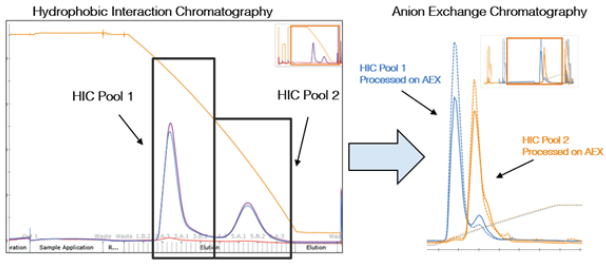

Figure 1: Hydrophobic Interaction Chromatography was first utilized to separate out to distinct peaks with near baseline resolution. Each peak was isolated and reprocessed on AEX individually.

We present how non-orthodox AAV purification techniques were utilized to isolate and further characterize the different AAV capsids that are difficult to resolve on a typical anion exchange chromatography (AEX) gradient. Surprisingly, we discovered that Hydrophobic Interaction Chromatography (HIC) resolved two different species of AAV capsids with near baseline resolution. Each species was reprocessed on AEX and all product quality attributes were assessed for the intermediate peaks that were generated. We found that the capsids that were more hydrophobic were also more negatively charged. LC-MS data demonstrated the capsids that were more hydrophobic and more negatively charged had significant levels of VP1 specific N57 deamidation which has been linked to a loss in gene expression. We hypothesize that the capsids are more hydrophobic due to VP1 extrusion which exposes the hydrophobic PLA2 domain on VP1u. This phenomenon would make VP1 N57 residue solvent exposed and susceptible to deamidation. We demonstrated that hydrophobic interaction chromatography can be used to separate non-deamidated capsids from deamidated capsids. We also present a novel, patent-pending approach to simultaneously remove deamidated species and enrich for full capsids on anion exchange chromatography.

Neurologic Diseases I

32. Promoter Influences Acute Liver Toxicity and Long-Term Hepatic Genotoxicity in rAAV SMA Gene Therapy in Mice

Xiupeng Chen, Qing Xie, Hao Liu, Veena Kumanan, Hong Ma, Phillip WL Tai, Guangping Gao*, Jun Xie*
Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA

The use of recombinant adeno-associated viruses (rAAVs) for human gene therapy has been a significant breakthrough, demonstrating therapeutic efficacy in an increasing number of clinical trials. However, liver toxicity is one of the major safety concerns. Onasemnogene abeparvovec (Zolgensma®) is an approved rAAV gene therapy for infants with spinal muscular atrophy (SMA). Currently, over 3,000 patients have been treated with Zolgensma. The high systemic dose at 1.1×10^{14} vector genomes/kg is required for efficacy but is associated with safety concerns as warned by a black box warning for severe liver injury and acute liver failure which is likely caused by strong ubiquitous expression of SMN1. We previously developed a second-generation SMA gene therapy expressing a codon-optimized *hSMN1* transgene driven by a promoter derived from the native *hSMN1* gene. This vector restored SMN expression close to physiological levels in the central nervous system and other major tissues of a severe SMA mouse model. In a head-to-head comparison between the 2nd-generation SMA gene therapy (SMA GTx) and a benchmark vector with a design identical to Zolgensma, the 2nd-gen. SMA GTx showed improved efficacy including a longer life span; increased motor, cardiac, and respiratory functions; and minimal peripheral tissue manifestations. Here, we investigated

those two vectors for acute liver toxicity in SMA mice and long-term hepatic genotoxicity in C57BL/6 mice. We first assessed transaminitis by measuring ALT and AST levels in SMA mice on Day 30 after treatment with the benchmark or 2nd-gen vector. SMA GTx vector at a dose of 3.3E+14 vg/kg by facial vein injection at P0. We detected significant elevations of ALT and AST in the benchmark vector-treated mice (150.4 U/L and 290.8 U/L respectively) but not in the 2nd-gen. vector-treated mice (35.2 U/L and 93.3 U/L, respectively, $p < 0.01$ for both comparisons) which were statistically indistinguishable from healthy carrier littermates ($p > 0.96$ for both comparisons). We next compared liver toxicities of the two vectors after intracerebroventricular (ICV) administration to C57BL/6 mice at P0 with a dose of 1.0E+14 vg/kg. In a 20-month study duration, we found ~44% (8/18) of mice died in the benchmark group, and 6% (1/17) of mice died in the 2nd-generation vector group. Among the surviving mice, all the animals (10/10) from the benchmark group developed hepatocellular carcinoma (HCC). In contrast, only one mouse (1/16) in the 2nd-gen vector group detected liver tumors. In addition, significant elevations of ALT and AST were found in the benchmark vector-treated mice (620.2 ± 410.7 U/L and 1518.2 ± 1097.0 U/L respectively) but not in 2nd-generation vector-treated mice (20.6 ± 3.0 U/L and 49.4 ± 6.1 U/L, respectively, $p < 0.05$ for both comparisons). We further analyzed the expressions of *Dlk1*, *Rian*, *Mir543*, *Mirg*, *Mir300*, *Mir134*, *Mir1188*, *Mir382*, and *Mir487b* which are associated with AAV genome integration-related hepatic genotoxicity. Our RT-ddPCR data revealed significant increases in the expression of these 9 genes in the liver tumors as compared to that of the tumor-adjacent tissues and livers from untreated C57BL/6 mice. Importantly, ICV delivery of 2nd gen. vector to SMA mice at P1 achieved significantly better therapeutic efficacy as compared to the benchmark vector. In sum, endogenous hSMN1 promoter-mediated SMA expression holds a promise to not only enhance therapeutic efficacy but also mitigate acute and long-term liver toxicity in AAV gene therapy. * **G.G., and J.X are co-corresponding authors**

33. Intra-CSF AAV9-GBA Delivery Produces Species and Route of Administration Differences in Safety and Efficacy

Neeta Abraham, Ana Amaral, Shawn Kyle Bourque, Yi Chen, Pete Clarner, Jim Fikes, Peter-Joseph De Giovanni, Davide Gianni, Kelly E. Glajch, Branka Grubor, Stefan Hamann, Warren Hirst, Melissa Kirkland, Lee Koetzer, Merilla Michael, Prasad Nadella, Kalyani Nambiar, Ed Plowey, Jennifer Sebalusky, Junghae Suh, Eric Tien, Patrick Trapa, Dominic Walsh, Shanqin Xu, Weike Zeng

Biogen, Cambridge, MA

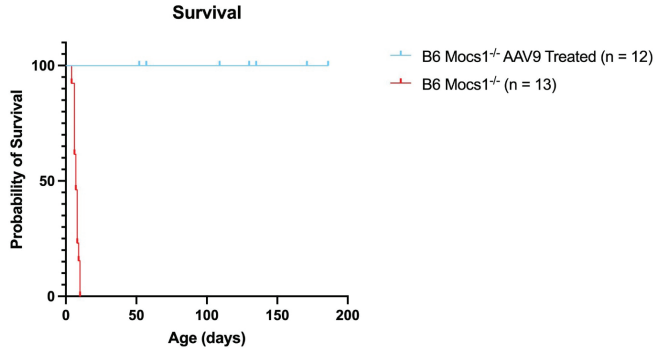
Previous studies have demonstrated AAV delivery of lysosomal enzymes to the brain is efficacious in rodent models of disease and this approach is currently being tested in clinical trials for several indications. Unfortunately, limited biodistribution, expression and safety data exist from non-human primate (NHP) studies testing AAV brain delivery, and very little using AAV9, which is a common capsid for this approach. In this study, we used AAV9 to deliver *GBA1*, the gene encoding the lysosomal enzyme glucocerebrosidase (GCase), to mice and NHPs. Loss of function mutations in GCase cause Gaucher's disease and are a major risk factor for Parkinson's disease. In mice, early postnatal intracerebroventricular (ICV) administration of AAV9-GBA1 produced significant brain viral biodistribution and a dose dependent increase in functional protein (as indicated by increased GCase activity) in several brain regions. Furthermore, histological analysis did not show any signs of inflammation (microglial reactivity) in the brain and no in-life clinical signs were detected. These findings allowed us to identify a target dose for scaling to NHPs that produced a sufficient increase in expression and activity without any histological signs of toxicity. Next, we performed two separate NHP studies to administer AAV9-GBA1 into the brain via intracisterna magna (ICM) or intraparenchymal (IPa) delivery. ICM delivery led to modest biodistribution and very minimal transduction and expression (RNA and GCase activity) in the brain. However, there was a significant transduction of dorsal root ganglia (DRG) neurons along with adverse microscopic findings in DRGs as well as in the spinal cord, dorsal nerve roots, and peripheral nerves. In contrast, IPa delivery into the thalamus and/or putamen produced significant biodistribution and transduction along with increased GCase expression and activity in several brain regions. While no DRG toxicity was observed with IPa delivery (in line with the limited transduction in this region), there were significant adverse microscopic findings in several brain regions and clinical signs that were procedure and AAV9-GBA1 related. In summary, these findings demonstrate that AAV9-GBA1 delivery in NHPs (via ICM or IPa) did not achieve the desired biodistribution and expression levels in the brain without concomitant safety findings, in contrast to our results in mice. Further technological advances are needed to obtain robust transduction and expression with AAV delivery to the NHP brain without significant safety findings.

34. AAV1.NT-3 Gene Therapy Improves Function, Electrophysiology, and Histopathology in *Sh3tc2*$^{-/-}$ Mouse, a CMT4C Model

Burcak Ozes[1], Lingying Tong[1], Kyle Moss[1], Morgan Myers[1], Lilye Morrison[1], Zayed Attia[1], Zarife Sahenk[1,2,3]

[1]Center for Gene Therapy, Abigail Wexner Research Institute, Nationwide Children's Hospital, Columbus, Columbus, OH,[2]Department of Pediatrics and Neurology, The Ohio State University, Columbus, OH,[3]Department of Pathology and Laboratory Medicine, The Ohio State University, Columbus, OH

Charcot-Marie-Tooth disease (CMT) is a group of heterogeneous inherited polyneuropathies. CMT4C is an autosomal recessive demyelinating subtype of CMT, caused by mutations in the SH3 domain and tetratricopeptide repeats 2 (*SH3TC2*) gene. Neurotrophin 3 (NT-3) is an autocrine factor supporting Schwann cell (SC) survival and differentiation and stimulates axon regeneration and myelination. NT-3 also has a role in the maintenance of neuromuscular junction (NMJ) integrity. In this study, we investigated the efficacy of AAV1.tMCK.NT-3 gene therapy in a CMT4C model, *Sh3tc2* $^{-/-}$ mouse. *Sh3tc2* $^{-/-}$ mice received 1x10^{11} vg dose of rAAV1.tMCK.NT-3 vector via intramuscular injection at four weeks of age (n=15, even sex distribution). Age- and sex-matched *Sh3tc2*$^{-/-}$ mice were used as untreated (UT) controls (n = 16). The mice were sacrificed six months post-treatment. Outcome measures included rotarod and grip strength functional tests, electrophysiology, quantitative histological assessment



of nerve and muscle and innervation status NMJs. Functional studies showed that NT-3 treated mice preserved function with time and performed better than the UT counterparts at the endpoint by 17% for both rotarod and grip strength (rotarod, p=0.0381; grip strength, p=0.0297). Electrophysiology performed at the endpoint also showed improvement in the mean nerve conduction velocity in the treated cohort by 31% compared to UT mice (NT-3: 29.7 ± 2.47 vs. UT: 22.7± 2.01 m/s; n=15 in each cohort, p=0.0256). G ratio quantified from the sciatic nerve images of the treated mice decreased significantly compared UT cohort indicating improvements in the myelin thickness. (p=0.0492). Quantification of the density of small myelinated fibers (MFs) and the SC nuclei associated with Remak bundles showed an increase in both sciatic and tibial nerves of NT-3 treated group suggesting that NT-3 promoted SC proliferation and regeneration associated myelination. A significant increase was observed in the total MF density in the tibial nerve (p= 0.0084) although this increase was not observed in the sciatic nerves indicating that treatment improved the length dependent axon loss. Moreover, percent of innervated NMJs were higher in the treated mice compared to UT counterparts in the lumbricals (p= 0.048). Fiber size analysis of gastrocnemius, and tibialis anterior muscles following succinic dehydrogenase stain indicated an increase in both muscles in females, being prominent in the type II fibers (gastrocnemius, p=0.045; tibialis anterior, p= 0.0199). *Sh3tc2*$^{-/-}$ model for CMT4C is the fourth CMT subtype model that we showed the efficacy of AAV1.NT-3 gene therapy, highlighting the potential for clinical applicability of this surrogate gene therapy approach to a large group of CMT patients.

35. AAV9-rMOCS1 Gene Therapy, a Bicistronic Gene Delivery, Fully Rescues Neonatally Lethal Mouse Model of Molybdenum Cofactor Deficiency Type A

Claire E. Shamber[1], Edwin Alyea[2], Guenter Schwarz[3], Pazhanichamy Kalailingam[1], Casey A. Maguire[4], Albert Misko[2], Patricia L. Musolino[5]

[1]Center for Genomic Medicine, Massachusetts General Hospital, Boston, MA,[2]Neurology, Massachusetts General Hospital, Boston, MA,[3]Cologne University, Cologne, Germany,[4]The Massachusetts General Hospital, Charlestown, MA,[5]Center for Genomic Medicine, Neurology, Massachusetts General Hostpial, Boston, MA

Objective: To show the feasibility and efficacy of a bicistronic gene therapy for Molybdenum Cofactor type A using a construct that recapitulates the complex expression of the endogenous MOCS1 gene. Molybdenum cofactor (MOCO) deficiency (MOCOD) is a devastating genetic, neurodegenerative disease characterized by neonatal intractable seizures and neurological disability that leads to death in the first three years of life. MOCOD affects one in 200,000 newborns globally. MOCOD Type A stems from mutations in the conserved bicistronic MOCS1 gene that produces proteins MOCS1A and B which form a complex in the MOCO pathway. Loss of activity abolishes production of MOCO and inactivates MOCO dependent enzymes. Among these enzyme deficiencies, the loss of sulfite oxidase, which metabolizes toxic sulfite into non-toxic sulfate, is necessary and sufficient to cause the neurodegenerative phenotype of MOCOD. Current available treatments are not well tolerated or fail to prevent disease progression. We designed an AAV compatible recombinant version of the endogenous human MOCS1 gene. In vitro validation of MOCS1 expression and restoration of sulfite oxidase was performed by transfection of WT and MOCS1 knockout HEK293 cells. Expression of MOCS1A and MOCS1B was measured by western blot. We compare survival, behavioral, tissue metabolism and histological characteristics of the Mocs1 knock out mouse with WT and Mocs1 heterozygote. Biodistribution and efficacy studies were performed at 7 days and 8 weeks following post-natal day 1 (P1) retroorbital AAV9-rMOCS1 injections. Molecular read-outs at these time points include protein expression, enzymatic activity, IHC and vector genome copies. Long term survival studies are ongoing with weekly weights and behavioral testing. Our designed rMOCS1 construct expressed MOCS1A and MOCS1B and successfully restored sulfite oxidase enzymatic activity in MOCS1 KO HEK293 cells. Untreated Mocs1 KO mouse showed established severe phenotype characterized by progressive spasticity, stunted growth, hyperkeratosis, and death before 10 days of life. Biodistribution studies confirmed liver expression of MOCS1A and MOCS1B five days after P1 injection of AAV9-rMOCS1. Treated mutant mice show no significant difference in neonatal neurological development when compared to control littermates. Long term studies have shown survival extending beyond 8 months after a single dose of AAV9-rMOCS1. Mutant and control treated animals show no apparent toxicity or significant abnormalities in growth, neurological examination or behavior. We demonstrated in vivo successful endogenous splicing and protein expression of a bicistronic human gene delivered by a single AAV vector. We completed the Mocs1 mouse model phenotypic assessments and confirmed survival and severe neurological phenotype seen in patients. Single dose systemic AAV-mediated gene delivery of our rMOCS1 construct fully rescued neurological and systemic disease long term. Our study serves as a proof of concept for a single dose AAV9 gene therapy with long-lasting effects enabling a first in human study for children suffering from MOCOD Type A.

36. Developing an AAV-Based Gene Replacement Therapy for Mitochondrial Alanyl-tRNA Synthetase 2 (*AARS2*) Leukodystrophy

Ruxiao Xing[1], Lingzhi Ren[1], Nan Liu[1], Chen Zhou[1], Jialing Liang[1], Jiaming Wang[1,2], Guangping Gao#[1,2], Dan Wang#[1,3]

[1]Horae Gene Therapy Center, University of Massachusetts Chan Medical School, Worcester, MA,[2]Department of Microbiology and Physiological Systems, University of Massachusetts Chan Medical School, Worcester, MA,[3]RNA Therapeutics Institute, University of Massachusetts Chan Medical School, Worcester, MA

The nuclear *AARS2* gene encodes mitochondrial alanyl-tRNA synthetase 2 that is responsible for attaching alanine onto the cognate tRNA in mitochondria. The resulting alanyl-tRNA participates in mitochondrial translation that produces the key proteins constituting the mitochondrial respiratory complexes. *AARS2* mutations have been implicated in two recessive diseases: infantile cardiomyopathy and late-onset leukodystrophy. Currently, there is no treatment available for *AARS2* related diseases.Animal models that recapitulate human disease are of paramount importance to AAV gene therapy development. However, homozygous *Aars2* knockout (KO) mice are embryonically lethal. Therefore, we sought to engineer an AARS2 leukodystrophy patient-derived mutation in the mouse endogenous *Aars2*, and successfully generated mice homozygous for the M146T mutation. The *Aars2*$^{M146T/M146T}$ mice showed 50%-80% reduction in AARS2 protein (but not mRNA) in multiple tissues compared with WT littermates. We are currently characterizing the phenotype of the *Aars2*$^{M146T/M146T}$ mice as they age. As another approach to overcome embryonic lethality due to constitutive *Aars2* knockout, we generated a mouse line harboring a loxP-flanked human *AARS2* transgene, which is expected to rescue endogenous *Aars2* KO and enable conditional AARS2 depletion after crossing with a Cre driver line. Resulting mouse strains will allow us to dissect the impact of AARS2 deficiency in specific tissue and cell types, and to test targeted AAV-based gene therapy.To develop a potential gene replacement therapy, we generated recombinant AAV9 vectors expressing human *AARS2* driven by a ubiquitous promoter (rAAV9.hAARS2), and injected wild-type (WT) mice to test the safety of AARS2 over-expression after birth. We found that systemic delivery to neonatal mice via facial vein injection caused animal death within a week, whereas intracerebroventricular injection was well tolerated. TUNEL assay revealed apoptotic hepatocytes in the animals receiving facial vein treatment, suggesting liver toxicity. Therefore, we modified the expression cassette to include miR122 binding sites that enable liver-specific, miR122-mediated transgene silencing (rAAV9.hAARS2.miR122BS). Indeed, the modified vector design prevented hepatocyte apoptosis and animal lethality following facial vein delivery. Together, our preliminary results support the safety of brain-directed, liver-detargeted *AARS2* gene replacement therapy. Studies on disease pathomechanisms and *in vivo* gene therapy efficacy involving various mouse models will be presented and discussed. (#Co-corresponding authors)

37. Extracellular Vesicles as the Underlying Mechanism for Cross-Correction with rAAV-Based Gene Therapy for GM3 Synthase Deficiency

Sophia Liu[1], Jonathan Valeros[2], Max Zinter[3], Travis Thomson[3], Jessica Spinelli[2], Guangping Gao[1,4], Phillip Wl Tai[1,4]

[1]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[2]Program in Molecular Medicine, UMass Chan Medical School, Worcester, MA,[3]Department of Neurobiology, UMass Chan Medical School, Worcester, MA,[4]Microbiology and Physiological Systems, UMass Chan Medical School, Worcester, MA

GM3 synthase deficiency (GM3SD) is a neurodevelopmental disorder caused by a loss-of-function mutation in the *ST3GAL5* gene. *ST3GAL5* encodes for GM3 synthase and loss of this enzyme results in perturbation of the ganglioside biosynthesis pathway. These gangliosides are important for cell-signaling pathways and dysfunction leads to various neurological deficits, including brain atrophy and cognitive issues. These biochemical and physiological phenotypes are observed in GM3SD mouse models. Treatment with recombinant adeno-associated viral vectors (rAAV) packaging an *ST3GAL5* expression cassette was able to reverse these effects. Not only was the rAAV able to reverse disease phenotypes, but widespread correction of gangliosides across the cortex suggests that some brain structures may be cross-corrected by a mechanism that extends beyond the direct effects of the transduced cells. We hypothesize that cross-correction is possible through the use of extracellular vesicles (EVs) as trafficking vehicles for gangliosides across cells. Based on preliminary data from transwell assays, we show that gangliosides can be trafficked between cells without direct cell-to-cell contact. We also show that *ST3GAL5* expression is linked to EV biogenesis. These results strongly suggest that EVs are associated with the correction of *ST3GAL5* in GM3SD model systems. Thus, GM3SD presents a valuable opportunity to explore cross-correction mechanisms associated with rAAV treatments in the brain. Ongoing investigations into EVs as a part of this mechanism is expected to reveal new methods for increasing rAAV efficiency for the treatment of GM3SD and other disorders. G.G. and P.T. are corresponding authors.

38. AAV Gene Therapy Corrects Neurological Phenotypes with Clinically Relevant Doses in a Mouse Model of *STXBP1*-Related Developmental and Epileptic Encephalopathy

Wu Chen[1,2], Joo Hyun Kim[1,2], Alysee Michaels[1,2], Armando Rivera[1,2], Yusuf Sham[1,2], Catalina Elwonger[1,2], Jose Paulo Carneiro[1,2], Shawn Nguyen[1,2], Zain Moin[1,2], Sheldon Zou[1,2], Kevin Jin[1,2], Amy Wang[1,2], Nikita Dhar[1,2], Peter Park[1,2], Jaimie Vega[1,2], Alice Chen[1,2], Brooke Horist[2,3], Hongmei Chen[1,2], Alberto Lopez[4], Allison Knoll[4], Nicholas Flytzanis[4], Mingshan Xue[1,2,3]

[1]Department of Neuroscience, Baylor College of Medicine, Houston, TX,[2]The Cain Foundation Laboratories, Jan and Dan Duncan Neurological Research Institute at Texas Children's Hospital, Houston, TX,[3]Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX,[4]Capsida Biotherapeutics, Inc., Thousand Oaks, CA

Developmental and epileptic encephalopathies (DEEs) are a group of devastating pediatric neurological disorders, manifesting with aggressive seizures and significant neurological comorbidities. *De novo* heterozygous pathogenic variants in *STXBP1* encoding syntaxin-binding protein 1 are one of the most frequent genetic causes of DEEs. The treatment options for patients with *STXBP1* encephalopathy are very limited, as the current antiepileptic drugs are often ineffective and there are no treatments for other neurological impairments. Furthermore, abnormal brain activity during early development is believed to contribute to the pathogenesis of *STXBP1* encephalopathy, presenting a great challenge for developing clinical treatments that can still be effective later in life. We previously demonstrated that *Stxbp1* haploinsufficient mice recapitulate all key neurological phenotypes of *STXBP1* encephalopathy and restoring Stxbp1 protein to the wildtype level in adult *Stxbp1* haploinsufficient mice rescued most of the phenotypes including epileptic seizures, motor, cognitive, and psychiatric impairments. To generate investigational new drug application enabling data, we tested intravenous delivery of an engineered AAV capsid expressing human *STXBP1* with low, medium, and high dosages in rescuing adult *Stxbp1* haploinsufficient mice. The vector biodistributions and mRNA/protein levels were quantified and correlated with the outcomes examined by health monitoring, video-electroencephalogram (EEG) recording, and neurobehavioral tests. We found that AAV mediated gene replacement therapy rescues most of the phenotypes of adult *Stxbp1* haploinsufficient mice in a dose-dependent manner with long lasting effects including abnormal hindlimb clasping, epileptic seizures, intellectual disability, motor deficits, and impaired innate mouse behaviors. The high dose rescues the most phenotypes whereas the medium and low doses rescue or partially improve some of the phenotypes. Importantly, our candidate, CAP-002, which consists of an engineered AAV capsid that is a product of our high-throughput, non-human primate (NHP)-based AAV engineering platform packaging the human *STXBP1* gene, can effectively cross the blood-brain barrier in NHPs and achieve a brain-wide distribution at levels expected to provide therapeutic benefit. Thus, gene replacement achieving widespread neuronal transduction by engineered capsids has the potential to be a promising gene therapy for *STXBP1*-related developmental and epileptic encephalopathy.

Genetically Modified Immune Cells for Malignant and Non-Malignant Diseases

39. An Allogeneic Engineered Tissue Treg Approach for the Treatment of Acute Ischemic and Inflammatory Diseases

Payam Zarin[1], Maegan Hoover[1], Yash Agarwal[2], Priya Saikumar[1], Madison Milazewski[1], Nicole Reed[1], Guoping Deng[3], Carlos Frias[1], Abigail Doherty[1], Dalia Gaddis[4], Marko Repic[1], Xiaoming Hu[5], Jun Chen[5], Tiffany F. Chen[6], Thomas Wickham[6]

[1]Discovery Research, GentiBio, Cambridge, MA,[2]GentiBio, Cambridge, MA,[3]Gentibio, Cambridge, MA,[4]Gentibio, Cambridge, CA,[5]University of Pittsburgh, Pittsburgh, PA,[6]GentiBio Inc., Cambridge, MA

FOXP3+ Regulatory T cells (Tregs) play a critical role in the prevention of fatal autoimmunity and maintaining tissue homeostasis. A specialized population of these cells within non-lymphoid organs, dubbed Tissue Tregs, modulate a diverse set of regenerative and homeostatic functions in addition to niche-adaptive immune surveillance. The function of these cells is imparted by their ability to respond to distinct survival factors, along with specific tissue homing and anchoring capabilities. Life-threatening acute inflammatory and ischemic diseases including acute kidney injury (AKI), ischemic stroke and acute respiratory distress syndrome (ARDS) are often associated with poor prognosis stemming from rapid-onset runaway inflammation and misguided tissue-repair, making off-the-shelf Tissue Tregs a fitting therapeutic approach for multiple disease modalities. We report for the first time, the generation of allogeneic Tissue Engineered Tregs (Tissue EngTregs) through a gene editing approach of PBMC isolated CD4+ T cells, leading to stable *FOXP3* expression and a rapamycin-activated signaling complex that provides tunable IL-2 signal combined with the expression of an alarmin tuned transgene. Tissue EngTregs express hallmark Treg proteins including FoxP3, CD25 and were shown to suppress conventional T cells in a Treg suppression assay. Tissue EngTregs recapitulated key aspects of naturally occurring Tissue Tregs, showing greater activation (based on Ki67 and HLA-DR) and an enhanced ability to modulate an acute inflammatory milieu (e.g. higher expression of CD39, TIGIT) and sequestration of pro-inflammatory cytokines (e.g. IL-2, IL-33 and TNFα). Further, Tissue EngTregs are enabled with rapid response to acute inflammation as a result of enhanced expression of key homing receptors (e.g. CCR4, and CCR8) enabling inflammation driven homing and anchoring. Finally, we show Tissue Tregs gain the ability to express repair mediators such as Osteopontin relevant to indications such as ischemic stroke. As a proof of concept, we made use of a surrogate allogeneic polyclonal murine Engineered Treg (mEngTreg) system in several models of acute inflammatory and ischemic diseases. Briefly, mEngTregs were generated by Cas-9 mediated editing of MND in the *Foxp3* locus of C57BL/6 (autologous) or CB6F1 (allogeneic) CD4 splenocytes and transferred following disease induction in models of AKI, LPS mediated acute lung injury and transient middle cerebral artery occlusion (tMCAO) model of ischemic stroke. mEngTregs showed efficacy in the aforementioned models based on key disease parameters. In models of AKI, mEngTreg treated animals showed significant reduction in serum kidney function (SCr, BUN), and inflammatory (Kim-1) parameters

while also showing significantly reduced kidney damage as assessed by H&E. LPS induced acute lung injury mice treated with allogeneic mEngTregs showed restored blood oxygen saturation, reduced immune infiltrates as assessed by flow cytometry, lower levels of BAL inflammatory cytokines and reduced tissue damage based on H&E. Finally, tMCAO mice treated with allogeneic poly mEngTregs showed enhanced sensori-motor, memory and learning function based on several key readouts including accelerated rotarod, and foot fault tests. Overall, Tissue EngTregs display enhanced Tissue Treg properties that positions them as an exciting therapeutic option for acute ischemic and inflammatory diseases.

40. Myelin-Specific Engineered Treg Exhibit Therapeutic Benefit in a Murine Model of Multiple Sclerosis

Travis Drow[1], Brock McKinney[1], Noelle Dahl[1], Peter J. Cook[1], David J. Rawlings[1,2]

[1]Center for Immunity and Immunotherapies and the Program for Cell and Gene Therapy, Seattle Children's Research Institute, Seattle, WA,[2]Departments of Pediatrics and Immunology, University of Washington, Seattle, WA

Regulatory T cells (Treg) represent a promising avenue for treating tissue-specific autoimmune diseases including multiple sclerosis (MS). Strikingly, in comparison to polyclonal Treg, antigen-specific Treg display superior therapeutic efficacy in animal models of autoimmunity and are predicted to exhibit similar benefits in human subjects. However, expansion of rare naturally occurring antigen-specific Treg represents a major hurdle in bringing therapeutic cell products into the clinic. To overcome this challenge, we previously developed robust strategies to create antigen-specific, engineered regulatory T cells (EngTreg) from $CD4^+$ T cells via homology directed repair (HDR)-based gene-editing and demonstrated efficacy in mouse and non-clinical human type 1 diabetes studies[1-5]. Expanding on this previous work, here, we describe studies assessing the efficacy of EngTreg in an Experimental Autoimmune Encephalomyelitis (EAE) model, a robust animal model of MS. First, we optimized our engineering strategy using $CD4^+$ T cells expressing a myelin oligodendrocyte glycoprotein (MOG)-specific TCR. HDR at the mouse *Foxp3* locus was used to precisely insert a strong, ubiquitous promoter upstream of the first coding exon of endogenous *Foxp3;* thereby converting antigen-specific $CD4^+$ T cells into antigen-specific Tregs *en masse*. Using a GLP compliant MaxCyte platform, we delivered *Foxp3* targeting RNPs to 100 million 2D2 $CD4^+$ T cells with minimal impact on cell viability. Co-delivery of rAAV donor template was combined with a DNA-PK inhibitor to enhance HDR, resulting in significant improvements in editing rates. Cryopreserved products exhibited uniform Treg phenotypic and functional properties and excellent post-thaw viability. Using these cell populations, we modelled MS therapy in a chronic progressive EAE model. Immunocompetent C57BL/6 mice were immunized with MOG_{35-55} peptide in complete Freund's adjuvant (CFA). Varying doses of polyclonal vs. MOG-specific EngTreg were adoptively transferred at Day -1 prior to- or Day 7 post-immunization. Animals were evaluated daily for differences in clinical score using standardized EAE-scoring criteria. Delivery of MOG-specific EngTreg led to either prevention or a marked reduction in disease manifestation reflective of the EngTreg dose and timing of administration. Our combined data demonstrate the robust efficacy of antigen-specific EngTreg in an immunocompetent model of MS and highlight the importance of improving scalability for assessing gene-edited cell therapies in autoimmune disease models. 1. Alzheimer's Disease (AD) is characterized by the presence of two disease hallmarks: amyloid plaques and neurofibrillary tangles (NFTs). Aggregation of Amyloid-β (Aβ) peptides leads to the formation of amyloid plaques and is thought to contribute to the production of NFTs[1]. While Aβ is an alluring therapeutic target, the development of Aβ-directed AD therapeutics is hindered by the physiological neuroprotective functions of monomeric Aβ[2]. Aducanumab is a monoclonal antibody with enhanced affinity for pathogenic Aβ aggregates over Aβ monomers[2], but in clinical trials it caused cerebral edema suggestive of unfavorable immune activation. To circumvent antibody-mediated Fc receptor activation in response to amyloid with Aducanumab, we engineered macrophages with a chimeric antigen receptor (CAR) lacking a signaling domain with Aducanumab's antigen binding domain. Aβ-CAR-macrophages (Aβ-CARMs) showed enhanced uptake of human Aβ in vitro, as well as the ability to clear Aβ following short-term exposure. The 5xFAD mouse model, which produces human Aβ, was used to assess the efficacy of the Aβ-CAR in vivo. 5xFAD mice were exposed to myeloablative busulfan conditioning before receiving a bone marrow transplant with CAR-expressing mouse hematopoietic stem cells (HSCs). Analysis of blood draws revealed reconstitution of the immune system of mice transplanted with CAR-positive cells, although live CAR macrophages were undetectable in the brains of mice 3 months post-bone marrow transplant. Despite being unable to detect CAR-positive cells in the brains of these mice, immunohistochemical staining revealed exacerbated amyloid plaque production in Aβ-targeting versus control CAR-HSC transplanted and untransplanted cohorts. We hypothesize that macrophage dysfunction and subsequent death are accelerated by enhancing Aβ-uptake via a CAR, and this dysfunction likely explains the CAR's contribution to the increased plaque deposition seen in vivo. Recent studies suggest

that, while brain macrophages are the primary phagocytes of Aβ, their ability to clear Aβ deteriorates over prolonged exposure. These macrophages adopt an exhausted-like, inflammatory phenotype, that is thought to contribute to their death and plaque seeding in mice[4], and this macrophage signature of impaired ability to respond to persistent stimuli are also observed in human AD patients[5]. To understand the contribution of our Aβ-CAR to plaque production, we evaluated Aβ-associated toxicities in Aβ-CARMs in vitro. Evaluating CARM response to their cognate antigen will further elucidate their potential efficacy in an in vivo model. References: 1. Ismail R, et al. With the November 2023 FDA bulletin highlighting T cell malignancies occurring in patients receiving commercial chimeric antigen receptor (**CAR**) T therapies, it's becoming clear that random integration of tumor-specific receptors poses safety risks in cell therapy products (fda.gov). Furthermore, as the circuitry of immune function becomes more clear, increasingly complex engineering is being pursued to improve therapy efficacies. We previously implemented base editors for multiplex gene knockout (**KO**) in CAR T cells to enhance efficiency and reduce genotoxicity associated with Cas9 nuclease. Here, we leverage the nickase activity of adenine base editor (**ABE8e**) to stimulate homology-directed repair (**HDR**) at targeted loci in support of an all-in-one platform for concurrent multiplex KO and knockin (**KI**) in primary T cells. Through a novel gRNA design strategy and a rAAV template, we enhanced the efficiency of ABE8e-stimulated HDR by >2-fold, achieving transgene KI rates of >30% in human T cells. We then combined KI of CD19, CD33, or mesothelin targeting CARs with >95% quadplex gene KO in T cells (*B2M*, 98% *TRAC*, 97% *PDCD1* 98%, *CISH* 95%). ABE8e multiplex-engineered CAR T cells showed enhanced functionality against multiple tumor lines. Specifically, in serial co-culture challenge assays, checkpoint KO CAR-T cells resisted exhaustion and sustained tumor cell killing when compared to controls and showed enhanced production of effector cytokines in later rounds of serial stimulation. In vivo, these cells controlled and improved survival in a Burkitt's Lymphoma xenograft model engineered to overexpress hPD-L1. Concurrent KI and multiplex KO using ABE8e in a one-step manufacturing process establishes a safe, scalable platform for complex therapeutic cellular manufacturing with broad applications across oncology, autoimmunity, and the treatment of rare disease.

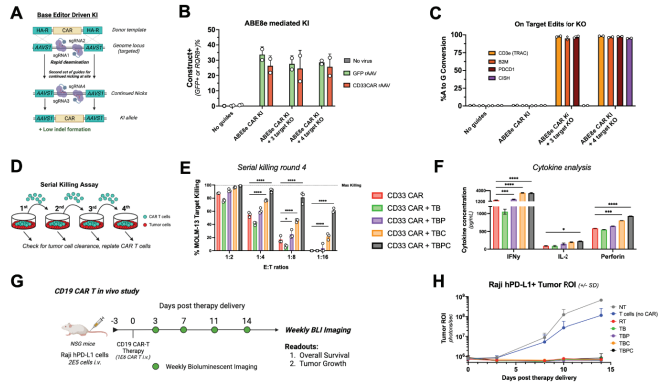

Fig 1. Adenine Base Editor (ABE8e) can carry out site-specific KI of a CAR and multiplex KO of target genes simultaneously in primary T cells to create functionally enhanced therapies. (A) Schematic of site-specific gene knockin using ABE8e and multiple guide strategy to induce HDR. (B) KI efficiency is not impacted by simultaneous addition of gRNA designed to KO target genes. (C) Multiple gene KO is achievable alongside site-directed cargo KI. (D) Diagram of serial killing assay to test long term functionality. (E&F) ABE8e multiplex engineered CD33 CAR T with CD3e (T), B2M (B), PDCD1 (P), and CISH (C) KO show functional enhancements at low Effector:Target (E:T) ratios (up to 1:16) in 4th round killing and enhanced cytokine production. (G) *In vivo* study design for testing CD19 CAR T cells. (H) ABE8e multiplex engineered CD19 CAR T cells show control of Raji-hPD-L1+ tumors *in vivo*. Images made with BioRender.

43. Peptide-MHC-Targeted Retroviruses Expand and Deliver Therapeutic Cargoes to Rare Populations of Anti-Tumor T Cells

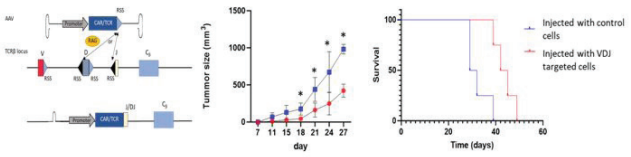
Engineered T cell therapies have introduced a new class of effective and durable cancer treatments. Current strategies to produce these "living drugs" for the clinic require *ex vivo* T cell manipulations that rely on lentiviral vectors with broad tropism for activated T cells. More precise fine-tuning of T cell phenotype could be achieved with more specific gene delivery methods. While progress has been made to design viral vectors to specifically transduce CD3+, CD4+ or CD8+ T cell



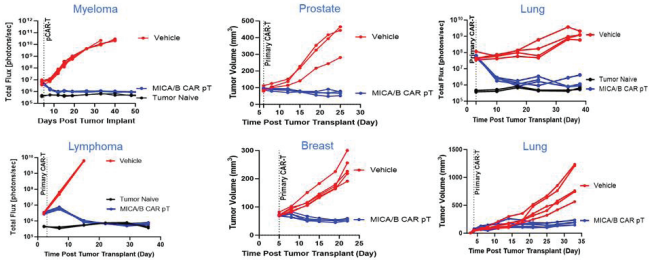
populations, no targeting method for antigen-specific T cells has been validated *in vivo*. Our lab has previously demonstrated that lentiviruses pseudotyped with single chain peptide-major histocompatibility complex (pMHC) in conjunction with a mutated form of the vesicular stomatitis virus glycoprotein (VSVGmut) allows antigen-specific infection of T cells. Here, we have developed pMHC pseudotyped gammaretroviruses to enable transduction of primary murine T cells with the goal of determining whether specifically engineered T cells can control tumors in an immunocompetent, syngeneic model. These pMHC-targeted gammaretroviruses were able to specifically transduce antigen-specific T cells in polyclonal populations while simultaneously activating and expanding those cells. After demonstrating specific targeting, we tested a tethered version of IL-12 as a therapeutic cargo that would be desirable to deliver in an antigen-specific manner given that systemic delivery induces adverse toxicities. In adoptive transfer experiments where cells were transduced *ex vivo* prior to injection into tumor-bearing mice, cells transduced by pMHC-targeted viruses delivering IL-12 (pMHC-IL12) were able to extend survival compared to cells transduced by pMHC-targeted virus delivering only ZsGreen or by traditionally pseudotyped gammaretroviruses. Furthermore, we hypothesized that the enhanced specificity of our targeted viruses could safely enable *in vivo* modification of antigen-specific cells, circumventing long and labor-intensive *ex vivo* manufacturing protocols. Preliminary experiments indicate that our pMHC-targeted viruses are able to target antigen-specific T cells at an initial frequency of 2-3% of the total CD8 population, expanding those anti-tumor T cells to 10-35% of CD8 T cells and transducing up to 15% of on-target cells. These data suggest that pMHC-targeted viruses have broad applications for engineering T cells both *ex vivo* and *in vivo.* While initial efforts have been focused on using pMHC-targeted viruses for cancer therapies, these viral vectors could also be applied to other applications where antigen-specific immune cell manipulation would be desirable, such as autoimmunity.

44. T Cell Engineering Using V(D)J Recombination

Miriam Horovitz-Fried[1], Carlo Cipriani[2], Natalia Gritsenko[1], Iris Dotan[1], Ayelet Dangot[3], Carmel Pundak-Mintz[1], Daniel Nataf[1], Tal Veig[1], Lee Reicher[3], Katia Beider[4], Arnon Nagler[4], Daniela Cesana[2], Adi Barzel[1]

[1]Tel Aviv University, Tel-Aviv, Israel,[2]San Raffaele Telethon Institute for Gene Therapy, IRCCS San Raffaele Scientific Institute, Milan, Italy,[3]Ichilov Medical Center, Tel-Aviv, Israel,[4]Shiba Medical Center, Ramat Gan, Israel

Autologous T cell therapies have shown clinical success in haematological malignancies, but they rely on prolonged and expensive ex vivo manipulations. Often applied as a late line of treatment, the efficacy of autologous therapies for both liquid and solid tumours is hampered by early T cell exhaustion, promoted by the prolonged culturing required for the scarcely retrieved cells. Conversely, "Off the shelf" allogeneic therapies reduce timelines and costs and may have favorable phenotypes, but they require disruption of the endogenous T cell receptor (TCR) to prevent graft vs. host disease (GVHD). We and others have demonstrated that nuclease mediated TCR disruption is associated with high rates of chromosomal aberrations and thus poses own challenges. Here, we propose "VDJ targeting": a novel immunotherapy approach targeting AAV-delivered immune genes into the genome using V(D)J recombination in developing T cells. In particular, we use adeno-associated viral (AAV) vectors coding for a transgenic TCR/CAR gene followed by a recognition signal sequence (RSS) for the recombination activating gene (RAG) complex, which is active only during T cell development. VDJ targeting is thus nuclease-free and produces potent naïve T cells that, compared to the products of conventional engineering, may be transplanted in lower numbers and have increased persistence in both autologous and allogeneic therapies. In addition, Targeted T cells express only the desired receptors, due to allelic exclusion. Finally, in younger patients, VDJ targeting could further be applied in vivo by direct intra-thymic vector administration, thus increasing efficacy and revolutionizing scalability. We have demonstrated VDJ targeting in ex vivo differentiated T cells of both human and mouse. Hematopoietic stem and progenitor cells (HSPCs) from mouse bone marrow were grown on OP9DL1 feeder cells in IL-7 and FLT-3 containing medium for 5 days, and then transduced with 1E6 vector genomes per cell of an AAV-DJ vector coding for a CAR gene against CD19. 13 days following transduction up to 40% of the CD3+ cells were found to express the CAR, but only when an RSS was coded on the CAR vector. Co-culture of the CAR-T cells with syngeneic CD19 expressing Eμ-ALL cancer cells led to high levels of IFNγ secretion. Concordantly, ultrasound-guided intrathymic injections of AAV8 vectors in immunocompetent mice allowed for in vivo CAR gene integration by VDJ targeting. Similarly, human cord blood derived HSPCs were grown on similar feeder cell with a SPEM-2 medium for 5 days and then transduced with an 7E5 vector genomes per cell of an AAV6 vector coding for either a CAR anti CD19 or a TCR targeting an NY-ESO1 peptide presented on HLA2-a2. 13 days post transduction, the receptor genes were detected on up to 36% and 12% of the CD3+ cells for the CAR and TCR respectively, and only when an RSS was coded on the vector. Co-culture with respective target cells allowed high levels of IFNγ secretion. As few as 200K Human T cells, engineered by VDJ recombination to express the TCR, were adoptively transferred into immunodeficient mice bearing the A375 melanoma cell line expressing NY-ESO-1. Importantly, we demonstrate tumor growth inhibition and prolonged survival (Figure 1). VDJ targeting is thus an efficient T cell engineering technology applicable in the autologous, allogeneic and in vivo settings.



45. Novel α3-MICA/B-Specific CAR T-Cell Immunotherapy Demonstrates Ubiquitous Targeting of Cancer Cells and Resistance to Immune-Surveillance Evasion

Alex Garcia[1], Samad Ibitokou[1], Spas Markov[1], Bryan Hancock[1], Carissa Dege[1], Mochtar Pribadi[1], Yijia Pan[1], Lauren Fong[1], Thomas Dailey[1], Tom Lee[1], John Goulding[1], Jode Goodridge[1], Kai W. Wucherpfennig[2], Martin Hosking[1], Bob Valamehr[1]

[1]Fate Therapeutics Inc., San Diego, CA,[2]Dana Farber Cancer Institute, Boston, MA

MHC class I related proteins A and B (MICA/B) are surface ligands induced by cellular transformation and genotoxic stress, and their expression is reported in a variety of diseases, including cancer. NKG2D, expressed on NK and T cells, targets the highly polymorphic, membrane-distal α1 and α2 domains of MICA/B. However, NKG2D is susceptible to immune cell evasion by proteolytic cleavage and shedding of MICA/B, resulting in antigen escape and disease progression. We have developed a novel chimeric antigen receptor (CAR) targeting the highly conserved membrane-proximal α3 domain of MICA/B (3MICA/B CAR) that is resistant to MICA/B shedding, to attenuate immune evasion, restore MICA/B immune surveillance and direct the targeting and elimination of a broad range of diseased cells. Specific targeting of the α3 domain by 3MICA/B CAR was confirmed in several experiments, including targeting of α3 domain-only expressing transgenic cells and protease induced MICA/B cleavage cytotoxicity assay, comparing 3MICA/B CAR to NKG2D CAR T cell activity. Specific to α3 domain targeting, only 3MICA/B CAR T cells could recognize α3-only transgenic cells, confirming their unique ability to recognize α3 domain compared to NKG2D CAR T cells (98.5% ± 0.5% vs. 8.9% ± 4.2% cytotoxicity). In the induced cleavage assay, short-term exposure to trypsin selectively eliminated the membrane distal α1 and α2 domains of MICA/B and resulted in limited cytotoxic efficacy of NKG2D based CAR-T cells, while most of 3MICA/B CAR-T cell activity was unaffected. *In vivo,* primary 3MICA/B CAR T cells demonstrated robust anti-tumor control in a broad range of liquid and solid tumor settings: remarkably achieving an average of 92.3% ± 12.8% tumor growth inhibition (TGI) in mouse xenograft models of lymphoma, multiple myeloma, breast, prostate and lung cancer (Fig. 1). Importantly, this pan-tumor control seen with 3MICA/B CAR T cells was comparable to CAR-T cells targeting conventional tumor associated antigens such as HER2 (4D5) or CD19 (SJ25C1), underscoring the novelty and broad applicability of targeting the α3 domain of MICA/B for pan-tumor targeting applications (3MICA/B CAR vs HER2 CAR, 92.3% ± 12.8% vs 84.6% ± 15.9%; 3MICA/B CAR vs CD19 CAR, 92.3% ± 12.8% vs 93.5% ± 7.9%). To generate an off-the shelf and pan-cancer targeting cellular immunotherapy product, induced pluripotent stem cells (iPSC) were engineered to express 3MICA/B CAR under the transcriptional control of the T cell receptor alpha constant promoter and differentiated into TCR-less CD8 αβ T (iT) cells that express high and homogenous levels of 3MICA/B CAR. *In vitro* 3MICA/B CAR iT cells demonstrated robust and sustained control of both liquid and solid tumor targets of diverse MICA/B expression. In vivo, 3MICA/B CAR iT cells demonstrated potent and durable control of subcutaneous prostate cancer xenografts (96.7% ± 1.3% TGI). Together, these data demonstrate that α3-MICA/B-specific CAR T-cell immunotherapy has the unique ability to target stress ligands while being resistant to antigen shedding and escape and represent a novel pan-cancer targeting immunotherapy with potential therapeutic application in a variety of cancers. **Fig. 1: α3-MICA/B CAR primary T cells provide in vivo efficacy against multiple human hematopoietic and solid tumor xenograft models.**

Lysosomal Storage Disorders

46. Hematopoietic Stem Cell Gene Therapy for Hurler Syndrome: Interim Skeletal Outcome and Skeletal Cross-Correction Mechanisms

Francesca Tucci[1], Giulia Consiglieri[1], Maurizio De Pellegrin[1], Matilde Cossutta[1], Chiara Filisetti[1], Marina Sarzana[1], Stefano Scarparo[1], Cristina Baldoli[1], Renata Mellone[1], Ludovica Santi[1], Stefania Crippa[1], Rossella Parini[1], Alessandro Aiuti[2], Maria Ester Bernardo[1]

[1]San Raffaele Telethon Institute for Gene Therapy, Milano, Italy,[2]San Raffaele Telethon Institute for Gene Therapy (SR-Tiget), Milan, Italy

Introduction: Skeletal dysplasia is a prominent feature of Mucopolysaccharidosis type I Hurler syndrome (MPSIH) which is not fully addressed by allogeneic haematopoietic stem cell transplantation (HSCT). Autologous *ex vivo* hematopoietic stem cell gene therapy (HSC-GT) is a promising therapeutic strategy for MPSIH since it is capable of producing supraphysiologic IDUA levels, leading to extensive metabolic correction. Here we report interim results from a Phase I/II clinical trial (NCT03488394) on the skeletal outcome of 8 MPSIH patients treated with HSC-GT (OTL-203) up to a median follow-up of 4 years. As there is limited knowledge of the pathogenesis of skeletal defects and skeletal correction mechanisms in MPSIH after HSC-GT, we have characterized *in vitro* the key players of skeletal remodelling before and after HSC-GT. *Methods:* Skeletal outcomes of the 8 MPSIH patients were assessed at baseline and at specific timepoints after treatment by clinical (growth), functional (motor performance and joint range of motion) and radiological parameters (X-Rays and MRI for the hip and X-Ray and MRI for the spine) up to a median of 4 years after HSC-GT. Specific skeletal measures were retrospectively compared with an external cohort of patients who underwent HSCT in Monza. Patient-derived osteoclasts (OCs), mesenchymal stromal cells (MSCs) and osteoblasts (OBs) were isolated and characterized before and at several timepoints after HSC-GT. *Results:* IDUA activity in peripheral blood reached supraphysiologic levels in all patients after HSC-GT resulting in extensive substrate depletion, which was maintained at the latest follow-up. All patients exhibited longitudinal

growth within expected reference ranges according to age and gender, with a median height gain greater than the one observed in Monza HSCT patients. Regarding functional outcome, all HSC-GT patients progressively acquired motor skills, as shown by the stability of Total Motor Quotient score over time, and experienced a complete and earlier normalization of joint mobility as compared with HSCT patients. Both hip X-ray and hip MRI parameters improved after HSC-GT, representing an amelioration of hip dysplasia up to the latest follow-up. A specific spine MRI score showed stabilization of the typical spine MRI features *(i.e.* dorsolumbar kyphosis, foramen magnum and spinal stenosis) in all HSC-GT patients at last follow-up.In the HSC-GT scenario, we hypothesized that OCs, deriving from genetically corrected haematopoietic precursors, could deliver the missing enzyme in the bone microenvironment as mediators of cross-correction of non-haematopoietic cells. We demonstrated that patient-derived OCs after HSC-GT and their supernatant show supraphysiologic IDUA activity which can be taken up by patient MSCs and OBs, thus rescuing GAGs engulfment in MPSIH-OBs. Osteomedullary biopsies of MPSIH patients obtained at baseline showed foamy appearance of the cytoplasm of the soft tissue cells adjacent to bone cells (i.e., entheses) which fully resolved after HSC-GT. *Conclusions:* Clinical, functional and radiological parameters indicate an early beneficial effect of HSC-GT on MPSIH-typical skeletal features. A longer follow-up and a direct comparison with HSCT are needed to draw definitive conclusions on the impact of HSC-GT on skeletal dysplasia. Biological studies aimed at unveiling skeletal correction mechanisms after HSC-GT will be key to advance the treatment of MPSIH patients.

47. Adeno-Associated Virus-Based Gene Therapy Delivering Combinations of Two Growth-Associated Genes

Shunji Tomatsu[1], Estera Rinz[1], Betul Celik[2], Shaukat Khan[1]

[1]Nemours/Alfred I. DuPont Hospital for Children, Wilmington, DE,[2]University of Delaware, Newark, DE

Background: Mucopolysaccharidosis type IVA (MPS IVA) is caused by a deficiency of the GALNS enzyme responsible for the degradation of specific glycosaminoglycans (GAGs), keratan sulfate (KS) and chondroitin-6-sulfate. The progressive accumulation of GAGs leads to various skeletal abnormalities (short stature, knock knees, hypoplasia, tracheal obstruction). To date, no treatment is effective for patients with bone abnormalities. Approach: To improve bone pathology, we propose a novel combination treatment with the GALNS enzyme gene therapy and a C-type natriuretic peptide (CNP) as a growth-promoting agent for MPS IVA. MPS IVA knockout mice were treated at 4 weeks old via tail vein injection with the AAV vector, followed for 12 weeks. The experiment involved injecting two separate vectors (AAV9-hGALNS and AAV9-hNPPC) or a single vector expressing both transgenes (AAV9-hGALNS-hNPPC). Results: An equal dose of two AAV vectors (AAV9-hGALNS and AAV9-hNPPC) was administered. The high dose of both transgenes increased the expression of both GALNS enzyme and CNP peptide, resulting in the sustained elevation of GALNS activity in the bloodstream and notable GALNS activity in crucial target tissues such as bone, heart, and liver. A significant decrease in the accumulation of KS was seen both in the blood and tissues, leading to improvements in bone pathology and the promotion of bone growth in a dose-dependent manner. However, the experiment was terminated at 13 weeks of age due to the overexpression of the CNP peptide, which led to excessive growth in the mice. The mice faced difficulties in movement, indicating that CNP-related adverse effects are dose-dependent. The low-dose group of the CNP-expressing vector minimized the mouse growth. With the middle dose of the CNP, the growth was linear without adverse effects. We also tested the effect of the growth pattern in the mice after injecting one vector with two transgenes. The growth was linear without overgrowing in this group. However, we did not detect the GALNS enzyme activity in bone. We observed the same decrease in the KS level as in other groups. We also detected high anti-GALNS activity, which may neutralize the GALNS activity. The GALNS protein level in liver was lower than in the other combination groups. The micro-CT assessment did not reveal significant differences in most parameters among the various groups. However, the group receiving the highest dose of the NPPC-expressing vector in combination exhibited the most noticeable changes, which correlated with the visible alterations in the skeleton. We performed toluidine blue staining for the knee joints to evaluate the effectiveness of AAV treatment. Bone pathology revealed significant differences in the score calculation of chondrocytes. The untreated MPS IVA chondrocytes were vacuolated with a disorganized structure. After combination therapy of two AAV vectors with CNP and GALNS, we observed marked improvements in growth plate organization and decreased vascularization of treated chondrocytes. Conclusions: Combination therapy induces bone growth with increased enzyme activity in tissues (bone, liver, heart, lung) and plasma and shows significant changes in bone morphology with increased CNP activity in plasma. Combining CNP and GALNS gene therapies enhances bone growth in MPS IVA mice more than in GALNS gene therapy alone. Our findings indicate that combination therapy is a potential alternative since the enzyme would not easily penetrate the growth plate region in the bone. Overall, Our study has offered valuable insights into the potential therapeutic use of CNP for progressive skeletal dysplasia in MPS IVA. Thus, more extensive studies are necessary to validate the effectiveness of CNP delivered through an AAV vector expression cassette in combination with the GALNS enzyme as a potential combination therapy.

48. CAMPSIITE™ Phase I/II/III: An Interim Clinical Study Update of RGX-121, an Investigational Gene Therapy for the Treatment of Neuronopathic Mucopolysaccharidosis Type II (MPS II)

Laura Pisani[1], Roberto Giugliani[2], Can Ficicioglu[3], Paul Harmatz[4], Deepa Rajan[5], Joseph Hagood[1], Michele Fiscella[1], Lin Yang[1], Michelle Gilmor[1], Yoonjin Cho[1], Caroline Mulatya[1], Dawn Phillips[1], Nidal Boulos[1], Paulo Falabella[1]

[1]REGENXBIO Inc., Rockville, MD,[2]Hospital de Clinicas de Porto Alegre, Porto Alegre, Brazil,[3]Children's Hospital of Philadelphia, Philadelphia, PA,[4]UCSF Benioff Childrens Hospital Oakland, Oakland, CA,[5]University of Pittsburgh, Pittsburgh, PA

Purpose: MPS II is an X-linked lysosomal storage disease caused by deficiency of iduronate-2-sulfatase (I2S) leading to accumulation

of glycosaminoglycans (GAGs). Neuronopathic MPS II (nMPS II) results in irreversible neurodevelopmental decline not addressed by intravenously administered enzyme replacement therapy. RGX-121 is an investigational gene therapy that uses the adeno-associated virus serotype 9 (AAV9) vector to deliver a human iduronate-2-sulfatase (IDS) gene to the central nervous system (CNS). RGX-121 is designed to provide a permanent source of secreted I2S, potentially correcting neurologic and systemic disease manifestations. **Design/Methods:** CAMPSIITE™ is a phase I/II/III, open-label, 104-week trial enrolling boys 4 months up to 5 years of age with nMPS II (NCT03566043) who receive one image-guided RGX-121 injection to the CNS. Assessments include safety and tolerability; cerebrospinal fluid (CSF), plasma, and urine biomarkers; neurodevelopmental scales; and imaging. Participants are encouraged to enroll in a long-term follow-up study. **Results:** As of January 3, 2023, 15 participants were enrolled in the phase I/II portion of CAMPSIITE in 3 dose cohorts ($1.3x10^{10}$, $6.5x10^{10}$, and $2.9x10^{11}$ genome copies/gram brain mass). RGX-121 was reported to be well-tolerated with no drug-related serious adverse events. Longest post-administration follow-up was > 3 years. CSF GAGs showed dose-dependent reductions with D2S6 continuing to approach normal levels in cohort 3 at 48 weeks. Interim neurodevelopmental assessments demonstrated CNS activity up to 3 years after RGX-121 administration. Evidence of systemic enzyme expression and biomarker activity was present after CNS RGX-121 administration. Updated interim results and topline pivotal results will be presented. **Conclusions:** RGX-121 has the potential to provide sustained CNS clinical outcomes and additional systemic effects in MPS II patients.

49. Rescue of Lysosomal Acid Lipase Deficiency in Mice by AAV Liver Gene Transfer

Marine Laurent[1,2], Rim Harb[1,2], Christine Jenny[1,2], Julie Oustelandt[1], Francesca Landini[3], Guillaume Core[1,2], Anaïs Brassier[4], Laetitia Van Wittenberghe1[1,2], Dagmar Kratky[5], Giuseppe Ronzitti[1,2], Mario Amendola[1,2]

[1]UMRS_951 Genethon, Evry, France,[2]Genethon, Evry, France,[3]Department of Clinical and Experimental Medicine, University of Foggia, Foggia, Italy,[4]Necker-Enfants-Malades University Hospital, Paris, France,[5]Division of Molecular Biology and Biochemistry, Medicine University of Graz, Graz, Austria

Lysosomal acid lipase deficiency (LAL-D) is an autosomal recessive disorder caused by mutation in *LIPA* gene resulting in fatal lipid accumulation in liver and spleen. The most severe form, if not treated, results in premature death within the first year of life due to hepatic insufficiency. Weekly administration of the enzyme replacement therapy (ERT) is the only available supportive treatment. Although life-saving, ERT is not curative and may be associated with development of neutralizing antibodies decreasing treatment efficacy. To develop a curative treatment for LAL-D, we first characterized a new $lal^{-/-}$ mouse model, generated by deleting the exon 4 of the *LIPA* gene, and then assessed an *in vivo* gene therapy. We confirmed the loss of LAL activity and the accumulation of lipids in liver and spleen which leads to an increase in organ weight, in liver transaminase and dyslipidaemia (HDL). $Lal^{-/-}$ mice display a dysregulation of the haematological compartment, with an inflammatory profile: increase of granulocytes, monocytes, and platelets. We also have new promising data using imaging flow cytometry to investigate the number of lipid droplets in blood cells as a novel method to easily assess disease burden. For gene therapy, we targeted the liver by systemically injecting 3-month-old $lal^{-/-}$ male mice using the AAV-8 serotype encoding the *hLIPA* gene under the control of hepatocyte-specific human α1-antitrypsin (hAAT) promoter. Transduced hepatocytes would both produce LAL to correct their own metabolic impairment and secrete the enzyme in bloodstream to cross-correct affected tissues. We conducted an 3-months follow-up study of 4 different AAV-8 doses: $5X10^{11}$ vg/kg; $1X10^{12}$ vg/kg; $3X10^{12}$ vg/kg; $1X10^{13}$ vg/kg. Starting from two weeks after injection, we increased LAL activity in plasma and we observed a therapeutic effect with decrease of hepatic transaminases and normalization of haematological parameter. At 3-months post-injection, we evaluated vector biodistribution, enzymatic activity and tissue correction by histological staining and cholesterol/triglycerides quantification. As expected, AAV-treated $lal^{-/-}$ mice displayed efficient hepatocyte transduction and LAL expression proportional to the injected doses. Noteworthy, all AAV doses were sufficient to reduce or correct hepatosplenomegaly and lipid accumulation with $3X10^{12}$ vg/kg being the best compromise between AAV dose and disease correction. With this minimal corrective dose, we assessed phenotype correction in $lal^{-/-}$ mice at 1-, 3-, and 8- months post-injection. Firstly, AAV administration extended survival, improved body weight, and stably normalize haematological parameters, hepatosplenomegaly, lipid accumulation and tissues architectures along the 8-months follow-up. Secondly, using liver transcriptomic analysis, we observed a previously unreported impairment of mitochondria, which was confirmed by biochemical analysis and fully corrected by gene therapy. To further decrease vector dose, we engineered a novel *LIPA* cDNA to improve LAL expression and secretion by optimizing the codon usage and changing its signal peptide sequence and we are currently evaluating its therapeutic benefit *in vivo.* Finally, we are testing this strategy in $lal^{-/-}$ human liver organoids. Overall, our *in vivo* gene therapy strategy represents an effective approach to achieve stable LAL expression and correct LAL-D disease opening the possibility of developing a curative treatment to improve patients' life expectancy and quality.

50. AAV-Ep+ in Preclinical Studies for Late Infantile Neuronal Ceroid Lipofuscinosis

Luis Tecedor[1], Yonghong Chen[1], David E. Leib[2], Paul T. Ranum[3], Bryan P. Simpson[2], Megan S. Keiser[4], Melanie McFadden[1], Alexis Mackiewicz[1], Brian Lewandowski[1], Elena Lysenko[1], Jang-Ho Cha[5], Beverly L. Davidson[1]

[1]Children's Hospital of Philadelphia, Philadelphia, PA,[2]Latus Bio, Philadelphia, PA,[3]Latus Bio, Saint Paul, MN,[4]Ohio State University Wexner Medical Center, Columbus, OH,[5]Latus Biosciences, Arlington, MA

Late Infantile Neuronal Ceroid Lipofuscinosis (LINCL) is a childhood neurodegenerative disease that appears between 2-4 years of age and progresses with visual, motor, and mental decline, with a life expectancy of less than two decades. Most cases of LINCL are caused by deficiency in the soluble lysosomal enzyme tripeptidyl peptidase (TPP1) as a result of mutations in the *CLN2* gene. We have previously demonstrated that gene therapy-mediated enzyme replacement of TPP1 produced significant clinical benefits in a LINCL canine model. In these experiments, therapeutic amelioration of LINCL pathology was achieved using wild-type AAV to target ependymal cells resulting in secretion of TPP1 into the cerebrospinal fluid. We hypothesized that

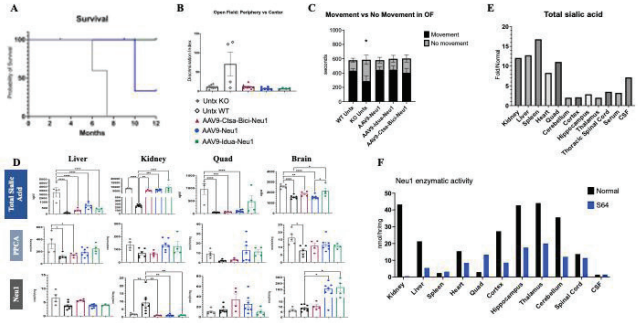
a more efficient delivery vector with improved tropism for ependymal cells and parenchymal neurons could enhance the efficacy of this TPP1 gene therapy strategy and help facilitate the translation of this successful therapeutic approach to humans. To achieve this, we applied a peptide-modified AAV vector screening methodology developed in our lab to identify new vectors with improved tropism for ependymal cells in non-human primates (NHPs). We found AAV-Ep+, which showed a cumulative rank enrichment of ~30,000 from the last rounds of screening. To characterize the transduction efficiency of AAV-Ep+ in ependyma cells of NHP brain, AAV-Ep+.mRuby3 was bilaterally injected in the lateral ventricles of a cynomolgus monkey. Ependymal cell transduction was highly efficient, with mRuby3 expression detected in 76-99% of cells across different regions of the brain ventricle system. Moreover, at this dose, AAV-Ep+ shows low levels of off-target transduction in peripheral tissues and dorsal root ganglia. We next tested AAV-Ep+ in a TPP1-deficient mouse model. Brain TPP1 levels in mice treated with AAV-Ep+ were up to 11-fold higher than mice treated similarly with wtAAV. Furthermore, extended lifespan and improved disease phenotypes were achieved to a significantly greater degree than the highest doses of WT serotypes tested. In summary, AAV-Ep+ results in broad and robust transduction of brain ependyma cells in non-human primates. Utilized as a vector to deliver gene therapy in a LINCL model, AAV-Ep+ increases recombinant TPP1 biodistribution and rescues phenotypes at doses significantly lower than conventional serotypes. AAV-Ep+ is a promising candidate for improving the translatability and applicability of gene therapy for LINCL and other diseases amenable to ependymal cell targeted treatments.

51. Long-Term Haematopoietic Stem Cell Gene Therapy in Mucopolysaccharidosis IIIB Mice Corrects Disease with No Evidence of Insertional Mutagenesis Despite High Vector Copy Numbers

Brian W. Bigger[1], Stuart M. Ellison[2], Shaun R. Wood[2], Rebecca Holley[2]

[1]Centre for Regenerative Medicine, University of Edinburgh, Edinburgh, United Kingdom,[2]Division of Cell Matrix Biology and Regenerative Medicine, University of Manchester, Manchester, United Kingdom

Mucopolysaccharidosis IIIB (MPSIIIB) is caused by a lack of the enzyme alpha-N-acetylglucosaminidase as a result of mutations in the *NAGLU* gene. Loss of NAGLU results in a build-up in heparan sulphate in cells and the extracellular matrix leading to cell damage and inflammation. Patients with MPSIIIB experience severe neurodegeneration and a progressive loss of acquired skills. There is no effective therapy. We designed a lentiviral-driven haematopoietic stem cell gene therapy (HSCGT), transducing with a CD11b-NAGLU lentiviral vector and transplanting corrected MPSIIIB haematopoietic stem cells into MPSIIIB mice. Use of this therapy resulted in significant delivery of NAGLU enzyme to the brain, due to the migration and engraftment of monocytes into the brain. Analysis of animals more than 1 year after transplant showed sustained NAGLU expression with brain enzyme activity of 26% of normal levels, increased over time compared to animals that were analysed at 6-months post-transplant (13% of normal). Widespread correction of heparan sulphate storage throughout the body was visible. Significantly, neuroinflammation which is widespread in untreated animals, was minimal in multiple brain regions. We also show, for the first time, prevention of cortical neuron loss in mucopolysaccharidosis IIIB mice following treatment. A single incidence of malignant lymphoma was seen in one mouse treated with LV-NAGLU HSCGT following histology, and was considered an incidental finding. However, this mouse exhibited high VCN and alongside animals transplanted with the same pool of HSCGTs was analysed for integration site analysis to rule out insertional mutagenesis. This mouse exhibited the relatively low number of IS (141 in leukocytes), suggesting a lower number of engrafting cells, but with no clonal expansion of any one integration site. Our data suggests a minimum brain enzyme level of 9.3% to enable behavioural correction, equating to approximately 1.07 vector copy numbers per bone marrow cell. These data make a strong case for rapidly moving haematopoietic stem cell gene therapy for mucopolysaccharidosis IIIB to clinical trial, providing hope for MPSIIIB patients and their families to alleviate the devastating neurological symptoms of this disease.



52. From Mouse to Sheep: Developing an AAV Gene Therapy for Sialidosis

Jillian Gallagher[1], Judith Gallant[2], Ping Xu[2], Rachael Gately[3], Stephanie Bertrand[3], Rachel Prestigiacomo[3], Abigail McElroy[1], Erin F. Hall[4], Hector Ribeiro Benatti[5], Leigh Fremuth[6], Diantha Van de Vlekkert[6], Camilo Toro[7], Cynthia J. Tifft[7], Scot A. Wolfe[5], Alessandra d'Azzo[6], Miguel Sena-Esteves[8], Yvette Lopez-Diaz[1], Heather L. Gray-Edwards[5]

[1]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[2]Department of Pediatrics, UMass Chan Medical School, Worcester, MA,[3]Cummings School of Veterinary Medicine at Tufts University, Grafton, MA,[4]University of Massachusetts Chan Medical School, Worcester, MA,[5]UMass Chan Medical School, Worcester, MA,[6]St. Jude Children's Research Hospital, Memphis, TN,[7]National Institutes of Health, Bethesda, MD,[8]Neurology, UMass Chan Medical School, Worcester, MA

Sialidosis is a rare lysosomal storage disease caused by mutations in the *NEU1* gene that encodes the lysosomal sialidase neuraminidase 1 (NEU1). Deficiency of NEU1 causes accumulation of sialylated glycopeptides and oligosaccharides in tissues and body fluids, resulting in cell and organ dysfunction. Sialidosis has two forms the late onset type I or early onset type II. Type I patients have adolescent onset with myoclonus, ataxia, seizures, cherry-red spot, and vision loss with death in midlife. Type II infantile/juvenile patients are more severe, including hepatosplenomegaly, coarse facial features, dysostosis multiplex, developmental delay, and death in childhood. There are no approved therapies for sialidosis. We developed an AAV-mediated gene therapy strategy to treat sialidosis that includes three AAV9 vectors: encoding either *Neu1* alone (AAV9-Neu1), or in combination with its chaperone protein cathepsin A (AAV9-Ctsa-Bici-Neu1) or encoding modifications to enhance secretion (AAV9-Idua-Neu1). Neonatal Neu1-KO mice were injected via intracerebroventricular with 1E11vg of each AAV vector. Increased survival was noted for all three vectors compared to untreated Neu1-KO mice, however both AAV9-Neu1 treated WT (n=1) and NEU1-KO mice developed seizures at ~10 months of age (**A**). Behavioral testing revealed significant motor improvement for AAV treated Neu1-KO mice for all three vectors compared to Neu1-KO untreated mice with a trend toward decreased anxiety-like behavior

(**B&C**). Reduction of sialic acid and PPCA levels were observed in the liver, brain, and quad, while mild reduction was seen in the kidney of treated mice compared to untreated Neu1-KO mice (**D**). Increased Neu1 activity was observed in the kidney, quadriceps, and brain of treated mice versus untreated Neu1-KO mice (**D**). Pathology of the liver, spleen, kidney, and pancreas was markedly ameliorated as well as diminished astrocytosis in the hippocampus of treated mice compared to untreated Neu1-KO's. Overall, the most efficacious vector is AAV9-Ctsa-Bici-Neu1, which will be further tested in a large animal model of sialidosis. We have successfully generated the first sheep model of sialidosis type II. Using CRISPR-SpCas9 technology, we generated a founder sheep heterozygous for a 3 base pair deletion within exon 5 of Neu1(A320del) that is in the same loation as the amino acid change in patients (A319V). the A320del in sheep recapitulates many aspects of sialidosis including increased sialic acid levels (**E**), reduced Neu1 activity (**F**), neurological deficits, hepatosplenomegaly, hydronephrosis in the kidney, bone deformities, contracted tendons, and short lifespan. Further characterization of this model is currently ongoing. Altogether these studies in parallel with natural history studies in sialidosis patients will inform future clinical trials for this devastating disease.

Epigenetic Editing and RNA Editing

53. A High-Fidelity CRISPR-Cas13 System Improves Abnormalities Associated with C9ORF72-Linked ALS/FTD

Tristan McCallister

Bioengineering, University of Illinois Urbana Champaign, Urbana, IL

An abnormal expansion of a GGGGCC (G_4C_2) hexanucleotide repeat in the first intron of the C9ORF72 gene is the most common genetic cause of amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD), two devastating disorders that are now thought to form a broad neurodegenerative continuum. One of the major mechanisms proposed to explain the pathogenicity of the hexanucleotide repeat expansion (HRE) is a gain-of-function toxicity originating from the bidirectional transcription of sense and antisense transcripts carrying it. Given the evidence in support of a role for the hexanucleotide repeat-containing RNAs in C9ORF72-linked ALS and FTD, hereafter referred to as C9-ALS/FTD, strategies silencing their production hold potential for treating the disorder. One emerging technology with the capabilities to enable this is the Cas13d nuclease from *Ruminococcus flavefaciens* XPD3002, known as RfxCas13d or CasRx, a class 2 type VI CRISPR effector protein that, when complexed with a crRNA molecule complementary to a target transcript, can cleave it via its intrinsic ribonuclease activity. RfxCas13d is compact enough to fit within a single adeno-associated virus (AAV) vector to enable its delivery to the nervous system and can be fused to nuclear localization signal sequences to target transcripts in the nucleus. Given these properties, we hypothesized that RfxCas13d could be used to silence expression of repeat-containing RNAs and influence the pathological hallmarks of C9-ALS/FTD. To facilitate the design of crRNAs to silence the G_4C_2 repeat-containing RNA, we searched the exon 1a and the intron 1 sequences flanking the HRE using the Cas13 Design Resource. We then developed a dual-reporter screen to determine the ability of the 15 highest ranking crRNAs to target their respective sequences. Through this screen, we identified several crRNAs that decreased the expression of the reporter transgene by up to ~90% and induced no apparent collateral effects in cells. We next evaluated the targeting capabilities of these lead crRNAs in HEK293T cells and SH-SY5Y cells, finding by qPCR that the most effective crRNAs decreased V3, a C9ORF72 transcript variant that carries the HRE, by 90-95% and had no effect on all-V, the reservoir of C9ORF72 transcript variants that consists most predominately of V2, a transcript variant that lacks the HRE. To evaluate targeting *in vivo*, we injected the motor cortex (MC) and hippocampus (HPC) of C9-BACexp mice with an AAV-PHP.eB vector encoding RfxCas13d with one of the three lead crRNAs. According to qPCR, our most potent crRNA reduced V3 mRNA by two-fold, both in the MC and HPC, and decreased the formation of RNA foci consisting of the G_4C_2 repeat-containing RNA by up to 37%. Because of their risk for inducing collateral effects, we next determined the ability for high-fidelity forms of RfxCas13d, which possess a reduced capacity to *trans*-cleave non-target RNAs, to target C9ORF72. In addition to decreasing V3 mRNA in HEK293T cells and SH-SY5Y cells by 80-95%, we found by RNA-seq that the most effective high-fidelity variant, RfxCas13d-N2V8, possessed improved transcriptome-wide specificity compared to the native protein, affecting the expression of nearly six-fold fewer genes. Given these improved capabilities, we determined if RfxCas13d-N2V8 could target C9ORF72 *in vivo.* Consistent with our earlier study, we measured a two-fold decrease in V3 mRNA in the MC and HPC of C9-BACexp mice injected with RfxCas13d-N2V8, as well as a ~37% decrease in RNA foci formation. Last, through an RNA-seq analysis of transduced nuclei from the MC of C9-BACexp mice and their wild-type littermates, we found that RfxCas13d-N2V8 reversed at least 50% of the transcriptional deficits that manifested in C9-BACexp mice. Altogether, our results illustrate the potential of CRISPR-Cas13 technology for C9ORF72-linked ALS/FTD.

54. Do Some Loci Have a Propensity to Retain Ectopic Methylation?

Henriette O'Geen[1], Alina Mihalovits[2], Benjamin D. Brophy[1], He Yang[1], Marketa Tomkova[2], David J. Segal[1]

[1]UC Davis Genome Center, Davis, CA,[2]Ludwig Institute for Cancer Research, University of Oxford, Oxford, United Kingdom

In this study, we aimed to identify if methylation hotspots exist, what pre-existing chromatin environments might enable long-lasting DNA methylation, and whether this could affect gene expression. Epigenetic editing is emerging as a safe way to treat genetic disorders. Indeed, great advances have been made recently to achieve long-term repression of

target gene expression. We and others have used a catalytically dead dCas9 tethered to a DNA-methyltransferase and a recruitment domain for a histone-methyltransferase to enable longer lasting methylation at the target locus. However, before epigenetic editors can be translated into clinical settings, we need to have a deeper understanding of longevity of gRNA-independent off-target events, how widespread off-target methylation really is, and if some loci have a propensity to retain ectopic methylation and therefore are considered ectopic methylation hotspots. Our study demonstrated that hundreds of CpGs can retain off-target methylation in cell culture even after transient delivery of dCas9-based epigenetic editors. We identify chromatin features that predispose genomic regions to not only gain, but also retain off-target methylation for at least 24 days. We identify a distinct subset of genes where retained CpG hypermethylation translates into long-lasting effects on gene-expression. Expansion of our analysis to other epigenetic targeting strategies and cell types corroborate our findings. In summary, we show how targeted DNA methylation can lead to unintended expression changes at genes with distinct epigenetic marks. Our results warrant further considerations for on-target efficiency and unintended off-target effects of epigenome editing.

55. Engineered Extrachromosomal Genetic Technologies for Persistent and Tunable Control of Therapeutic Human Cell Types

Daniel A. Brenner[1], Hailey Szadowski[2], Sofia Aguilera[1], Ana Naqvi[1], Isaac B. Hilton[1,2]

[1]Department of Bioengineering, Rice University, Houston, TX,[2]Systems, Synthetic, and Physical Biology Graduate Program, Rice University, Houston, TX

Retroviral vectors have seen clinical success with respect to delivering transgenes to primary human cells. For instance, these vectors are the gold standard for the delivery of chimeric antigen receptors (CARs) in T-cells and other cell types. However, retroviral vectors are prone to random genomic integration of payloads, which poses important clinical drawbacks, such as the disruption of endogenous genes, epigenetic silencing of integrated transgenes over time, and oncogene activation. These drawbacks converge to make the use of programmable non-integrating methods of transgene expression attractive. Current non-integrating viral expression systems used in therapeutic contexts are either very restricted in terms of payload capacities (e.g., adeno-associated virus) or are modified to eliminate any potential for virulence and/or immunogenicity (e.g. adenovirus). These modifications tend to result in transient payload expression. Further, both integrating and non-integrating cargo expression approaches lack facile tunability of transgene expression. To overcome these limitations, we developed a new class of technology that combines the strategies displayed by latent non-integrating viruses to maintain long-term gene expression with synthetic biology tools. In doing so, we created persistent and programmable extrachromosomal expression systems that allow user-defined tunability of payload expression and maintenance of genetic components. Specifically, we have built and optimized a class of programmable and stably maintainable non-integrating DNA systems containing modular cassettes that confer mitotic stability and host-mediated replicative ability. We hypothesized that this system would allow extrachromosomal or episomal DNA to persist in dividing human cells without genomic integration. We first constructed and tested an engineered tethering system that permitted us to site-specifically control the targeting and frequency of engagement between extrachromosomal DNA and the human genome in live cells. Using ChIP-qPCR, we confirmed that our tethering modules can bind to both the human genome and synthetic extrachromosomal DNA. We also used fluorescence in situ hybridization (FISH) and high-resolution microscopy to verify co-localization. Next, we transfected human cells with episomes containing EGFP, our tethering system, and an engineered replication module. We optimized the number of tether binding sites in the host genome and showed the long-term persistence of payload expression (EGFP) out to ~3 months post-transfection. We also isolated genomic DNA and used qPCR to verify that persistence was not due to off-target payload integration into the genome. To streamline constructs for more versatile viral and non-viral delivery modalities, we also created truncated versions of tethering and replication modules. Using these compact designs, we demonstrate delivery to primary human cell types, including T cells, and in turn, use these platforms to express high levels of therapeutics tunably and persistently. In summary, we developed a novel method of maintaining extrachromosomal DNA payloads in human cells and successfully demonstrated that we can maintain therapeutic gene expression in dividing primary cells without genomic integration. Our extrachromosomal genetic technology opens new possibilities for treatments that rely upon transgene delivery without the associated risks of altering the endogenous human genome.

56. Compact Epigenetic Modulators for CRISPR Mediated Persistent Gene Activation

Giovanni Carosso[1], Robin Yeo[1], T. Blair Gainous[1], M. Zaki Jawaid[1], Xiao Yang[1], James Y. S. Kim[1], Kavita Jadhav[1], Nina Juan-Sing[1], Siddaraju Valagerehalli Boregowda[1], Vincent Cutillas[1], Lei S. Qi[2], Alexandra Collin de L'Hortet[1], Timothy P. Daley[1], Dan Hart[1]

[1]Epicrispr Biotechnologies, South San Francisco, CA,[2]Stanford University, Stanford, CA

CRISPR-mediated epigenetic gene silencing is a powerful tool with significant therapeutic potential, due to its ability to induce long-lasting changes in gene expression without introducing mutations to genomic DNA. This holds great promise in the field of genetic medicine, potentially allowing for the treatment of complex human diseases. However, the lack of tools for robust and persistent activation of target gene expression remains a significant obstacle to epigenetic editing. To overcome this limitation, at Epic Bio we have established a screening platform to discover novel epigenetic activators. Through this platform, we have discovered multiple Gene Expression Modulation System (GEMS) activators capable of inducing persistent gene activation following transient delivery. In initial studies, GEMS activators containing a vIRF2 core domain (vCD) outperformed dCas-VPR (a fusion of VP16, P65 and Rta) and other potent activators in terms of gene activation potency, robustness, and persistence after transient delivery, in both immortalized and primary cells. This was observed when GEMS were transiently delivered to target genes in multiple cell types and chromatin states (from quiescent to highly expressed). Notably, novel hypercompact activators (64 to 98 amino acids) derived from vCDs demonstrated durable activation of IL-21, an interleukin crucial for enhancing CAR-T cell function, lasting for 41 days after

transient expression in Jurkat cells. These GEMS activators achieved superior potency when compared to a benchmark transcriptional activator VPR. Initial potencies of vCD and VPR were ~730-fold and ~4 fold respectively, indicating that vCD outperforms VPR by a factor of ~177-fold. Throughout this period of gene activation, the vCD maintained an IL-21 activation plateau of ~30-fold, whereas VPR, in contrast, was unable to sustain IL-21 activation beyond 11 days. In hepatocyte HepG2 cells, flow cytometry studies were performed to assess the ability of vCDs to activate LDLR (Fig.1 a), a gene of therapeutic significance as *LDLR* haploinsufficiency constitutes 85 to 90% of genetically confirmed cases of familial hypercholesterolemia. We compared the activation potential of vCDs against VP64 and found that vCDs, but not VP64, were able to activate LDLR to levels approaching those achieved by transfection of an LDLR-encoding ORF cDNA (Fig.1 b). This activation was sustained in HepG2 cells for at least 16 days post-transient plasmid delivery. We then performed a direct comparison between vCDs and the potent activator VPR and demonstrated that vCDs were able to induce LDLR activation that persisted for 70 days post transient delivery in HepG2 cells (Fig.1 c). *In vivo* testing of vCD activators further demonstrated their efficacy and persistence. Modulating the expression of LDLR in primary human hepatocytes within a humanized mouse liver model, we achieved two-fold activation of LDLR, sustained for up to 5 weeks post-single dose administration of vCD GEMS activators encapsulated in lipid nanoparticles (LNPs), far beyond any previous report of *in vivo* CRISPR-mediated epigenetic gene activation (Fig.1 d-g). These results validate proof of concept for CRISPR-mediated persistent gene activation *in vitro* and *in vivo*, showcasing the potential of epigenetic activation of disease-modifying genes *in vivo*.

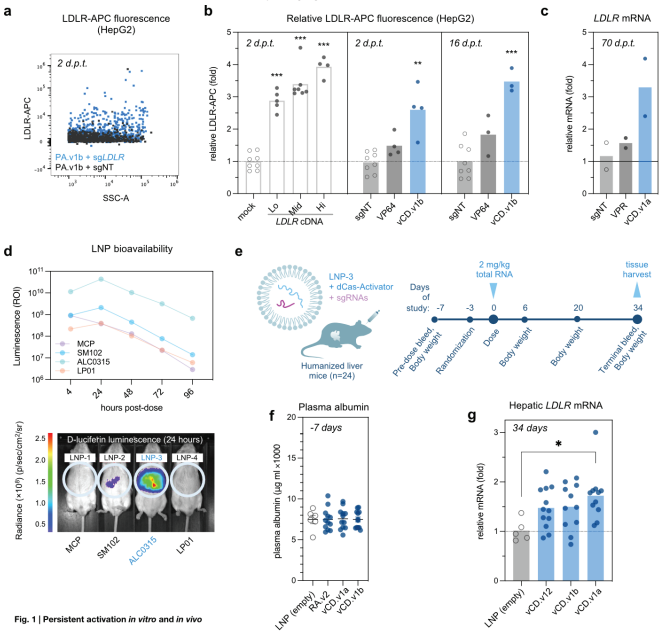


Fig. 1 | Persistent activation *in vitro* and *in vivo*

57. >95% Targeted RNA Editing in Brain with High Durability and Specificity Enabled by Systemic Injection of AAV-Packaged ADAR Guide RNAs

Alison VanSchoiack, Eric M. Chadwick, Yiannis A. Savva, Lina R. Bagepalli, Scott A. Rich, Henry Lee, Susan M. Byrne, Stephen M. Burleigh, Clay M. Patton, Robyn Laing, Robert Lloyd, Palmer Fliss, Ted Gniffke, Jana Henry, Jonathan H. Wang, Crystal G. Pontrello, Leah Helton, Evan E. Kania, Aditya Radhakrishnan, Thomas J. Long, Brian Booth, Yue Jiang, Ronald J. Hause, Melissa Works, Adrian Briggs, David J. Huss

Shape Therapeutics, Inc., Seattle, WA

Programmable RNA editing using guide RNAs (gRNAs) that recruit endogenous adenosine deaminase acting on RNA (ADAR) has great potential as a versatile gene therapy approach, without the need to deliver a protein or protein-encoding transgene. ADAR enzymes recognize double-stranded RNA substrates and deaminate adenosines into inosines. Due to structural similarity, inosines are read as guanosines by the cellular machinery, creating a functional A-to-G base change. RNA editing can be used to correct pathogenic G-to-A mutations, regulate RNA splicing, and modulate protein expression or function. The many molecular applications of RNA editing, combined with the ubiquitous expression of ADAR enzymes throughout all tissues of the body, enable vast therapeutic opportunities. We developed the RNAfix® platform to advance the therapeutic application of programmable RNA editing. RNAfix uses generative machine learning to design gRNAs that hybridize to a target RNA transcript, create an ideal double-stranded RNA substrate for endogenous ADAR recruitment, and drive efficient and specific RNA editing of the target adenosine. RNAfix gRNAs are delivered via AAV for sustained, high level expression that maximizes the durability and therapeutic impact of a single administration. Natural RNA editing is highly active in the central nervous system (CNS) and is critical for neuronal development and synaptic transmission; therefore, we hypothesized that RNAfix would be particularly well-suited to treat CNS disorders. Here we present preclinical data highlighting efficient and specific RNA editing in *in vitro* and *in vivo* disease-relevant CNS model systems. RNAfix gRNAs delivered *in vitro* demonstrate 85-97% target-specific RNA editing in mouse, non-human primate, and human neural cell models. In mouse studies, systemic administration of AAV-PhP.eB-encoded gRNAs at 1e11 viral genomes (vg)/mouse yielded efficient, specific, and durable RNA editing in disease-relevant brain regions from 4 to 16+ weeks. RNA editing was evaluated by Sanger sequencing on microdissected brain tissue, without sorting for gRNA+ cells. At 16 weeks post-treatment, we observed high efficiency editing in the mouse cortex (73%), hippocampus (75%), striatum (79%), substantia nigra (82%), and cerebellum (57%). gRNA expression, measured by ddPCR and *in situ* hybridization, strongly correlated with RNA editing efficiency in each brain region. Increasing the RNAfix AAV-PhP.eB dose to 1e12 vg/mouse increased RNA editing efficiency to 93-96% in bulk cerebrum. Importantly, RNAfix gRNAs are highly specific to the target adenosines of interest with no discernable off-target editing events across the entire transcriptome and no disruption to natural ADAR activity as measured by deep RNA-sequencing. For certain therapeutic targets, RNAfix was harnessed to edit translation

initiation sites (**A**UG>**G**UG) and inhibit protein translation. In both *in vitro* and *in vivo* model systems, RNA editing efficiency strongly correlated with target protein knockdown, highlighting an additional molecular application of the RNAfix platform. Collectively, these data highlight the cross-species conservation of ADAR-mediated RNA editing and provide confidence in the translatability of the RNAfix platform. Furthermore, these results demonstrate the highest *in vivo* CNS editing data reported to date and emphasize the potential of RNAfix to deliver durable, precise, and efficient programmable RNA medicine to the clinic.

58. Durable and Specific Silencing of Therapeutically Relevant Genes Using Epigenetic Editors is Reversible *In Vivo*

Frederic Tremblay, Yesseinia Anglero-Rodriguez, Kenneth Kelly, Shrijal Shah, Gabriel El Sebae, Chih-Wei Ko, Glen Acosta, Christine Waters, Rayman Choo-Wing, Liam Lofgren, Tess Sevetson, Caroline Mugambwa, Jhon Medina, Scott Clarkson, Ricardo N. Ramirez, Erica Hildebrand, Shane Wright, Kendra Bayne, Mary Morrison, Haley Sharp, Gabrielle Mitchell-Lee, Kara Allison, Songlei Liu, Sam Linder, Sahar Abubucker, Ari E. Friedland, Morgan L. Maeder, John Xiong, Vic Myer, Aron Jaffe

Chroma Medicine, Boston, MA

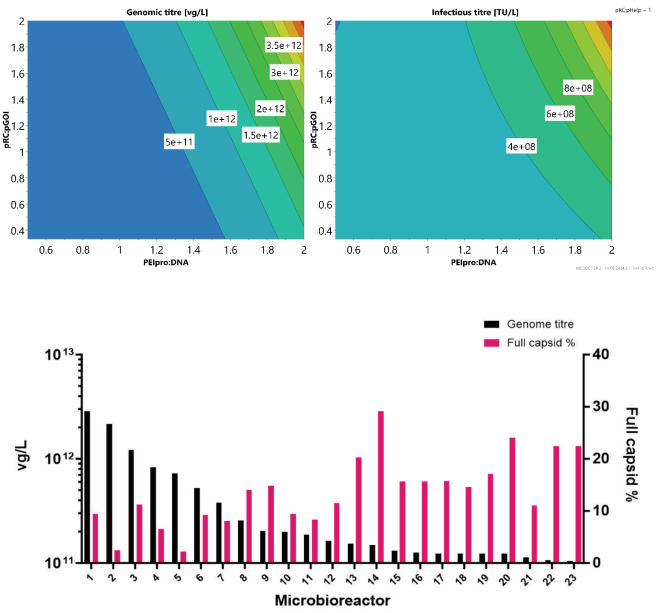
Epigenetic editing is a powerful approach designed to durably silence or activate genes by leveraging nature's endogenous cellular mechanism for gene regulation without the inherent genotoxic risks of other editing approaches that nick or cut the DNA. Our epigenetic editors have a distinct mechanistic advantage by utilizing DNA methylation and demethylation to silence or activate genes, respectively, a targeted approach for regulation of gene expression rather than indirect regulation through cutting or nicking the DNA, which can cause unintended chromosomal effects. We have identified epigenetic editors (EEs) that have demonstrated efficient silencing activity against human hepatitis B virus (HBV) and PCSK9 in primary human hepatocytes (PHH) and mice. To characterize the specificity of epigenetic editing, we profiled PHHs treated with either HBV-EE or PCSK9-EE by RNAseq, methylation array, and whole-genome methylation sequencing. No statistically significant differentially expressed off-target genes or methylated regions were identified, confirming the specificity of our EEs in PHHs. We then evaluated the durability of epigenetic editing in transgenic mice expressing HBV and showed potent reduction (>2-log) in circulating HBsAg with durability out to 5 months. Similarly, transgenic mice carrying the human PCSK9 genomic locus treated with PCSK9-EE showed >98% reduction in circulating PCSK9 over 300 days. In addition, we confirmed that the efficient PCSK9 silencing observed after treatment with PCSK9-EE was fully maintained following a 2/3 partial hepatectomy, an established model of liver regeneration. Furthermore, targeted CpG methylation at the PCSK9 promoter region was highly correlated with PCSK9 expression and faithfully maintained in the regenerated liver of partially hepatectomized mice. Finally, we explored the reversibility of epigenetic editing in vivo by using an epigenetic activator that was identified for its ability to restore PCSK9 expression in previously silenced cells in vitro via targeted CpG demethylation. Mice that had been previously silenced with PCSK9-EE were treated with a PCSK9 epigenetic activator, resulting in a near-complete restoration of PCSK9 levels to baseline levels within 14 days after treatment and maintained for at least 56 days. Taken together, we believe our data further support the utility of epigenetic editors to specifically, durably and reversibly silence therapeutically-relevant target genes in the liver without altering the DNA sequence.

59. Predicting CRISPR-Cas13 On-Target Efficiencies and Intrinsic RNA Off-Targets

Xiaolong Cheng[1], Zexu Li[2], Zihan Li[2], Teng Fei[2], Wei Li[1]

[1]Center for Genetic Medicine Research, Children's National Hospital, Washington, DC,[2]Northeastern University, Shenyang, China

CRISPR-Cas13 systems have emerged as versatile toolkits for RNA-related applications. However, mechanisms governing their on-target efficiencies and specificities are still not clearly known. Here we present two studies to understand and predict Cas13 efficiencies and off-target activities. In the first study, we conducted a systematic evaluation of several popular Cas13family effectors delivered via lentiviral vectors. Surprisingly, we uncovered distinct defects and characteristics among these systems. By employing RNA immunoprecipitation sequencing, transcriptome profiling, biochemistry analysis, high-throughput CRISPR-Cas13 screening, and machine learning techniques, we elucidated novel mechanisms through which Cas13 targets intrinsic RNA in mammalian cells, which differ from known RNA targeting activities of Cas13. Unlike traditional cis/trans effects, we discovered that intrinsic RNA cleavage mediated by Cas13 can exhibit crRNA-independent, transcript-specific, and dynamically tunable properties based on the various states of Cas13 nucleases. Furthermore, we identified host genes involved in viral processes that are intrinsically targeted by Cas13, contributing to lentiviral defects observed in our experiments. In the second study, we employ deep learning methods to accurately predict Cas13d guide-dependent on-target and off-target effects. We perform CRISPR-Cas13d proliferation screens and design a deep learning model, named DeepCas13, to predict the on-target activity from guide sequences and secondary structures. DeepCas13 outperforms existing methods to predict the efficiency of guides targeting both protein-coding and noncoding RNAs. Guides targeting non-essential genes display off-target viability effects, which are closely related to their on-target efficiencies. Choosing proper negative control guides during normalization mitigates the associated false positives in proliferation screens. We apply DeepCas13 to the guides targeting lncRNAs, and identify lncRNAs that affect cell viability and proliferation in multiple cell lines. The higher prediction accuracy of DeepCas13 over existing methods is extensively confirmed via a secondary CRISPR-Cas13d screen and quantitative RT-PCR experiments. DeepCas13 is freely accessible via http://deepcas13.weililab.org.



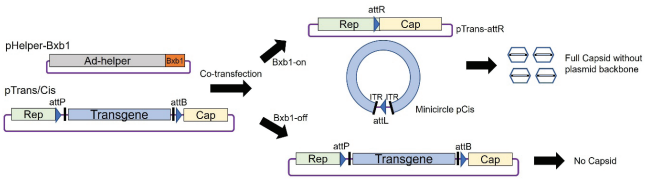
AAV Manufacturing II

60. pAAVing the Way to High Titres: Plasmid Ratio Optimisation for AAV Production Utilising the Ambr 15 Stirred-Tank Bioreactor

Sandeep Mangrati[1], Érica Schulze[2], Ulrike Jung[3], Stefano Boi[3], Sven Mathias[3], Yi-Hsuan Huang[3], Qasim Rafiq[1]

[1]Department of Biochemical Engineering, University College London, London, United Kingdom,[2]Sartorius Stedim Biotech GmbH, Goettingen, Germany,[3]Sartorius Stedim Cellca GmbH, Ulm, Germany

Background. Stirred-tank bioreactors (STBs) are the most promising candidates for large-scale rAAV vector manufacturing. However, rAAV bioprocess optimisation in bench-top STBs is challenging due to prohibitively high costs and resources. This is of particular concern when optimising plasmid ratios (pGOI, pRC, and pHelper plasmids) which requires running many vessels. Here, we investigated the impact of plasmid ratios on titres and full capsid percentages of an AAV2 vector, incorporating novel pAAV-GFP and pRC2 plasmids. In the literature, such optimisation has often been limited to shake flasks, however herein we utilised the Ambr® 15 high throughput microscale STB which has proven scalability and is more commercially relevant. **Method.** A design-of-experiment (DOE) was performed in MODDE® to evaluate a wide range of plasmid ratios (pRC:pGOI and pRC:pHelper) under PEIpro® and FectoVIR®-AAV transfection reagents. We selected a multilevel full factorial approach incorporating 83 microbioreactors using the Ambr® 15, a high throughput STB system with 48 microbioreactors (15 mL). Crude lysates were used to determine genomic, capsid, and infectious titres. **Results and conclusions.** We observed that increasing pRC:pGOI significantly improved genomic and infectious titres. Under PEIpro®, increasing pRC:pGOI from 0.33:1 to 2:1 improved genomic and infectious titres approximately 3-fold. By contrast, the effect of pRC:pHelper on titres was not significant. We also observed that when both pRC:pHelper and PEIpro:DNA were at low (or high) setpoints, full capsid percentage was negatively impacted. And notably, the standard 1:1:1 ratio resulted in infectivity below the limit-of-detection indicating the importance of plasmid ratio optimisation to evaluate functionality of new rAAV vectors. Under FectoVIR®-AAV transfection, there was a significant negative correlation between genomic titres and full capsid percentage, likely because the plasmid ratios had opposite effects on genomic titres and full capsid percentages (increasing pRC:pGOI improved genomic titres but lowered full capsid percentages). This indicated that a "sweet spot" may be needed and that it could be achieved by simply adjusting the plasmid ratios. Currently, the main challenge in AAV gene therapy is efficient and cost-effective production of rAAV vectors. This study demonstrated the applicability of the Ambr® 15 system in conjunction with a DOE approach for improving rAAV production and it highlighted the importance of plasmid ratio optimisation on CQAs. Such bioprocess improvements are important for ensuring successful commercialisation of rAAV drugs.



61. Producing High-Purity rAAV Vectors by Recombination-Dependent Minicircle Dual Transfection

Hao Liu[1], Lingzhi Ren[1], Nan Liu[1], Chen Zhou[1], Guangping Gao[1,2], Dan Wang[1,3]

[1]Horae Gene Therapy Center, University of Massachusetts Chan Medical School, Worcester, MA,[2]Department of Microbiology and Physiological Systems, University of Massachusetts Chan Medical School, Worcester, MA,[3]RNA Therapeutics Institute, University of Massachusetts Chan Medical School, Worcester, MA

Triple transfection of HEK293 cells is the most widely used method for producing recombinant adeno-associated virus (rAAV), a leading vector for human gene therapy. It involves three plasmids co-transfected to cells at roughly equal molar or mass ratio: a helper plasmid that delivers adenoviral helper genes (pHelper), a trans plasmid that expresses AAV rep and cap genes (pTrans), and a cis plasmid that harbors a therapeutic transgene cassette flanked by AAV inverted terminal repeats (pCis). Depside its tremendous success, this method still faces many challenges. One important concern is vector impurity, including plasmid backbone encapsidation that can not be removed by downstream processing and empty capsid that compromises vector potency. Here we developed a recombination-dependent minicircle dual transfection method that reduces the backbone DNA encapsidation by 20-40 folds and improves full capsid ratio by 2-3 folds compared with triple transfection, while generating comparable rAAV yield with reduced plasmid demand in the upstream rAAV production stage. This methodology consists of two plasmids, pHelper-Bxb1 that provides adenoviral helper genes and the recombinase Bxb1, and pTrans/Cis with the attP- and attB-flanked cis element inserted into the C-terminus of Rep in pTrans plasmid (See Figure). When pHelper-Bxb1 and pTrans/Cis are co-transfected into HEK293 cells, Bxb1 catalyzes the recombination between attP and attB sites in pTrans/Cis, generating a functional pTrans-attR that expresses Rep and Cap proteins, and a minicircle pCis that contains

only ITR-flanked transgene without any plasmid backbone sequences, which serves as the template for further vector genome amplification. In this way, the packaged AAV vectors are devoid of plasmid backbone DNA. When HEK293 cells receive only pTrans/Cis, the ITR-flanked transgene cassette embedded in the Rep gene serves as a disrupting insertion that abolishes Cap expression, thus avoiding empty capsid formation. Using EGFP as a model transgene, we demonstrated that this newly developed dual transfection method dramatically improved vector purity compared with triple transfection: (1) it reduced bacterial backbone encapsidation from 5.2% to 0.14% for rAAV2, and from 3.3% to 0.16% for rAAV9; (2) the full capsid ratios in crude lysate, as determined by ddPCR of genome titer normalized to ELISA capsid titer, increased from 11% to 23% for rAAV2, and from 14% to 46% for rAAV9. Mechanistically, we found that the asynchronous presence of pTrans and pCis contributes to high empty capsid levels in triple transfection. Intracellular genetic coupling of pTrans and pCis in triple transfection improves the full capsid ratio to similar levels of recombination-dependent minicircle dual transfection. Altogether, these results demonstrate that recombination-dependent minicircle dual transfection serves as a cost-saving and easy-to-implement manufacturing method that produces rAAV with significantly improved vector purity. In addition, it highlights the importance of spatial synchronization of pTrans and pCis plasmids in mitigating empty capsid formation. *G.G. and D.W. are corresponding authors.*

62. Elucidating the Function of Adenovirus Late Gene Products and Impact on AAV Production

Hao Pan, Qingliang Li, Huimin Na, Karen A. Vincent, Yingchao Nie

Predevelopment, Genomic Medicine Unit CMC, Sanofi, Waltham, MA

Recombinant adeno-associated viral vectors (rAAV) are being developed for a wide variety of gene therapy applications, but efficient production at large scale remains challenging. The producer cell line (PCL) platform is an economical and scalable approach for rAAV manufacturing. AAV Rep/Cap genes and gene of interest (GOI) elements are stably integrated in the producer cell line, and rAAV production is induced by infection with a wild-type, replication-competent Adenovirus (wtAd5). The adenoviral helper function in AAV production has been studied extensively, however, the interplay of the AAV and wtAd5 genomes is not yet fully understood. To better understand the helper function provided by wtAd5 in the PCL platform, we infected a PCL with a variant Adenovirus serotype 5 virus (Ad5ts149), which harbors a temperature-sensitive mutation in the Ad5 polymerase gene E2B. Suppression of Ad5ts149 replication and packaging at the restrictive temperature (39°C) resulted in a 3-to-50-fold reduction in rAAV production compared to that of wtAd5. However, replication of the AAV genome was comparable or higher in Ad5ts149-infected cells. AAV Rep/Cap protein expression was analyzed to assess the underlying mechanism. An altered Rep expression pattern was detected, accompanied by reduced expression of Cap protein. Orthogonal methods were employed to further understand transcription of AAV and adenoviral genes in the context of an Ad5ts149 infection at 39°C. Analysis of Ad5ts149 gene expression via RT-qPCR showed that expression of the minimal essential Ad helper genes were similar to wtAd5 while the expression of the Ad late gene products was decreased. Hypotheses were tested via siRNA knockdown in conjunction with wtAd5 infection to gain insight on the role of Ad5 late gene products. The outcomes reveal a novel role of an Ad5 late gene product in the regulation of AAV rep/cap gene expression and efficient production of rAAV in Sanofi's AAV producer cell line platform.

63. Process Development of HEK293-Based rAAV2 Manufacturing Platform

Alexander Burns

Bioprocessing, Keck Graduate Institute, Claremont, CA

The Adeno-associated virus (AAV) has been successfully used as a viral vector for gene therapy in its recombinant form, as seen by the relative commercial successes of AAV-based gene therapy products like Luxturna® and Zolgensma®. Nonetheless, these gene therapy products are significantly expensive, thus, making them relatively inaccessible to many patients who wish to get the therapy but choose not to get it due to financial reasons. One of the main reasons for the high cost of these therapies, besides the R&D expenditures that were necessary to get the therapy to commercialize, is the Cost-of-Goods-Sold (COGS) for manufacturing these therapies; especially the raw materials and labor to manufacture these therapies. There exist various technical gaps in the manufacturing and quality control of recombinant AAV (rAAV) particles that make these processes more challenging. A classic method for the production of rAAV particles is the triple transient (TT) transfection of HEK293 cells, where three vector DNA plasmids are required to be transfected in a HEK293 cell simultaneously to deliver all the necessary genes to the host cell to produce rAAV particles. Due to the inherently low efficiency of the transfection technique, vector DNA plasmids are not used effectively for rAAV production. Also, during anion-exchange chromatography, a chromatographic technique for AAV full-capsid enrichment, there is an inherently low resolution between full and empty AAV capsids; empty capsids are a product-related impurity of rAAV bioprocessing. The low chromatographic resolution makes it difficult to identify and quantify the empty and full AAV capsids, which adds to the challenge of quality control of rAAV products. Also, AAV particles are prone to aggregation during downstream and formulation bioprocessing due to the complex protein structure of AAV capsids; aggregation amount is a critical quality attribute (CQA) of rAAV as a final product for gene therapy. Thus, aggregation adds to the challenges of rAAV downstream and formulation bioprocessing. To improve the transfection efficiency of the TT transfection method of HEK239-based rAAV2 production, we have results of a significant increase in full-capsid AAV2 titer from TT transfection of HEK293 cells to produce AAV2 capsids, by exposing the cells to DMSO during the standard transfection protocol. To improve the resolution between empty and full AAV2 capsids in anion-exchange chromatography, an elution method of AAV2 capsids in anion-exchange HPLC (AAV2 AEX HPLC) was developed. Development of the AAV2 AEX HPLC elution method was

achieved by optimizing the loading conditions of the AAV2 sample to be loaded into the AEX HPLC column. To minimize aggregation of AAV2 capsids in solution, the effect of a combination of different types of salts and sugars was studied and an optimum combination of salt and sugar was found to minimize AAV2 capsid aggregation the most. Cryo-preservative agents (CPAs), such as DMSO, glycerol and certain sugars, normally used to extend the shelf-life and freeze-thaw cycles of cells and proteins, can also serve as transport modulators of macromolecules, such as proteins and nucleic acids, without affecting their structure and function. Thus, harnessing the full power of CPAs can help alleviate some of the technical gaps mentioned earlier for rAAV manufacturing and quality control. The following work will present how CPAs can be used for the process development of HEK293-based rAAV2 manufacturing platform; a gold-standard platform for rAAV manufacturing for gene therapy applications.

64. Transforming AAV Vector Production with the TruStableTM AAV Producer Cell Line

Sandhya Pande, Corey Johnson, Carla Villela, Tina Bi, Chris Abeles, Blake Engelbert, Ramsey Saleem, Ken Prentice

Shape Tx, Seattle, WA

We have developed the TruStable cell line, a serum-free suspension adapted human cell line, which is genetically engineered to incorporate all elements needed for stable recombinant adeno-associated virus (rAAV) production, enabling seamless scalability. At the heart of this system lies an inducible, recombination-based production circuit that silences cytotoxic viral elements during the preliminary expansion phase of the cells, subsequently enabling a simple activation for viral production when optimal culture conditions are attained. The development of stable producer cell lines marks a paradigm shift in the manufacture of AAV vectors as it circumvents transient transfection limitations (e.g. scale-up limitations, challenging supply chain). Further enhancing this system, we have introduced successive iterations of the core molecular circuit. We substituted native AAV P5, P19, and P40 promoters with alternative heterologous promoters while maintaining the overlapping genetic architecture of the Rep open reading frame. This allowed us to precisely adjust the expression levels of rep and capsid proteins to enhance AAV titer and quality while keeping a simplified plasmid design. These strategic modifications have culminated in the creation of highly productive polyclonal pools, exhibiting exceptional packaging efficiency. The result is a significant increase in volumetric titers and encapsidated genomes (~8e14 vg/L and ~70%, respectively) as measured from crude cell extracts. Additionally, monoclonal cell lines derived from these polyclonal pools exhibit exceptional productivity, routinely exceeding 100,000 viral genomes/cell. Our custom biphasic upstream process for TruStable cell lines enhances AAV vector production, merging a high cell density cell growth phase with a rAAV-synthesizing production phase. Advanced fed-batch and perfusion methods have fine-tuned N-1 seed train for maximum cell viability. After several rounds of screening, we've selected chemically defined media that bolster high AAV titers, with the process proven effective in 3L benchtop and scaled up in 10L bioreactors. This innovative approach — combining sophisticated molecular circuits, selective clone development, and a scalable suspension protocol — substantially improves upon prior rAAV production methods. TruStable lines are adept at packaging varied payloads across AAV serotypes, reliably yielding high-titer clones to accommodate manufacturing needs from small to large scales.

65. Developability Assessment of Novel AAV Capsids and Payloads at Early Preclinical Stage to Enable Development of Gene Therapies

Matteo P. Placidi[1], Himabindu Ramachandrareddy[2], Robert Vass[3], David Alvarez[1], Kumar Dhanasekaran[1]

[1]TechOps, Voyager Therapeutics, Lexington, MA,[2]Voyager Therapeutics, Inc. - Cambridge, MA, Sharon, MA,[3]Voyager Therapeutics, Lexington, MA

Developability assessments, similar to those performed on antibodies, refer to the likelihood that an adeno-associated virus (AAV) development candidate can be advanced towards the clinic by being a manufacturable, safe and efficacious drug. These attributes of clinical grade AAV material manufacturing are well established through the requirements of drug product safety, identity, strength, purity and quality (SISPQ) to enable release for use in the clinic. However, developability refers to the likelihood that an AAV development candidate will go smoothly through the chemistry, manufacturing and control (CMC) process. For this reason, it is important to consider this as part of a development candidate nomination criteria. Traditionally, preclinical studies, leading up to the nomination of a development candidate, involve very limited analytical testing or characterization. This delay in the application of advanced analytics can lead to issues that must be resolved in tandem with the necessary process development activities, impacting CMC development timelines and ultimately time to clinic. In this work we outline analytical methods that can be utilized early in assessing several critical quality attributes that may have an impact on developability. Here, the payload concentration and sequence, capsid occupancy, integrity, sequence, aggregation state and functional output were examined using multiple techniques to provide a holistic view of the different candidates during early development. The detailed analytical characterization approach distinguished key methods able to provide early indicators of loss of structural integrity. Specific assays indicated the impacts of different capsid/transgene combinations and storage conditions. When examined in conjunction with in vivo data, these methods should be carefully monitored due to their potential impact on performance in animal studies.

66. Comparative Analysis of Sterile Grade Filters in Adeno-Associated Virus (AAV) Manufacturing: Accelerating First-in-Human AAV Therapeutic Production with Quality by Design Principles

Morven McAlister[1], Alexander Lambropoulos[2], Limin Wang[3], Andreia Domingues[4], Melanie Sorensen[4], Angela N. Johnson[5,6]

[1]Global Scientific & Validation Services, Cytiva, New York, NY, MA,[2]Bioprocessing, Cytiva, Boston, MA,[3]Global Regulatory Science, Cytiva, Marlborough, MA,[4]Global Regulatory Sciences, Cytiva, Boston, MA,[5]Global Regulatory, Cytiva, Boston, MA,[6]School of Professional Studies, Regulatory Sciences, Northeastern University, Boston, MA

Background: Commercial sterile grade filters are important in producing adeno-associated virus (AAV) vector gene therapies, yet performance of filters in this context varies widely. As AAVs become more attractive for their ability to elicit robust and durable transgene expression, we have increased need to optimize transition from bench to production scale manufacturing. Identifying optimal sterilizing grade filters early in process development is essential to efficient and cost-effective manufacturing to meet clinical demand. **Methods:** The objective of this study was to evaluate commercial sterile filter characteristics in terms of performance at bench vs production scale, providing insights into early decision-making on process development and filter selection to enable first-in-human AAV therapeutic production. Applying a Quality by Design (QbD) framework, laboratory tests were completed at bench and production scale to assess the impact of sterilizing grade filter clarification (post-depth filtration; n = 20) and final sterile filtration of drug product (n = 32). Data were analyzed on filter type, differential pressure, throughput, and capacity. Filterability trials were conducted post-depth filtration on typical feed stream and AAV titers determined by ddPCR. **Results:** Differential pressure was a robust critical quality parameter (CPP) with minimal impact on AAV titer as a critical quality attribute (CQA; **Fig. 1**), and other AAV characteristics also impacted post-depth filtration and clarification. The resulting model (**Fig. 2**) is useful in selection of filters performing at bench scale and production scale, while considering AAV product characteristics that significantly correlated with filter performance, including cell line, suspension versus adherent, total cell density, viability after lysis, turbidity of harvest lysis, lysing agent & hold time, endonuclease agent / hold time, additives (e.g., NaCl, AAV serotype, titer, and filtration flux. **Conclusions:** This demonstrates the impact of selecting appropriate filters during bench development, considering process type, target removal and transport product. By employing QbD principles systematically, these results suggest we can improve the transition from bench to production scale AAC therapeutics via careful section of optimal filtration components, thereby contributing to reduced time and cost burden of manufacturing gene therapy drug candidates for the clinic.

AAV Vector Biology and Development I

67. Novel AAV8 and AAVrh39 ITRs and ITR-Proximal Regions Significantly Enhance Transgene Expression through Enhancer/Promoter-Like Activities

Suk Namkung[1], Elisabet Mandon[1,2], Jialing Yang Liang[1], Mengtian Cui[1], Fang Zhang[1], Jackson McGowan[1], Mitchell Yip[1], Thomas Leland[1], Sophia Liu[1], Tapan Sharma[1], Dan Wang[1], Guangping Gao[1], Phillip Tai[1]

[1]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[2]RNA Therapeutics Institute, UMass Chan Medical School, Worcester, MA

Advancements in adeno-associated virus (AAV)-based gene therapy engineering have greatly increased within the past decade. These trends have been mainly within the scopes of capsid engineering and regulatory cassette design. However, there has been an underwhelming amount of research focused on exploring genetic elements of wildtype AAV and their roles in transcription. Previous research has demonstrated that inverted terminal repeats (ITRs), the last viral elements in AAV vectors, have promoter-like activities. Furthermore, ITR-proximal regions (IPRs) at the 3' ends of wildtype AAV genomes also show tissue-dependent enhancer-like activities. These results have shown the potential for native elements within the AAV genome to further improve gene therapy vectors. To study the different contributions of AAV genetic elements towards vector transduction, we tested the ITRs and IPRs of AAV8 and AAVrh.39 for their potential to act as enhancers and/or promoters *in vitro* and *in vivo*. As previously reported, we found that the ITRs of AAV2, AAV8, and AAVrh.39 (ITR2, ITR8, and ITRrh.39 respectively) have very weak promoter-like activities on their own. However, we found that the IPRs of AAV8 and AAVrh.39 (IPR8 and IPRrh.39, respectively) have a stronger impact on transcription, conferring four-fold greater activity than achieved by the human phosphoglycerate kinase (*hPGK*) promoter. In addition, while AAV2's IPR (IPR2) only showed liver-specific activity, IPRrh39 was equally active in HEK293 and cultured hepatocytes. We next produced vectors carrying ITRs and IPRs from AAV8 or AAVrh.39. Vector production and sequencing of the vectors by third-generation sequencing showed that the these elements are fully compatible with standard triple-plasmid transfection production schemes using Rep proteins from AAV2. Surprisingly, we found that AAV vectors carrying ITR8 and ITRrh.39 showed a >10-fold enhancement in mouse liver transduction over vectors that carried conventional ITR2. We are currently working toward understanding the mechanisms that underpin ITR and IPR function. In conclusion, we demonstrate that there are still facets of AAV biology that remain to be uncovered and further studied in order to improve gene therapy vectors. G.G. and P.T. are corresponding authors

68. A Genome-Wide CRISPR/Cas9 Screen Identifies an Essential Role of SLC35A1 in rAAV Transduction

Xiujuan Zhang[1], Kang Ning[1], Siyuan Hao[1], Zehua Feng[2], Cagla Aksu Kuz[1], Shane McFarlin[1], Donovan G. Richart[1], Fang Cheng[1], Ziying Yan[2], Jianming Qiu[1]

[1]University of Kansas Medical Center, Kansas City, KS,[2]University of Iowa, Iowa City, IA

Recombinant Adeno-associated virus (rAAV) has become an important tool for delivering genetic material into cells, offering potential treatments for a variety of genetic disorders. Despite its significance, the mechanisms underlying rAAV transduction are not fully understood. GPR108 has been identified as an essential factor for the transduction of various rAAV vectors, excluding rAAV5. This dependence arises from the interaction between GPR108 and the N-terminal unique region of the large capsid protein (VP1u). Notably, VP1u region of AAV5 is divergent from that of other serotypes. To identify the essential host factors that are used by AAV5, we conducted a genome-wide CRISPR/Cas9 screen in suspension 293F cells transduced with rAAV5, employing the Brunello gRNA library. Following two round screens, the highly selected genes included the previously reported genes, *KIAA039L*, *TM9SF2*, and *RNF121*, along with a cluster of genes involved in glycan biogenesis. In this report, we focused on solute carrier family 35 member A1 (*SLC35A1*), a Golgi apparatus-localized CMP-sialic acid transporter, as AAV5 utilizes 2,3-linked sialic acid as a primary attachment receptor. Our study verified that knockout of *SLC35A1* reduced rAAV5 transduction to a level similar to that in *KIAA0319L* and *TM9SF2* knockout cells. Importantly, although *SLC35A1* knockout abolished 2,6-linked sialic acid expression on the cell surface, as detected by specific sialic acid-binding lections, the expression of 2,3-linked sialic acid, as well as rAAV5 binding to cells and internalization, was not affected. Moreover, the *SLC35A1* knockout significantly diminished the transduction of other rAAV serotypes, AAV2, AAV3B, and AAV13, which were previously reported not to use sialic acid for entry, suggesting that SLC35A1 plays a critical role in rAAV transduction after vector internalization. Overall, our study suggests that SLC35A1 serves as a crucial host factor facilitating the transduction of various AAV vectors beyond the initial steps of vector binding and endocytosis. This discovery unveils an unanticipated role of the CMP-sialic acid transporter in rAAV transduction, involving intracellular trafficking of vectors after internalization into the host cell.

69. Screening for Cellular Factors Underlying Mechanisms of AAV Tropism

Hagoon Jang[1], Qianhui Du[1], Mark A. Kay[2]

[1]Stanford University, Stanford, CA,[2]Stanford University School of Medicine, Stanford, CA

Understanding the intricate interplay between the AAV capsid and host cellular factors is crucial for optimizing AAV efficiency and achieving precise targeting. Our research group previously engineered the LK03 AAV capsid, demonstrating robust transduction in human liver but poor efficacy in rodent liver (Lisowski 2014). Further work established that differential transduction was not due to vector entry and nuclear uptake but rather related to the concentration of active epigenetic modifications, including histone acetylation (H3K27ac),

on the LK03 AAV genome in a species-dependent manner (Gonzalez-Sandoval 2023). Our studies went on to establish that the capsid protein can influence the epigenetic state of the vector genome in a species-dependent manner.To unravel the cellular key factors influencing LK03's epigenetic regulation, we employed two distinct approaches. Firstly, we established a Hepa1-6 mouse hepatoma cell line expressing the dCas9-p300 protein, designed to enhance site-specific histone acetylation guided by AAV genome-targeting guide RNAs. Following LK03-luciferase and DJ-luciferase transduction in Hepa1-6 dCas9-p300 stable cells, we introduced guide RNAs targeting the AAV genome promoter, gene body, and 3' region. Importantly, targeting the promoter region increased luciferase activity only in LK03 transduced cells and not in DJ transduced cells, indicating potential associations with histone acetylation events specifically linked to the AAV-LK03 capsid-delivered genomes.Secondly, we utilized histone deacetylase (HDAC) inhibitors (Panobinostat and Trichostatin A) to modulate the histone modifications in a non-sequence-specific manner. In this case, both LK03 and DJ-delivered genomes exhibited a two-fold increase in luciferase activity.We are currently determining the specific histone modifications associated with each of the dCas9-p300 guide RNA and HDAC-treated cells transduced with AAV-LK03 and AAV-DJ. Through these comprehensive approaches, our goal is to unravel the underlying molecular mechanisms driving the variation in LK03 AAV tropism between mouse and human hepatoma cells. The data here further supports a direct causal role linking the AAV capsid protein to histone modifications placed on the vector genome that ultimately causes differential transduction efficiencies observed with different capsids between different species and cell types.

70. Consequences of Human Genetic Variations of the Adeno-Associated Virus Receptor (AAVR) Gene (KIAA0319L) on AAV-Mediated Gene Transfer

Jenifer M. Vasquez, Hailey C. Lephart, Caner Günaydin, Mahboubeh R. Rostami, Philip L. Leopold, Ronald G. Crystal

Genetic Medicine, Weill Cornell Medical College, New York, NY

Vectors based on adeno-associated virus (AAV) mediate persistent gene expression with relatively low toxicity making them ideal vehicles for gene therapy. However, patients receiving identical doses of vector scaled to body weight yield variable levels of the therapeutic protein. Based on our prior report (Rostami et al. Mol Ther Methods Clin Dev 2023; 31:101136) of more than 69,000 human genetic variants among more than 60 genes encoding proteins that influence AAV expression levels, we hypothesized that some of these naturally occurring genetic variants are determential, mediating less receptor number and/or function, thus modifying the trafficking of AAV vectors, resulting in variable expression of the expressed gene. As an initial test of this hypothesis, we focused on AAVR, a cell surface receptor that mediates the initial steps in intracellular trafficking for most AAV serotypes . We assessed 10 naturally occurring human mutations of AAVR predicted to have deleterious effects on AAVR structure and function. HeLa-AAVR-knockout (HeLa-KO) cells were transfected with either wild-type human AAVR or one of the AAVR genetic variants. Following transfection, cells were modified with 1 of 6 different AAVR-dependent AAV serotype vectors (2, 5, 8, 9, and rh.10, representing 4 different AAV clades) coding for the nano-luciferase reporter gene. Luciferease expression levels were quantified 3 days post-infection. Four of the 10 variants encoding AAVR frameshift mutations mediated significant reduction in gene transfer for all serotypes (all $p<10^{-3}$). The 6 missense variants in AAVR also affected AAV-mediated gene expression, but did so differently depending on the AAVR domain containing the human genetic variant and the AAV serotype. For example, gene expression to serotypes in closely related clades E and F (AAV8, 9, and rh.10) were significantly decreased (all $p<10^{-3}$) by human variants in the N-terminal domain (Lys3Thr), PKD2 domain (Val440Ile), and in C-terminal domain (Lys959Glu, Gly1022Arg, and Ser1031Phe). In contrast, gene expression mediated by serotypes in clade E and F were not affected by a human mutation in the PDK3 domain (Ala563Val). More distantly related serotype AAV2 (clade B) was also mildly sensitive to Lys3Thr ($p<0.05$) but gene transfer was not affected by the variants in PKD2, PKD3 or C-terminal regions. AAV5, a serotype not assigned a clade, was distinct from other serotypes in that it was not sensitive to the human N-terminal, PKD2, or PKD3 variants but showed elevated gene expression in the context of C-terminal variants, Gly1022Arg and Ser1031Phe (both $p<10^{-2}$). In conclusion, naturally-occurring human genetic variations in AAVR influence the efficiency of AAV-mediated gene transfer and may be a factor in the variability that is observed when gene therapy treatments are administered to patients in clinical trials.

71. Epigenetic Blueprint: Understanding How the AAV Capsid Influences the Vector Epigenome

Eirini Vamva[1], Katja Pekrun[2], Yuqian Jiang[3], Adriana Gonzalez[4], Ningyang Gu[5], David A. Dean[5], Mark A. Kay[6]

[1]Genetics, Stanford University Laboratory for Cell & Gene Medicine, Palo Alto, CA,[2]Stanford University, Stanford, CA,[3]Stanford, Palo Alto, CA,[4]Stanford University, Burlingame, CA,[5]University of Rochester, Rochester, NY,[6]Stanford University School of Medicine, Stanford, CA

We recently showed that the AAV capsid plays a role in establishing the AAV-epigenome(Gonzalez-Sandoval, 2023). The AAV-LK03 capsid, which shows robust transduction in non-human primates and humans (Lindsey 2021), does not transduce rodents well. Insertion of a single Glycine into position 266 of the primate specific LK03 capsid, (266iG) named AAV-AM, changed the vector properties allowing efficient transduction in both mice and human cells. We found that vector-mediated transgene expression was unrelated to cell entry, nuclear transport, and double-strand vector DNA formation but related to the concentration of activating histone H3 epigenetic modifications (H3K4me3 and H3K27ac) present on the vector genome itself. We set out to understand how the different capsids interact with host proteins in the nucleus to set up the vector DNA epigenome. First, we performed direct intranuclear and intracellular AAV injections to study potential spatial differences in nuclear localization between the AAV-LK03 and AAV-AM delivered genomes and their effect on transgene expression. We discovered that intranuclear, but not intracytoplasmic vector injections led to successful transduction of mouse and human hepatoma cell lines. The intranuclear AAV-AM and AAV-LK03 injections led to transgene expression that followed the same pattern observed in natural transductions, supporting the notion that post nuclear entry events are responsible for setting up the vector

epigenome. Trans-complementation studies revealed that the effect of the AAV capsid on the vector epigenome occurs in *cis*. Changing and/or inserting various amino acids into the 260-270 hypervariable region of LK03 and AM revealed that maintaining a glycine in position 266 was the most important parameter to maintain pan-species transduction. To test this further, we found that insertion of a glycine (266iG) into AAV-NP59, another primate selective capsid, enhanced the capsid's ability to transduce both rodents and primates. Structural predictions suggest that this additional glycine in position 266 allows for a more flexible local structure that could have an influence on interactions between the capsid and the AAV genome and/or interactions of the vector genome with key host factor(s). To identify host factors that interact with the capsid and/or vector genome and are involved in this process, we performed anti-A20 immunoprecipitation and mass spectometry, followed by evaluation of candidate proteins on AAV-LK03 and AM transduction efficiency with siRNA silencing. Our siRNA screen identified the RPA complex as a novel host restriction factor critical for vector epigenome modifications. Using both siRNA technology and two small molecule RPA inhibitors, we showed that, RPA efficiently inhibited AAV-LK03 transduction in mouse but not in human hepatoma cell lines. Further analysis demonstrated that improvement of transduction efficiency facilitated by RPA inhibition was unrelated to cell entry but rather due to increased transgene mRNA expression. We are currently investigating the effect of RPA inhibition on the histone epigenetic modifications of the rAAV genome itself as well as the nature of the interaction between RPA and the rAAV genome. Our study supports the idea that the capsid sequence plays a major role in transgene expression by interacting with host nuclear proteins and by influencing the modified histone marks that bind to the vector genome. This mechanism may explain the variation in AAV-mediated transduction between species, tissues, and dose responses observed in clinical trials.

72. Lack of the Ability to Bind Heparin and a Y-to-F Mutation are Sufficient for AAP-Independent AAV2 Capsid Assembly

Anusha Sairavi[1], Yoya Vashi[1], Swapna Kollu[1], Hiroyuki Nakai[1,2]

[1]Molecular and Medical Genetics, Oregon Health and Science University, Portland, OR,[2]Molecular Microbiology and Immunology, Oregon Health and Science University, Portland, OR

The assembly of adeno-associated virus (AAV) capsids is primarily mediated by assembly-activating protein (AAP) and other host factors, which could potentially vary among different serotypes and production systems. AAP supports capsid assembly through a multitude of functions with the ultimate goal of stabilizing VP monomers and multimers, subsequently allowing them to assemble into capsids, the process of which is still not well understood. Although this mechanism applies to AAVs in the viral life cycle in nature, our group discovered AAP-independent (AAPi) serotypes capable of assembling into capsids in the absence of AAP in experimental settings. These include AAV 4, 5, 11 and rh32.33. We had previously reported that the AAPi serotypes exhibit a higher propensity for VP subunit association at the 2 and 5-fold axes compared to AAP-dependent (AAPd) serotypes, conferring AAPi capsids an equilibrium favorable for capsid formation. Understanding how and why the AAPi serotypes emerged would not only further our knowledge of AAV biology and evolution but also provide clues to exploring novel means to enhance AAV vector production for gene therapy purposes. Given this background, we have been seeking to identify mutants and their respective positions that could render AAPd serotypes independent of AAP for assembly (i.e., AAPd-to-AAPi phenotype conversion). Here, we report that we have successfully identified such mutants derived from AAV2, an AAPd serotype, through directed evolution, which has provided mechanistic insights into AAP requirements in AAV capsid assembly. Briefly, an ITR2-Rep2-AAV2Cap-ITR2 plasmid construct was generated with a codon-modified VP3 with the AAP2 ORF knocked out. The construct was subjected to error prone PCR to generate a library of mutants. AAV2 production was carried out in the absence of AAP2, applying stringent pressure, and the library was subjected to three rounds of directed evolution in HEK293 cells. The third-round AAV2 mutants were randomly selected and those that produced viable capsids were sequenced and found to commonly have a mutation at R585 and a mutation at position 370 from F to Y with other mutations variedly dispersed between mutants. A mutant, AAV2mt1, producing high vector yields, was selected for further analysis and its yields were compared to the wild-type (AAV2wt) and an AAV2 with AAP knockout ($AAV2^{AAPKO}$) in the presence or absence of AAP2. In the absence of AAP2, AAV2mt1 yielded vectors at decent levels comparable to the yield obtained from the standard AAV2 vector production. In the presence of AAP2, AAV2 mt1 yielded vectors 2 times and almost a log higher than AAV2wt and $AAV2^{AAPKO}$, respectively. Based on these observations, we propose a hypothesis that ablation of heparin binding accompanied by a Y-to-F mutation at position 370 is sufficient to render AAV2 independent of the AAP2 requirement for assembly. Further work are currently underway to identify more AAPi mutants, including those derived from AAV9, another AAPd serotype. We have also introduced molecular dynamics simulations in our study to understand how changes in capsid flexibility and conformation play roles in determining AAP requirements.

73. Specific Di-Nucleotide Pattern in Adeno-Associated Virus Genomes

Conradin Baumgartl[1], Man Xu[1], Lena Naber[1], Dirk Grimm[2]

[1]Universitätsklinikum Heidelberg, Heidelberg, Germany,[2]Heidelberg University Hospital, Heidelberg, Germany

Viral genomic DNA is known to interact with the inside of the capsid in Adeno-associated virus (AAV) and other parvoviruses, but the extent of the interaction and the shape the single-stranded (ss)DNA genome has to assume are largely unknown. Intrinsic DNA shape has a well-known function in facilitating nucleosome formation in eukaryotes or supercoiling propensity in prokaryotes. Periodic appearances of different di-nucleotides about every 10-11 bp are known to shape double-stranded (ds)DNA into a bend and thus facilitate protein interaction or DNA coiling. The exact repeating di-nucleotide differs between species. Using spectral density estimators and non-linear regression, we have discovered a specific di-nucleotide periodicity in wild-type dependoparvoviral genomes in which the YY di-nucleotide repeats every ~15 bp. As genome-wide di-nucleotide periodicities become more obvious with sequence length and as viral genomes are considerably smaller than eukaryotic ones, we analyzed individual

taxonomic genera to gather comprehensive sequence information. Next to dependoparvovirus, we also investigated periodicities within members of the entire *Shotokuvirae* virus kingdom and found di-nucleotide periodicities to be relatively prevalent. Especially genera from *polyomaviridae* and *papillomaviridae* show a distinct 10-11 bp YY di-nucleotide repeat pattern. Another noteworthy genus is the turncurtovirus from the *geminiviridae* that shows a repeat of 9 bp in YY di-nucleotides. Notably, the 15-bp YY periodicity appears to be unique for the genus dependoparvovirus. While di-nucleotide periodicities have never been described in parvoviruses and their function in linear ssDNA remains enigmatic, their presence implies a biological significance. In fact, in libraries of genetically engineered AAV cap genes, we found that the periodicity of the packaged DNA sequences increased upon production compared to the parental sequences, which implies that these repeats provide an advantage during production. To investigate the function of this genomic pattern further, we introduced an inert AAV wild-type fragment containing the di-nucleotide pattern into a reporter construct flanked by AAV packaging signals and used it to produce recombinant AAV. Indeed, the rAAV containing the wild-type fragment yielded higher titers compared to controls and other viral genomes in a small-scale production format. Our surprising discovery of a genome-wide and periodic di-nucleotide pattern in AAV DNA raises the intriguing hypothesis that, next to traditional *cis*-acting packaging signals, AAV has evolved as-of-yet-unknown mechanisms involving molecular interactions of its genome e.g. with the viral capsid or host proteins that facilitate its replication and assembly, and that could be harnessed in the future to improve AAV vector manufacturing and application.

Next Generation Gene & Cell Therapies for Heart, Lung, and Kidney Diseases

74. Rescue of Lethal SP-B Deficiency in a Murine Model Using Lentiviral Vector-Mediated Gene Therapy

Kamran M. Miah, Aimee Ruffle, Mariana A. Viegas, Emily Castells, Hamid Dolatshad, Stephanie G. Sumner-Jones, Rebecca Dean, Yue Du, Alexandra McStea, Rosie J. Munday, Altar M. Munis, Stephen C. Hyde, Deborah R. Gill

Radcliffe Department of Medicine, Nuffield Division of Clinical and Laboratory Sciences, University of Oxford, Oxford, United Kingdom

There remains a clear unmet need for a curative gene therapy for the rare, but neonatally lethal, surfactant protein B (SP-B) deficiency. The autosomal recessive disease is caused by a lack of functional SP-B expression, which leads to an impairment in pulmonary surfactant homeostasis soon after birth in full-term infants. Surfactant is secreted from alveolar type II (ATII) cells in the lung as a complex mixture of lipids and surfactant proteins, including SP-A, -B, -C, and -D. It functions to prevent alveolar collapse and to allow efficient gas exchange at the air liquid interface. SP-B deficiency manifests clinically as a complex spectrum of lung pathologies, including pulmonary alveolar proteinosis, pulmonary inflammation, interstitial fibrosis, and severe respiratory distress. The respiratory distress presents shortly after birth and necessitates long-term mechanical ventilation to keep affected babies alive. Without lung transplantation SP-B deficient babies succumb to disease within the first year of life. To address this unmet clinical need we evaluated gene therapy for SP-B deficiency using a proprietary lentiviral vector platform based on recombinant Simian Immunodeficiency Virus (rSIV) pseudotyped with Sendai Virus Fusion (F) and Haemagglutinin-Neuraminidase (HN) glycoproteins (rSIV.F/HN) for efficient lung targeting. Here we report the use of rSIV.F/HN vector to deliver the human SP-B (hSP-B) transgene under the control of our hCEF promoter, to the lungs to protect a conditional SP-B knockout (KO) mouse model from lethal respiratory distress. We found that the rSIV.F/HN hSP-B vector, when administrated intranasally (2E8 TU daily over 4 consecutive days), prevented disease progression and restored SP-B levels and surfactant homeostasis to therapeutic levels. Lung histology, pulmonary neutrophil recruitment, and surfactant protein C (SP-C) processing were all restored to near wildtype levels. Importantly, the administration of rSIV.F/HN provided a substantial survival benefit after induction of the conditional SP-B deficiency, with >10 months ongoing survival, compared to ~5 days median survival of untreated control animals (Mantel-Cox test, Log-rank, $P = 0.0001$). At the time of abstract submission, our longest surviving treated animals were still alive at >300 days post disease induction. Following a single dose of rSIV.F/HN, the risk of respiratory decline in treated animals was substantially reduced (Hazard Ratio 9.3; 95% confidence interval 2.9-30.2), without the need for repeated administration of the vector to sustain therapeutic levels of SP-B expression over the course of these studies. This high degree of protection from respiratory decline means that treated animals have a survival indistinguishable from control (non-disease induced) littermates (69.2% versus 74.2% survival, respectively, measured up to 1-year from birth, $P = 0.9812$). We also aim to evaluate the efficacy of the rSIV.F/HN platform for SP-B gene therapy by expressing the hSP-B transgene under the control of several new ATII-specific promoters. In summary, our observations support the use of the rSIV.F/HN platform expressing hSP-B as a novel and potentially curative treatment for new-borns diagnosed with SP-B deficiency.

75. Aerosolized Gene and Oligonucleotide Therapy Targeting microRNA-224 Ameliorates Pulmonary Hypertension by Orchestrating the BMP Pathway

Olympia Bikou[1,2], Aymen Halouani[3], Catherine Swarts[2], Petros Avramopoulos[4], Malik Bisserier[2], Erik Kohlbrenner[5], Hajjar Roger[6], Stefan Engelhardt[4], Lahouaria Hadri[2], Sebastien Bonnet[7], Yassine Sassi[3]

[1]LMU University Hospital, Munich, Germany,[2]Icahn School of Medicine at Mount Sinai, New York, NY,[3]Fralin Biomedical Research Institute at Virginia Tech Carilion, Virginia, VA,[4]Institute of Pharmacology and Toxicology, Technical University, Munich, Germany,[5]Spark Therapeutics, Philadelphia, PA,[6]Gene and Cell Therapy Institute, Massachusetts General Brigham, Boston, MA,[7]Pulmonary Hypertension Research Group, Université Laval, Québec, QC, Canada

Pulmonary arterial hypertension (PAH) is a severe vascular disease that leads to right heart failure and death. PAH therapies primarily

target pulmonary vasoconstriction, but only modestly affect pulmonary vascular remodeling. Currently there is no cure for PAH and new therapeutic options targeting the roots of the disease are desperately needed. MicroRNAs (miRs) have emerged in the last decades as key regulators in health and disease. We identified miR-224 as a lung enriched miR and *in silico* approaches for PAH predicted miR-224 among the miRs that target PAH related genes. In this study we aimed to investigate the role of miR-224 in pulmonary vascular remodeling, to define the mechanism of miR-224 action in PAH and to test the therapeutic effect of miR-224 gene- and oligonucleotide therapeutic approaches in PAH. We found pulmonary miR-224 levels to be increased in PH-diseased lungs cross-species: in mice, rat, pig and humans. Furthermore, miR-224 was increased in human pulmonary artery smooth muscle cells (hPASMCs) isolated from PAH patients compared to healthy controls. *In vitro* studies revealed that miR-224 is enriched in hPASMCs and its expression is necessary and sufficient to induce hPASMCs proliferation. We next tested the therapeutic effect of miR-224 inhibition using three different PAH animal models in mice and rats. In a first approach, we intra-tracheally aerosolized an adeno-associated virus1-tough decoy-miR-224 (AAV1-TuD-224) to PH diseased mice (Sugen/hypoxia model). AAV-Control-treated mice displayed all the hallmarks of PAH (i.e., increased Fulton index, elevated pulmonary arterial- and right ventricular pressure, cardiomyocyte hypertrophy and pulmonary arterial medial thickness), whereas AAV1-TuD-224-treated mice displayed a marked and significant decrease in these parameters. We next intra-tracheally delivered a chemically modified antisense oligonucleotide specific for miR-224 (LNA-224) to PH diseased mice and rats (Sugen/hypoxia model). Consistent with our genetic approach, LNA-224 significantly protected mice and rats from cardiac hypertrophy and pulmonary vascular remodeling at the tissue and cellular levels. We finally delivered LNA-224 to monocrotaline-treated rats and found (by magnetic resonance imaging, hemodynamics, morphometric and histological measurements) that miR-224 inhibition improves survival and suppresses PAH. Mechanistically, we found that miR-224 represses BMP signaling by directly targeting four pathway factors. Our data suggest that miR-224 plays a pivotal role in pulmonary vascular remodeling by targeting the BMP pathway. Aerosolized gene and oligonucleotide therapy targeting miR-224 may have therapeutic value for PAH.

76. AAV2-GEC: Advancing Gene Delivery for Precision Treatment of Antibody-Mediated Kidney Diseases

Shuya Liu, Guochao Wu, Jakob Körbelin, Shun Lu, Tobias B. Huber

University Medical Center Hamburg-Eppendorf, Hamburg, Germany

Background: The breakdown of glomerular filtration barrier (GFB) is relevant to the pathogenesis of most kidney diseases. Targeting the renal glomeruli by conventional drugs is challenging due to the lack of cell-targeting specificity, which significantly limits the development of novel kidney therapies. Adeno-associated virus (AAV) is a promising *in vivo* gene delivery platform showing the advantage in delivering therapeutic molecules to those difficult or non-druggable cells. However, natural AAV serotypes have insufficient targeting specificity and transduction efficiency in kidney cells. **Methods:** We developed an evolution-directed selection protocol specifically for kidneys and screened a random AAV2 display peptide library *in vivo*. Integrative experimental and bioinformatics workflows identified the most promising AAV vectors enriched in the renal glomeruli. The transduction specificity and efficiency of the selected AAV were evaluated *in vivo* under both physiological and pathological conditions, as well as in primary human glomerular endothelial cells (GEC). The potential for kidney-targeting therapies was evaluated in antibody-mediated kidney diseases. **Results**: A new AAV vector termed AAV2-GEC was identified, which specifically and efficiently transduced the GEC in the renal glomeruli after systemic administration. AAV2-GEC exhibited robust GEC tropism in C57BL/6J, Balb/c, BTBR mice and Sprague Dawley rats, as well as in disease models causing GFB breakdown. As a proof of concept, AAV2-GEC was used to deliver a bacterial cysteine proteinase named IdeS to GEC in the kidney. IdeS is an antibody-cleaving enzyme used to eliminate pathogenic IgG. AAV2-GEC mediated IdeS expression efficiently produced IdeS in the renal glomeruli, which provided sustained clearance of IgG bound to the glomerular basement membrane (GBM), thereby successfully prevented the onset or progression of anti-GBM glomerulonephritis. **Conclusion:** This study establishes an efficient selection protocol for renal glomeruli and identifies a novel GEC-targeting AAV vector with robust tropism maintained cross rodents in both physiological and pathological settings. The successful application of AAV2-GEC in treating antibody-mediated kidney diseases represents a significant step forward and opens up promising avenues for kidney medicine.

77. Adoptive Transfer of Allogeneic Murine Engineered T Regulatory Cells Ameliorates Disease in Models of Acute Kidney Injury in Mice

Maegan E. Hoover, Madison Milaszewski, Nicole R. Reed, Abigail Doherty, Dalia E. Gaddis, Marko Repic, Aravind Kancharla, Thomas Wickham, Tiffany F. Chen, Payam Zarin

GentiBio, Cambridge, MA

Foxp3$^+$ T regulatory cells (Tregs) are important mediators of tissue homeostasis and immune tolerance. The rarity and heterogeneity of Treg populations in circulation, as well as their instability in inflammatory environments, however, has limited the applications of Tregs in recent cellular therapy approaches. Our platform addresses these limitations, creating stable, tissue targeted, and selectively activated Tregs from more abundantly available T cell populations. Specifically, we utilize CRISPR-Cas9 mediated gene editing of PBMC isolated CD4$^+$ T cells to engineer Tregs for stable expression of Foxp3, and a rapamycin-activated signaling complex that provides tunable IL-2 signaling, divorcing Foxp3 expression from regulatory elements known to promote Treg instability under inflammatory conditions. A murine surrogate was developed to allow for *in vivo* evaluation of our cellular therapy in mouse models of inflammation and tissue injury. Polyclonal murine engineered Tregs (mEngTregs) were generated from bulk splenic CD4$^+$ T cells via CRISPR-Cas9 mediated knock-in of the MND promoter at the Foxp3 locus. To allow for allogeneic assessment, CB6F1 (C57BL/6 x BALB/c F1 cross) donor mice were used for cell generation. Acute Kidney Disease (AKI) is a life-threatening condition defined by a rapid decline in renal function. Common biomarkers of

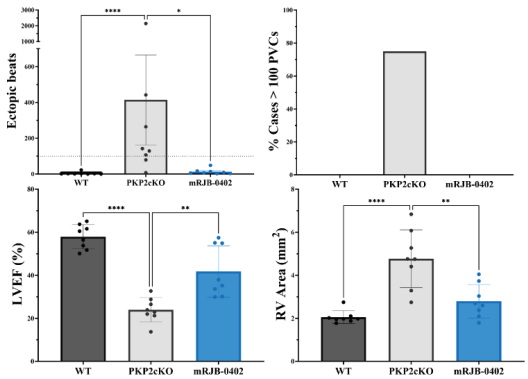
AKI include gross tubular degeneration, increased local inflammatory cytokine response, shedding of kidney injury molecule-1 (kim-1) into both serum and urine, a severe reduction in glomerular filtration rate, and increased levels of blood urea nitrogen (BUN) and serum creatinine (sCR). AKI can be triggered by any condition in which renal blood flow is restricted, cardiac output is reduced, or direct tissue insult occurs via toxins, infection, medication, or local inflammation. Despite significant advancements in the field, treatment options for patients experiencing renal failure are limited and prognosis remains poor. In the current work, we assess the ability of mEngTregs to ameliorate disease in models of acute kidney injury in mice. Kidney injury was induced in recipient animals by either surgical or chemical intervention and mEngTregs were adoptively transferred by intravenous injection. mEngTregs were found to effectively engraft at the site of the kidney and significantly improve disease outcome in multiple models of AKI. Specifically, animals treated with mEngTregs showed a significant reduction in sCR, BUN, and Kim-1 levels compared to AKI controls. Key inflammatory cytokines such as IL-1α, TNF-α, and IL-6 were lower in the kidney of mEngTreg treated animals and reductions in infiltrating neutrophils were visible by flow cytometry. Animals treated with mEngTregs also showed normalization of the renal macrophage compartment by activation markers such as MHCII and CD64. Importantly, histopathology analysis of the kidneys of mEngTreg treated AKI animals showed significantly less tubular degeneration, cast formation, and loss of brush border as compared to AKI controls. Overall, the ability of mEngTregs to ameliorate AKI as measured by key, translatable, biomarkers of renal function, supports the potential for developing a potent off-the-shelf allogeneic engineered Treg cellular therapy for human AKI.

78. Addressing a Critical Limitation of First-Generation Dystrophin-Mimetics: AAV-Nanotrophins Provide Superior Cardioprotection and Circumvent Junctional Fragmentation *In Vivo*

Kyle A. Hubble, Coral M. Kasden, Maria P. Corzo, Tanvi Singh, Alaine I. Castillo, Rufranshell Reyes, Benjamin W. Kozyak, Hansell H. Stedman

University of Pennsylvania, Philadelphia, PA

Introduction. Duchenne muscular dystrophy (DMD) results from genetic, usually deletional, deficiency of the 427 kD isoforms of dystrophin. Despite groundbreaking progress, two enduring challenges have complicated the development of effective, durable, and safe gene therapy. 1) mRNAs encoding the native 427 kD isoforms of dystrophin are ~ 14 kb in length, vastly exceeding the < 5 kb cloning capacity of the AAV platform. Miniaturized variants of dystrophin encoded by internally deleted cDNAs have been advanced to the clinic by multiple groups, but data released to date suggest limited durability consistent with the pathobiology of Becker muscular dystrophy (BMD), including the instability of mutant dystrophin. 2) Reported findings in DMD patients receiving systemically administered adeno-associated virus (AAV)-dystrophin vectors include T cell mediated myositis/myocarditis and limited durability of therapeutic efficacy associated with progressive loss of transgene expression. Here we present the development and rigorous testing of a novel class of therapeutics providing compelling evidence for emerging solutions to address the limitations of current therapies. **Methods.** We have used complementary approaches to develop solutions to both problems. We addressed T cell immunity by substituting epitopes from the self protein utrophin for those of the non-self protein dystrophin. We addressed the problem of protein functionality by avoiding a pitfall of previously used approaches to dystrophin "downsizing" for AAV: non-native protein folding geometry at the deletional splice junction(s) with the capacity to locally destabilize the rod domain as in severe BMD. Our reconstruction of the evolutionary history of dystrophin (presented elsewhere) enabled insight into structural and functional constraint on proteins in this supergene family, most notably the conservation of junctions between adjacent triple helical repeats throughout animal phylogenesis. This allowed us to predict and subsequently address the instability of the rod with load bearing in the first-generation gene therapies. We harnessed structural biology tools such as Hidden Markov Modeling to develop a simple set of testable hypotheses about biomechanical load bearing and structure-function relationships. We used novel, clinically relevant pathobiological assays to investigate both physiological functionality and protein structural integrity under mechanical stress. **Results.** We constructed and tested in *mdx* mice a series of AAV vectors encoding dystrophin- and utrophin-based miniaturized proteins, including three nanotrophins in which the splice junctions in the rod domain share the unique capacity to preserve the three-dimensional folding geometry of adjacent triple helical repeats. To rigorously test our hypothesis, we performed randomized, blinded *in vivo* tests to provide quantitative indices of functionality conferred by each of the vectors. Following catecholamine-induced cardiac stress, multiple quantitative assays for acute myocardial injury revealed statistically significant differences between groups of *mdx* mice injected with microdystrophin or our best performing nanotrophin-5U (cardiac troponin I: 8.09 vs 1.07 ng/mL, p=0.0016 and Evans blue dye: 2.04 vs 0.25%, p=0.0100, respectively). Concordant with these functional results, by western blot analysis only the nanotrophins were resistant to load-dependent fragmentation in the rod domain. **Conclusions.** Rigorously designed and executed *in vivo* tests support the hypothesized correlation between load-dependent fragmentation and superior physiological performance of nanotrophin-5U, a novel candidate therapeutic for DMD based on the non-immunogenic utrophin sequence.



79. AAV FGF21 Gene Therapy as a Variant Agnostic Treatment for Arrhythmogenic Cardiomyopathy

Kristy Brown[1], Christopher De Solis[1], Mingliang Zhang[2], Sarah Boyce[2], Manuela Gencarelli[2], Xianming Lin[2], Maritza C. McIntyre[3], Daniel Oliver[1], Deborah D. Ascheim[4], Marina Cerrone[2], Mario Delmar[2], Noah Davidsohn[1]

[1]Rejuvenate Bio, San Diego, CA,[2]NYU, New York, NY,[3]Advanced Therapies Partners, Raleigh, NC,[4]Rejuvenate Bio, Los Angeles, CA

Arrhythmogenic cardiomyopathy (ACM) is a severe, debilitating, life threatening, and rare inherited heart disease. While more than 10 different genes have been implicated in the approximately 60% of patients with variant associated ACM, the majority involve one or more variants in desmosomal genes, which are key components of the cardiac

intercalated disc. The desmosome is a protein complex responsible for cell-to-cell adhesion, stability, and transmission of contractility and force in a coordinated fashion between cardiomyocytes. These gene variants result in premature ventricular contractions (PVCs) and life-threatening ventricular arrhythmias, risk of sudden cardiac death, and progressive fibrofatty replacement of ventricular myocardium resulting in cardiac dysfunction that can lead to heart failure. No disease modifying treatments have proven effective in humans for ACM, highlighting the profound unmet medical need. RJB-0402 is a novel systemically administered investigational adeno-associated virus (AAV) gene therapy that drives liver-specific expression of FGF21 protein, which targets multiple key pathological drivers of ACM in cardiomyocytes. FGF21 has known salutary effects on cardiac dysfunction as well as ventricular arrhythmias, adipogenesis, inflammation, and fibrosis, all of which are ACM hallmarks. Preliminary exploration suggests that FGF21's antiarrhythmic effect may be, at least in part, attributed to its role in restoring cardiomyocyte calcium handling. RJB-0402 efficacy was studied in a conditional PKP2 knockout (PKP2cKO) mouse model of ACM. FGF21 gene therapy significantly reduced arrhythmias following isoproterenol challenge, as evidenced by decreased incidence and severity of ventricular arrhythmias manifest by PVC burden in RJB-0402 treated PKP2cKO mice (n=8) relative to untreated PKP2cKO controls (n=8), with PVC frequency in treated PKP2cKO mice approaching those of the wild type controls (n=8). Partial preservation of cardiac function in PKP2cKO mice assessed by echocardiography was also observed in the FGF21 treated cohort compared to vehicle treated controls. Furthermore, a reduction in cardiac fibrosis was observed by histological assessments in FGF21 treated cKO mice relative to untreated controls. These findings demonstrate early proof of principle that FGF21 gene therapy is a promising variant-agnostic candidate for treatment of ACM that warrants further investigation and potential clinical application. This novel approach is particularly promising for treatment of ACM due to variants not amenable to gene replacement therapy; genes too large for traditional gene replacement such as the *desmoplakin* gene, or due to multiple variants.

In vivo evaluation of RJB-0402 in vehicle treated WT and PKP2cKO mice and PKP2cKO mice treated with 1.5 × 10^{13} vg/kg of mRJB-0402 (n=8 per group). Top left panel: total ectopic beats observed in 30 minutes following a challenge of ISO; Top right panel: PVC burden of mice with greater than 100 ectopic beats in 30 minutes following a challenge ISO. Bottom left panel: left ventricular ejection fraction. Bottom right panel: right ventricle area. *=p <0.05, **=p <0.01, ***=p <0.001, ****=p <0.0001

80. Increasing Saline Tonicity Enhances Airway Gene Transfer

Ashley L. Cooney[1], Kenan Najdawi[1], Christian Brommel[1], Laura I. Marquez Loza[2], Paul B. McCray[1], Patrick L. Sinn[1]

[1]Pediatrics, University of Iowa, Iowa City, IA,[2]Molecular Medicine, University of Iowa, Iowa City, IA

A fundamental challenge for cystic fibrosis (CF) gene therapy is ensuring sufficient transduction of airway epithelial cells to achieve therapeutic correction. Vehicles such as lysophosphatidylcholine (LPC), EGTA, perfluorocarbon, or methylcellulose have been used to enhance gene transfer of Ad, AAV or lentiviral vectors. However, advancing these formulations to a clinical setting adds an additional layer to translating a gene therapy therapeutic. To this end, we screened FDA approved reagents for their ability to enhance viral vector transduction of primary human airway epithelial cells. Hypertonic saline conferred a clear benefit. Hypertonic saline (3-7%) is frequently administered as an agent to enhance mucus clearance in people with CF. Hypertonic saline transiently disrupts epithelial cell tight junctions, but its ability to improve gene transfer has not been investigated. Here we asked if increasing NaCl tonicity in the vector formulation enhances the transduction efficiency of 3 gene therapy vectors: adenovirus, AAV, and lentiviral vectors. We observed that vectors formulated *in vitro* with 3-5% NaCl exhibited markedly increased transduction for all 3 platforms (**Figure 1A-D**), leading to phenotypic correction of the anion channel defect in primary cultures of human CF epithelial cells. The NaCl-enhanced transduction was enhanced by ionic strength but not osmolarity or pH. Ad entry remained receptor dependent and required low pH endosomal escape. Gene transfer *in vivo* was also enhanced in mouse and pig airways by formulating vectors in NaCl (5% or 7%). Increasing saline tonicity has the potential to increase the viral delivery efficacy with a reduced amount of vector. These studies open the door to many possibilities for other genetic lung diseases, far beyond CF.

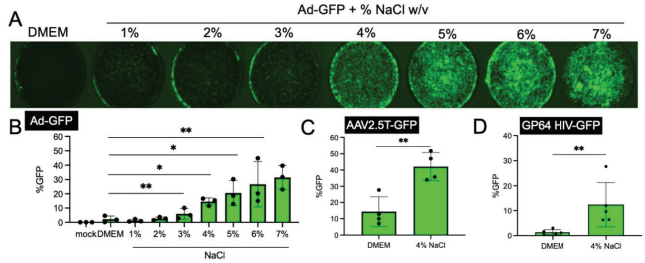


Figure 1: *Increasing saline tonicity enhances transduction efficiency of Ad, AAV, and GP64 HIV.* A) Ad CMVeGFP (MOI=250) was applied to the apical surface of well-differentiated human primary airway epithelia alone or with NaCl (1-7%) for 2 hours. B) GFP expression quantified by flow cytometry 5 day later from cultures in A). C) AAV2.5T CMVeGFP (MOI=100,000) was applied apically alone or in the presence of 4% NaCl for 2 hours. GFP expression was quantified by flow cytometry 2 weeks later. D) GP64 HIV CMVeGFP (MOI=50) was delivered with 4% NaCl for 2 hours. GFP expression was quantified by flow cytometry 2 weeks later. N=3-5 human donors, *p<0.05, **p<0.05.

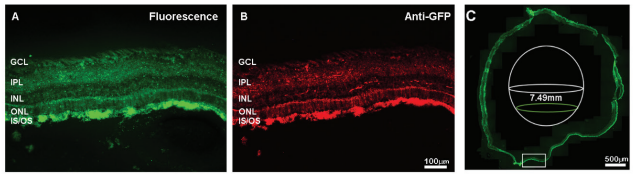
Ophthalmic and Auditory: Delivery Innovations

81. Optimization of Viral Gene Therapy for Inherited Retinal Diseases Using Fibrin-Mediated Delivery

Aubrey Berger[1,2], Travis Knudsen[2], Raymond Iezzi[2], Francesca Zenti[2], Brittni Scruggs[2], Alan D. Marmorstein[2]

[1]Mayo Graduate School of Biomedical Sciences, Mayo Clinic, Rochester, MN,[2]Mayo Clinic Department of Ophthalmology, Mayo Clinic, Rochester, MN



Purpose: Treatment of RPE65-mediated Leber Congenital Amaurosis involves an injection of AAV2 suspension between the RPE and retina. While this achieves RPE transduction, the procedure requires subretinal bleb formation. This increases the risk of macular holes, progressive chorioretinal atrophy, and choroidal neovascularization. These complications create a need for an alternative method of administration that avoids puncturing and detaching the retina. We hypothesize that a virus-embedded fibrin hydrogel will release virus to transduce RPE cells, and when placed on the epiretinal surface, the gel will result in locally transduced RPE. **Methods:** Fibrin hydrogels were cast with GFP-encoding AAV2/2 at 5.7e11 viral genomes (vg)/cm^3. These gels were characterized using electron microscopy, optical coherence tomography, immunofluorescence, and an ELISA-based diffusion assay. The gels were placed on the surface of confluent ARPE19 [BS2] cells to determine *in vitro* infectivity through detection of GFP expression. Domestic pigs underwent vitrectomy with implantation of virus-hydrogels placed directly the epiretinal surface (N=6) and in the subretinal space (N=3). AAV solution without hydrogel was injected using subretinal (N=3) and intravitreal injections (N=3) as controls at comparable viral titers. Eye exams were completed weekly, and after a month, eyes were enucleated. FITC imaging was used to observe expression of GFP in whole mount imaging and in histological sections. PCR was preformed to identify AAV genome presence in ocular tissues and the liver. **Results:** Immunofluorescence demonstrated that gels have a homogenous distribution of AAV. In the diffusion assay, gels achieved 50% viral diffusion after 48 hours with the remaining virus accounted for in the non-degraded gel. When placed in culture, observed cells displayed GFP signal after 2-4 days, confirming that released virus retained infectivity *in vitro*. In the pig, hydrogels degraded in the eye within five days. Observation of GFP signal in the RPE confirmed cell transduction from the epiretinal and subretinal implant groups with fewer complications (*e.g.*, chorioretinal atrophy, intraocular inflammation) than the groups without hydrogel. **Conclusion:** AAV2 transduces RPE and RPE-like cells *in vivo* and *in vitro*, respectively, when released from a fibrin hydrogel. Strong RPE transduction in pig eyes receiving epiretinal hydrogel highlights this novel surgical approach as an alternative delivery to subretinal bleb formation. These data hold promise for fibrin-mediated viral gene therapy delivery in patients with inherited retinal diseases. Future studies will test the effect of implant location, viral titer, and gel size on efficacy and safety with further characterization of viral diffusion, gene expression, and gel degradation across different conditions.

82. Suprachoroidal Injection of Poly(Beta-Amino Ester) Nanoparticles Enables Safe, Efficacious, and Durable Gene Delivery Across Multiple Species

Jordan J. Green[1,2], Jikui Shen[2], Raquel Lima e Silva[2], Mingliang Zhang[2], Kathryn Luly[1], Yeongseo Lim[1], Sean Hackett[2], Shirley Lowmaster[1], Sydney Shannon[1], David R. Wilson[1], Stephany Yi Tzeng[1], Peter A. Campochiaro[3]

[1]Biomedical Engineering, Johns Hopkins University, Baltimore, MD,[2]Ophthalmology, Johns Hopkins University, Baltimore, MD,[3]Ophthalmology, Johns Hopkins Hospital School of Medicine, Baltimore, MD

Introduction. Current challenges with ocular gene therapy to the retina include incomplete biodistribution and retinal penetration, limitations to DNA cargo carrying capacity, expensive manufacturing costs at scale, and potential safety risks. To overcome these challenges, we created hydrolytically degradable end-group modified poly(beta-amino ester) (PBAE) NPs that can safely and effectively deliver plasmids to photoreceptors in the retina. We combined this chemical innovation in gene delivery with innovation to the method of physical gene delivery through suprachoroidal injection. ***Methods.*** Cationic PBAEs were synthesized via Michael addition reactions and formed nanoparticles (NPs) with anionic plasmid DNA via self-assembly in acidic buffer. NPs were then lyophilized and stably stored until use. For NP administration, a needle was used to make a partial thickness circumferential opening in the sclera and a second needle was used to perform suprachoroidal injections into the scleral opening to reach the suprachoroidal space. Gene expression was quantified by immunohistochemistry and ELISAs. This NP delivery system was evaluated in multiple species including Brown Norway rats, Yucatan minipigs, and Göttingen minipigs. ***Results.*** PBAE NPs were found to encapsulate 100% of the plasmid DNA during particle self-assembly and hold on average 250 ± 20 kbp in each particle. The PBAE NPs are designed to be hydrolytically degradable in physiological conditions, and no signs of toxicity were observed following administration of the biodegradable PBAE NPs in any of the rats or minipigs evaluated, suggesting that this approach may be a broadly safe non-viral method for ocular gene transfer. In the human-sized eyes of minipigs, penetration of the NPs into the retina was found to be good, with photoreceptors non-virally transfected (**Fig 1A-B**). Biodistribution of the NPs and their corresponding gene transfer was also found to be broad, throughout the circumference of the minipigs eyes, from the anterior to the posterior (**Fig 1C**). Although the NPs break down quickly in water, the plasmids were observed to persist and exhibit durable gene expression for all time points evaluated, including lasting at least 8 months following a single suprachoroidal injection in rats. ***Conclusion.*** The PBAE NPs are easily scalable and avoid the challenges of viral manufacturing. They were found to have a large cargo capacity for nucleic acid delivery and to safely deliver those cargos to the retina without causing toxicity or retinal degeneration. The suprachoroidal approach was found to enable broad biodistribution throughout the circumference of human-sized eyes and could readily be administered in an outpatient setting. Together, this system led to durable non-viral ocular gene transfer and is promising for the treatment of inherited retinal degenerations as well as other causes of blindness.

Suprachoroidal injection of PBAE/DNA nanoparticles induces strong transgene expression in the retina of Yucatan minipigs. Robust expression throughout the retina is observed by **(A)** Direct GFP fluorescence as well as **(B)** Anti-GFP staining. Expression is observed throughout the retina including in **(C)** Posterior sections that demonstrate GFP fluorescence around the entire circumference of the eye.

83. Efficient Spiral Ganglion Neuron Transduction with a Novel Capsid-Engineered AAV Vector for Improved Cochlear Implant Outcomes in Hearing Loss

Jennifer Marx[1], Peixin Huang[2], Sereina Sutter[3], Moritz Ertelt[4], Odett Kaiser[5], Jennifer Harre[5], Juliane Schott[1], Josephine Macdonald[1], Axel Rossi[1], Athanasia Warnecke[5], Clara T. Schoeder[4], Axel Schambach[1], Hinrich Staecker[2], Hildegard Büning[1]

[1]Institute of Experimental Hematology, Hannover Medical School, Hannover, Germany,[2]Department of Otolaryngology Head and Neck Surgery, University of Kansas School of Medicine, Kansas City, KS,[3]Institute of Virology, University of Zurich, Zurich, Switzerland,[4]Institute for Drug Discovery, University Leipzig Medical Faculty, Leipzig, Germany,[5]Department of Otolaryngology, Hannover Medical School, Hannover, Germany

Hearing loss (HL) affects over 460 million people worldwide, significantly affecting quality of life. Cochlear implants (CI) are used for severe to profound HL, but outcomes differ based on spiral ganglion neuron (SGN) survival. Recognizing the potential of neurotrophins to enhance SGN survival and improve CI outcomes, we developed a novel AAV vector by capsid-engineering displaying a heptamer peptide previously derived from a phage library screen. Our novel AAV vector, Var9, efficiently transduces SGN in adult mice already at low doses. Structure-focused modeling of Var9 revealed a distinct alteration in cell attachment receptor binding due to peptide insertion compared to its parental serotype AAV2. Predictions indicating reduced attachment receptor affinity were validated through affinity chromatography and competition assays. Interestingly, Var9 demonstrated faster transgene expression in HEI-OC1 cells, a murine auditory cell line, despite significantly lower entry efficiency, indicating enhanced intracellular processing. Subsequent IF-FISH analysis at single-cell level visualized Var9 uncoating to approximately threefold higher levels than AAV2 after 24h. In contrast to AAV2, Var9 uncoating appeared independent of cell cycle progression, potentially providing an advantage in post-mitotic otic cells. Furthermore, Var9 outperformed AAV2 with faster uncoating in vitro (HEI-OC1) in an indirect assay, correlating with corresponding transduction efficiencies. This advantage extended to in vivo settings, with Var9 demonstrating 6-, 4-, and 3-fold greater uncoating compared to AAV2 in isolated mouse cochleae at 1, 3, and 7 days post-injection, respectively. Finally, in a neurotrophic factor gene therapy approach, Var9 prevented SGN degeneration comparable to control levels by overexpressing BDNF in SGN of deafened mice. In conclusion, our novel AAV vector demonstrated superior properties crucial for efficient SGN transduction and will be further refined for clinical applications, aiming to enhance neural survival and improve outcomes for cochlear gene therapy in CI recipients.

84. Optimizing Ocular Gene Therapy: Harnessing the Potential of the Proteolipid Vehicle Nucleic Acid Delivery Platform

Douglas Brown[1], Maryam Hejazi[2], Ping Wee[1], Prakash Bhandari[3], Jitendra Kumar[4], Liliya Grin[1], Arun Raturi[1], John Lewis[3]

[1]Entos Pharmaceuticals, Edmonton, AB, Canada,[2]Entos, Edmonton, AB, Canada,[3]Entos Pharmaceuticals, San Diego, CA,[4]Entos Pharmaceuticals Inc, San Diego, CA

Age-related macular degeneration, retinitis pigmentosa, diabetic retinopathy, Stargardt disease, and glaucoma are prevalent eye conditions that lead to vison loss. Gene therapy has the potential to combat and prevent vision impairment; however, conventional viral and non-viral gene delivery platforms have limited their success due to challenges with delivery of nucleic acids, immunogenicity, and tolerability. We developed the Fusogenix™ proteolipid vehicle (PLV™) nucleic acid delivery platform to combat these limitations. The PLV platform leverages a proprietary fusion-associated small transmembrane (FAST) protein and a well-tolerated lipid formulation to achieve optimal delivery of nucleic acids to tissues throughout the body including the retina. Here, we investigated the ocular tropism of the FAST-PLV platform encapsulating short interfering RNA (siRNA), messenger RNA (mRNA), and plasmid DNA (pDNA). The FAST-PLV platform enables robust delivery and expression of mRNA and pDNA cargo in primary mouse and human retinal cell cultures without cytotoxicity. In mice, intravitreal injection of FAST-PLVs encapsulating siRNA targeting a functional protein resulted in potent gene knockdown throughout the eye. Intravitreal injection of FAST-PLVs encapsulating reporter pDNA and mRNA encoding firefly luciferase (FLuc) or eGFP resulted in localized and prominent FLuc expression in mice. Immunofluorescence analysis confirmed stable expression of pDNA and mRNA in retinal ganglion and photoreceptor cells. The efficacy demonstrated in rodents extended to rabbits and non-human primates, with pDNA-GFP and mRNA-GFP yielding substantial GFP expression in the retina. Optical coherence tomography confirmed minimal toxicity following these injections in both models. These collective findings underscore the promising potential of the FAST-PLV platform for ocular gene therapy.

85. Cochlear Gene Therapy Delivery Innovations, AAV Capsid Variants and Cell Type-Specific Regulatory Elements to Facilitate CSF-Mediated Administration

Paul T. Ranum[1], Ellie Carrell[2], Jenna Devare[3], Luis Tecedor[2], Yonghong Chen[2], Ryan Giovenco[2], Alejandro Mas Monteys[4], Stephen R. Chorney[5], Robert C. O'Reilly[5], Beverly L. Davidson[2]

[1]Latus Bio, Philadelphia, PA,[2]Children's Hospital of Philadelphia, Philadelphia, PA,[3]The Children's Hospital of Philadelphia, Philadelphia, PA,[4]University of Pennsylvania, Philadelphia, PA,[5]Division of Pediatric Otolaryngology, Children's Hospital of Philadelphia, Philadelphia, PA

The recent clinical success of AK-OTOF has demonstrated the feasibility and value of gene therapies for hearing and deafness. Current approaches to cochlear gene therapy use AAV intracochlear infusion via an inner ear surgical approach. This method necessitates general anesthesia, perforation(s) of the sealed inner ear space, and patients of sufficient age to facilitate the approach. However, the complexity of the auditory system and extreme diversity of genetic causes of hearing loss remain barriers to broader targeting of most hearing loss genes. Delivery continues to pose challenges at every level: the therapeutic window of opportunity, the vectors to target various hearing-relevant cochlear cell types, and payload design that limit expression to therapeutically relevant cells. Toward these goals we used our recently developed cerebrospinal fluid (CSF)-mediated route of gene therapy administration to the inner ear and round window membrane + canalostomy (RWM) infusions of WT and modified AAVs into NHPs to identify new hearing-relevant AAV capsids that target primate cochlear cells and developed a pipeline for splicing-based regulatory element discovery with validation in murine auditory inner hair cells (IHCs). CSF-mediated delivery of our top modified AAV variants yielded capsids capable of nearly complete IHC transduction across all cochlear turns, robust transduction of spiral ganglion neurons, and transduction of non-sensory supporting cells in the organ of Corti of the NHP cochlea. Additionally, using available single-cell RNA-Seq data, we tested a hair-cell-specific splice event with 100% sequence conservation between mouse and human for its ability to confer hair cell-specific payload expression. After ICV administration to mouse CSF there was auditory hair cell specific gene expression, and no expression throughout the non-cochlear central nervous system. In summary, we show an alternative method for gene delivery to the inner ear via the CSF, identified new capsid variants for cochlear gene delivery, and developed regulatory elements to limit gene expression to a cochlear cell-type of interest, all steps towards further development of gene therapies for hearing loss.

86. Identification of Novel Ligand-Conjugated AAV Vectors with Enhanced Properties for Suprachoroidal Gene Delivery

Gaelle M. Lefevre[1], Adrien Savy[1], Sigmund K. S. Tejada[2], Sungyeon Cho[2], Bezawit Ejigu[2], Delphine Compere[1], Andrew C. Mercer[2], April R. Giles[2]

[1]Coave Therapeutics, Paris, France,[2]REGENXBIO Inc., Rockville, MD

Adeno-associated virus (AAV) mediated gene therapy shows potential for treating prevalent retinal diseases like age-related macular degeneration and diabetic retinopathy, but it has not been widely applied yet. One of the main challenges is delivering the therapy effectively to the targeted areas in the eye, in particular the retinal pigment epithelium (RPE)/choroid and retina. The traditional method, subretinal administration, is considered effective but is an invasive surgery that must be performed in an operating room, which presents challenges for widespread implementation. As an alternative, administration to the suprachoroidal space (SCS) offers a less invasive way to deliver AAV gene therapies to the back of the eye, and developing capsids specifically tailored to delivery by this route of administration would further support its implementation, especially for delivering intracellular transgenes to the RPE and retina. To achieve this, we used the AAV-ligand conjugate platform (ALIGATER™) to create new AAV vectors optimized for SCS delivery. This platform relies on the chemical conjugation of functionalizing biomolecules to the surface of AAV capsids. As it does not require prior modification of the AAV capsid, this platform is compatible with virtually any natural or engineered AAV serotype. The conjugation process is performed in a single step, without the need for a catalyst, and is carried out post-AAV production, enabling platform manufacturing processes and a rapid translation of new candidates to the clinic. We built a barcoded library of conjugated AAV (coAAV) vectors and performed a parallel evaluation of these vectors with a benchmark capsid in non-human primates following SCS administration. Three weeks post injection, we evaluated the vector genome distribution and transgene mRNA expression in ocular and peripheral tissues. Several coAAV vectors showed significantly enhanced relative expression in the RPE/choroid and retina compared to the benchmark capsid, with lower transduction of off-target systemic tissues such as liver and kidney. These coAAVs represent the first chemically-improved capsids for SCS delivery, opening a potential path forward for the development of more efficient, more targeted, and well -tolerated gene therapies for the treatment of common retinal disorders.

87. Development of an *In Vivo* Non-Viral Ocular Editing Platform and Application to Potential Treatments for Glaucoma

Dominique L. Ouellet, Michael J. Lukason, Jack Philp, Marja Pimentel, Jimmy Breen, Izele Abure, Marian Themeles, Sushant Karnik, Jilong Li, Anass Agrud, Jordan Paine, Yen-Yu Liu, Anandan Paldurai, Daniel Pascual, Nicole Flanagan, Lauren Tso, Yin Tang, Kayla Urbaez, Nicolette Lee, Nassim Ajami, Katie Schum, Shashwat Nagar, Bethany Winans, Parin Sripakdeevong, Seshidhar Reddy Police, Alex Harding, Laura Serwer, Jonathan Terret, Lorenzo Aulisa, Mary-Lee Dequeant

CRISPR Therapeutics, Boston, MA

Open-angle glaucoma, one of the most common causes of blindness worldwide, is a condition for which the main risk factor is high intraocular pressure (IOP), which causes damage to the optic nerve and results in progressive vision loss. High IOP is a consequence of reduced aqueous humor outflow caused by blocked or altered trabecular meshwork (TM) tissue, a sieve-like structure located inside the eye

at the cornea-sclera junction. Lines of treatment involve mainly eye drops and trabeculectomy surgery aimed at reducing aqueous humor production or favoring the passage of aqueous humor. Unfortunately, patient non-adherence and surgical limitations often lead to disease progression. We developed a lipid nanoparticle (LNP) approach to deliver RNA molecules to the trabecular meshwork cells for potential treatments for glaucoma. LNP formulations were screened using primary TM cells *in vitro* and *in vivo* in the mouse eye. Selected LNP candidates carrying enhanced green fluorescent protein (eGFP) were confirmed in a human or non-human primate (NHP) *ex vivo* anterior segment organ culture (ASOC) model, as well as in NHPs following intracameral injection. Moreover, LNP candidates carrying Cas9/gRNA cargo targeting the mouse actin alpha 2 (ACTA2) gene successfully reduced the expression of the alpha smooth muscle actin (α-SMA), a resident protein of the trabecular meshwork, by more than 75% at 4 weeks post-injection. As a proof-of-concept of LNP delivery to the TM cells for glaucoma, we designed a gRNA targeting the myocilin (MYOC) gene. Mutations in the MYOC gene, and its altered expression in the trabecular meshwork cells, have been linked to severe glaucomatous conditions in which the manifestations often begin at a juvenile age. Myocilin mutations have been shown to be gain-of-function mutations, which makes the knockdown of this protein a potential target for a gene editing approach. The delivery of LNP candidates carrying Cas9 and a gRNA targeting MYOC in glaucomatous TM cells and in human and NHP ASOC models showed editing at the MYOC locus and reduction of the myocilin protein, including up to 98% editing and 85% protein knockdown in human primary TM cells. This novel approach aims to facilitate glaucoma treatment using transient expression of editing machinery in the trabecular meshwork cells to target genes, like MYOC, involved in glaucoma.

CAR T and Other Genetically Modified Immune Cells

88. Development of a FAP-CAR T Cell Protocol to Reduce Skeletal Muscle Fibrosis in a Murine Model of Duchenne Muscular Dystrophy

Maxime Ferrand[1], Celine Rocca[1], Sonia Albini[1], Valentina Buffa[1], Elodie Bôle-Richard[2], Francine Garnache-Ottou[2], Isabelle Richard[1], Anne Galy[1,3]

[1]UMR_S951 Integrare Research Unit, Genethon, Evry-Courcouronnes, France,[2]UMR1098 RIGHT, Université Franche-Comté, EFS Besançon, Besançon, France,[3]Art-tg, Inserm, Corbeil-Essonnes, France

Fibrosis is a feature of Duchenne muscular dystrophy (DMD) which progressively weakens skeletal and cardiac muscles. Immunotherapy with fibroblast activating protein (FAP)-specific CAR T cells has already been used to reduce cardiac fibrosis in mice during a drug-induced condition but this approach has not been tested in muscular dystrophy. The DBA2mdx mouse is a model of severe DMD in which rapid and strong fibrosis is observed, characterized by dense collagen deposits in skeletal muscles, with over-expression of the FAP and Col3 genes in the TA, GA, EDL muscles at 2, 3, and 4 months of age compared to their aged-matched DBA2 littermates. We developed a third-generation mFAP-CAR lentiviral vector (LV) to generate mFAP-specific CAR T cells from DBA2 spleen T cells. The transduction conditions were initially established with a LV co-expressing the mFAP-CAR and a CD19 tag, but subsequently, the CD19 tag was removed to increase titer and transduction efficacy, as measured by provirus digital PCR. The specificity and potency of the mFAP CAR T cells was demonstrated on FAP-expressing 3T3 cells using cytotoxicity and degranulation assays. To evaluate their *in vivo* efficacy, mFAP-CAR T cells were adoptively transferred into DBA2mdx mice. Dose finding tests showed that at least two injections of 1xE+06 FAP-CAR-LV-transduced cells were necessary to significantly reduce the histological and molecular biomarkers of fibrosis in muscles, as measured 2 weeks post-cell injection by reduced Col3 and FAP mRNA expression. Altogether, these results establish a basal protocol to reduce muscle fibrosis in DBA2mdx mice. Further studies are warranted to understand the effects of FAP CAR T cells in this model. *MF and CR contributed equally. IR and AG are co-senior authors of this study.*

89. Genetic Depletion of TIGIT Augments CAR-NK Cell Effector Function in the Solid Tumor Microenvironment

Ishwar Navin[1], Matthew Dysthe[2], Corrine Baumgartner[3], Robin Parihar[4]

[1]Immunology, Baylor College of Medicine, Houston, TX,[2]Translational Biology and Molecular Medicine, Baylor College of Medicine, Houston, TX,[3]Pediatrics, Baylor College of Medicine, Houston, TX,[4]Baylor College of Medicine, Houston, TX

Chimeric antigen receptor-expressing natural killer cells (CAR-NKs) have shown success against hematological malignancies. However, their efficacy has been limited in solid tumors which generate a tumor microenvironment (TME) that includes inhibitory myeloid derived suppressor cells (MDSCs) and M2 macrophages (M2s). We demonstrated that several methods of ex vivo manufacture of CAR-NKs significantly upregulated T cell immunoreceptor with Ig and ITIM domains (TIGIT), an inhibitory NK receptor. Neuroblastoma and sarcoma biopsy tissues showed TIGIT ligand expression on tumor cells and intratumoral MDSCs and M2s. *Our objective* was to determine the impact of TIGIT on CAR-NK function in the TME. Current TIGIT-targeting approaches using antibodies are handicapped by transient binding and poor bioavailability in the TME. *We hypothesized* that genetic deletion of TIGIT on CAR-NKs leads to a more robust and durable anti-tumor response within the TME. TIGIT knockout (KO) CAR-NKs expressing a 2nd generation GD2 CAR containing the 4-1BB endodomain were generated by sequential CRISPR/cas9 and retroviral transduction of expanded primary human NK cells. Degranulation (CD107a) and IFN-gamma by TIGIT^{KO}GD2.CAR-NK were assessed in short-term TME co-cultures containing LAN-1 neuroblastoma and human MDSCs. A novel long-term TME co-culture wherein CHLA255 neuroblastoma and human monocytes pre-established a suppressive TME for 72 hours prior to addition of TIGIT^{KO}GD2.CAR-NK was used to assess tumor growth and changes in caspase3/7, mitochondrial mass, and activated MTOR expression. In vivo efficacy and persistence were assessed in NSG mice containing a novel neuroblastoma TME xenograft.CRISPR/Cas9 and retroviral transduction resulted in TIGIT^{KO}CAR-NKs with >90% TIGIT deletion and >60% GD2.CAR

expression. TIGIT deletion did not alter surface expression of DNAM-1, NKG2D, NKG2A, TIM-3, PD-1 or LAG-3 on TIGIT^{KO}CAR-NKs. TIGIT^{KO} and GD2.CAR expression was stable in TIGIT^{KO}GD2.CAR-NKs over 7 days of secondary NK expansion. TIGIT^{KO} enhanced GD2.CAR-NK IFN-g secretion but not degranulation in short-term TME co-cultures. In long-term tumor co-cultures, TIGIT^{KO}GD2.CAR-NKs demonstrated greater anti-tumor activity vs TIGIT-expressing GD2.CAR-NKs (<10% viable tumor vs 35% viable tumor, p<0.01; n=4 donors). In TME co-cultures, TIGIT^{KO}GD2.CAR-NKs rapidly expanded and controlled tumor compared to control CAR-NKs (50% viable tumor vs 88% viable tumor, p<0.05; n=4 donors). Compared to control CAR-NKs, TIGIT^{KO}GD2.CAR-NKs continued to limit tumor growth in serial TME co-cultures but without changes in GD2.CAR expression, degranulation, nor differences in CAR-NK surface receptor profile. Furthermore, in long-term TME co-cultures, TIGIT^{KO}GD2.CAR-NKs compared to GD2.CAR-NKs expressed similar levels of caspase3/7, activated MTOR, and mitochondrial mass. Deletion of the activating receptor DNAM-1, the competitive binder of TIGIT ligands, did not abrogate the anti-tumor activity of TIGIT^{KO}GD2.CAR-NKs. Gene expression profiling was performed to define differentially expressed genes in TIGIT-expressing vs. TIGIT^{KO} GD2.CAR-NK prior to and after exposure to the TME. In vivo studies demonstrated improved NK cell persistence, stable GD2.CAR expression, and enhanced anti-tumor efficacy in TME xenograft-bearing mice treated with TIGIT^{KO}GD2.CAR-NKs compared to mice treated with TIGIT-expressing GD2.CAR-NKs.We defined a role for TIGIT in suppression of CAR-NK function and suggest TIGIT deletion as a novel CAR-NK therapeutic platform to evade immune suppression in the TME. This underscores the potential of gene-edited CAR-NKs to improve clinical outcomes in patients with solid tumors.

90. HLA-A2 CAR/IL-2-CISC Engineered Treg Exhibit Robust *In Vitro* and *In Vivo* Efficacy

Subhash Kumar Tripathi[1], Noelle P. Dahl[1], Annaiz Grimm[1], Yuchi C. Honaker[1], Peter J. Cook[1], David J. Rawlings[1,2]

[1]Center for Immunity and Immunotherapy, Seattle Children's Research Institute, Seattle, WA,[2]University of Washington, Seattle, WA

Chimeric antigen receptor expressing T regulatory cells (CAR-Treg) represent a promising potential cell therapy for autoimmunity, allograft rejection and graft-versus-host-disease (GvHD). Alloantigen-specific Treg are more potent than polyclonal Treg in suppressing GvHD in mouse models. Notably, HLA-A*02 antibody-based CAR (A2-CAR) expressing human natural (n)Treg exhibit significant clinical efficacy in animal models and are currently in use in Phase I/II clinical trials for renal allograft protection. However, nTreg based cell products face challenges associated with both production at therapeutic scale and *in vivo* engraftment and stability. We previously addressed these challenges, using homology-directed-repair (HDR)-based gene editing to generate antigen-specific and chemically induced IL-2 signaling complex (CISC) expressing CD4$^+$ EngTreg from CD4$^+$ T cells. This engineering approach results in high-level, stable FOXP3 expression, robust Treg phenotype and function and therapeutic benefit in Type-1-diabetes models[1-5]. Here, expanding on this engineering platform, we generated and tested the functional activities of CD4$^+$ A2-CAR EngTreg. First, we utilized lentiviral (LV)-mediated A2-CAR delivery in association with HDR editing to introduce the IL2-CISC (designed to mimic IL-2 signaling in response to an exogenous dimerizer) and the MND promoter into the *FOXP3* locus in human CD4$^+$ T cells. CD4$^+$ A2-CAR EngTreg expanded and enriched to high purity. Cell products exhibited stable expression of FOXP3 and Treg markers with minimal proinflammatory cytokine production and robust suppressive activity. *In vitro*, A2-CAR EngTreg responded in HLA-A*02 antigen-specific manner and exhibited minimal cytotoxicity. In comparison to polyclonal CD4$^+$ EngTreg, A2-CAR EngTreg exhibited superior control of GvHD mediated by HLA-mismatched allogeneic effector T cells in NSG recipient mice. Next, we assessed the efficacy of A2-CAR CISC EngTreg using sub-therapeutic doses in association with chemical dimerizer therapy to engage IL2-CISC signaling *in vivo*. Recipient mice were treated with the rapamycin analog, AP21967, that activates IL-2 CISC system without impacting the mTOR signaling in a xenogeneic allo-GvHD model. Strikingly, dimerizer therapy led to elimination of xenogeneic allo-GvHD at sub-therapeutic EngTreg doses correlating with improved engraftment of A2-CAR CISC EngTreg. Finally, to eliminate the requirement of LV-based CAR delivery, we demonstrate strategies that permit generation of A2-CAR CISC EngTreg using dual-HDR-based gene editing. Together, these findings illustrate the robust capabilities of CAR-CISC EngTreg products and suggest that this platform may provide broad therapeutic potential in transplantation, autoimmune and/or autoinflammatory diseases. ***References:*** **1.** Honaker, Y., et al. 91. Anti-B7-H3 Chimeric Antigen Receptor NK Cells Suppress the Growth of Atypical Teratoid / Rhabdoid Tumor Orthotopic Xenografts

Jun Choe, Sachiv Chakravarti, Natalie Holl, Ruyan Rahnama, Megan Zinsky, Danielle Grace Jones, Stamatia Vorri, Arjun Modi, Eric H. Raabe, Challice L. Bonifant

Johns Hopkins University School of Medicine, Baltimore, MD

Background: Atypical teratoid/rhabdoid tumors (AT/RTs) are the most common malignant CNS tumor in infants. AT/RT patients have a 5-year overall survival rate of ~35% and high rates of relapse, emphasizing a dire need for new safe and effective therapies. These therapy-resistant tumors frequently overexpress the immune checkpoint cell surface molecule B7-H3 (CD276). CAR-T cell studies have an established safety profile in pediatric patients. We developed B7-H3 targeted chimeric antigen receptor (CAR) natural killer (NK) cells as a tumor-specific cell therapy for aggressive pediatric brain tumors. CAR-NK cells have several advantages over CAR-T cells. NK cells can be obtained from healthy donors and produced as an "off-the-shelf" product. NK cells also have a lower risk of inflammatory toxicity and graft-versus-host disease compared to T-cells when transferred across the HLA barrier from healthy donors to patients. **Methods:** We have designed a library of variable affinity B7-H3-targeted CARs, produced replication incompetent γ-retroviral vector, and used this for generation of B7-H3 CAR-NK cells. We verified B7-H3 expression in a panel of AT/RT

cell lines, and further engineered firefly luciferase expressing AT/RT (CHLA06.ffLuc, BT12.ffLuc, BT37.ffLuc) as well as a CHLA06-derived B7-H3 knockout. We developed an orthotopic CHLA06.ffLuc xenograft model. We tested CAR-NK cell functionality using *in vitro* co-culture and cytotoxicity assays. *In vivo* study was performed in our xenograft with intratumoral delivery of CAR-NK cells. Results: B7-H3 targeted CAR-NK cells demonstrate target-specific cytotoxicity when compared to untransduced NK cells (36.8±12.5% vs. 72.4±24.2% at effector:target ratio of 1:1, n=3). CRISPR/Cas9 mediated knockout of B7-H3 in target cells abolished the difference in CAR vs. no-CAR NK-mediated target killing. When delivered intracranially to CHLA-06 orthotopic xenograft bearing mice, B7-H3 CAR NK cells eliminate tumor cells and prolong survival, whereas unmodified NK cells did not (Figure 1. log-ranked median survival = 20 vs. 84 days, p<0.0001). We are currently testing intracranial delivery of our B7-H3 CAR NK against other AT/RT orthotopic xenografts. **Conclusions:** Targeting pediatric brain tumors with an anti-B7-H3 CAR-NK cell therapy may provide a safe and effective treatment for patients who have extremely limited therapeutic options. Direct intracranial injections of cell therapies into pediatric patients is currently being explored in clinical trials. As B7-H3 is a tumor associated antigen found to be overexpressed in a large variety of tumor types, this strategy may also be useful for treatment of other B7-H3 expressing cancers.

92. An Immune Synapse-Stabilizing Receptor Enhances Sensitivity of CAR- and TCR-Mediated Tumor Targeting

Chiou-Tsun Tsai[1], Jorge Andres Ibanez[2], Norihiro Watanabe[1], Giedre Krenciute[2], Maksim Mamonkin[1]

[1]Center for Cell and Gene Therapy, Baylor College of Medicine, Houston, TX,[2]Bone Marrow Transplantation and Cellular Therapy, St. Jude Children's Research Hospital, Memphis, TN

Downregulation of the target antigen is a common mechanism of tumor escape in cellular immunotherapy. Multi-antigen targeting with cytotoxic receptors can reduce the risk of antigen escape but, in many indications, also increases off-tumor toxicity. We have developed an alternative strategy to improve targeting of tumor cells with suboptimal antigen expression without broadening the unwanted off-tumor toxicity. We designed an additional non-cytotoxic receptor that augments immune synapse and boosts signaling from the main antigen receptor (e.g., a CAR or a TCR), thus selectively improving cytolysis of antigen-low tumors. This synapse-stabilizing receptor (SSR) targets a secondary tumor antigen without inducing direct cytotoxicity, thus limiting the cytolysis only to cells expressing the CAR or TCR target. We evaluated this concept in preclinical models of acute myeloid leukemia (AML) where CAR T-cells targeting CLL1 antigen induce robust killing of CLL1-high targets but poor cytolysis of CLL1-intermediate/low leukemia. We designed an SSR targeting CD38, an antigen commonly expressed in acute leukemia but also in critical hematopoietic cells and primitive progenitors thus making direct cytotoxic targeting risky. To augment SSR function and further boost CAR signaling, we attached signaling endodomains derived from IgSF and TNFRSF genes as well as native and modified LAT. We found a modified LAT truncated at the amino acid 177 (modLAT177) produced highest amplification of CAR signaling and strongest cytotoxicity against antigen-low AML lines Molm13 and THP-1 compared to other SSR configurations. SSR co-expression did not affect cytolysis of antigen-high leukemia but augmented production of IFN-γ and IL-2 and enhanced lytic degranulation (measured by GzB and CD107a) and intracellular Ca++ flux in CLL1 CAR T cells upon coculture with antigen-low leukemia. Mechanistically, SSR engagement increased accumulation of F-actin and SLP76/WASP at the T-cell immune synapse and enhanced polarization of the microtubule organizing center (MTOC) and lytic granules demonstrating improved cytolytic immune synapse formation. In a mouse xenograft model of AML (MOLM13), SSR-armed CLL1 CAR T cells produced higher expansion and superior control of circulating leukemia significantly extending mouse survival compared to unarmed CAR T cells (p=0.0023). Of note, SSR-armed CLL1 CAR T cells did not induce cytolysis of normal CLL1-negative CD38+ NK cells or normal CD38+ hematopoietic progenitors in colony-forming assays with CD34+ cord blood cells thus illustrating desired tumor selectivity. To evaluate the benefit of SSR beyond CARs, we paired it with a TCR targeting a pan-cancer antigen survivin (SurTCR). SSR arming significantly enhanced targeting of HLA-low/intermediate AML cell line THP1 by SurTCR T cells while unarmed SurTCR T cells produced minimal cytotoxicity. Notably, SSR expression enhanced lytic degranulation of CD8+ SurTCR T cells and augmented production of IFNγ and TNFα in both CD8+ and CD4+ T cells, whereas unarmed SurTCR only activated CD8+ T cells, suggesting SSR can functionally replace a CD4 co-receptor. Finally, we showed

SSR expression markedly increased cytotoxicity of T cells redirected by a leukemia-targeting bispecific T-cell engager (BiTE) highlighting strong augmentation TCR-mediated tumor cytolysis. Collectively, these results demonstrate an effective strategy to boost sensitivity of CAR- and TCR-redirected T cells against tumors with suboptimal expression of the target antigen without broadening off-tumor toxicities with a non-cytotoxic synapse-stabilizing receptor.

93. Transduction with Bicistronic CD20 CAR with NIS Reporter Allows PET/CT Visualization of CAR-T Cell Trafficking *In Vivo*

Brynn B. Duncan[1], Justin Mirazee[2], Christopher Chien[2], Kevin Quiroz[1], Shiqin Judy Yu[1], Sogun Hong[1], Naomi Taylor[2], Noriko Sato[3], David Young[1], Cynthia Dunbar[1]

[1]TSCBB, NHLBI, NIH, Bethesda, MD,[2]Pediatric Oncology Branch, NCI, NIH, Bethesda, MD,[3]Molecular Imaging Branch, NCI, NIH, Bethesda, MD

Background: Tracking CAR-T cell expansion and persistence in patients with hematologic malignancies is currently limited to peripheral blood and marrow sampling, providing limited insights into how and where CAR-T cells traffic and persist beyond these compartments. Costimulatory endodomains that are known to influence CAR biology have unclear downstream effects on CAR-T cell trafficking. The sodium-iodide symporter (NIS) is a plasma membrane glycoprotein that actively uptakes iodide and iodide analogs that can be transduced into T cells along with a CAR, allowing real-time *in vivo* PET/SPECT imaging of CAR-T cells. **Methods**: CAR constructs with specificity for human and non-human primate (NHP) CD20 that contain various costimulatory endodomains (4-1BB, CD28, CD27) were generated via Golden Gate assembly. Rhesus NIS or truncated EGFR (for CAR identification) reporters were inserted downstream via a T2A skip sequence for expression under control of the same EF1a promoter driving CAR expression. *In vitro* cytotoxicity and functional iodide and fluorine-18 tetrafluoroborate (^{18}F-TFB) uptake was tested. NSG mice bearing CD20$^+$ Raji lymphoma xenografts were treated with CAR-T cells and imaged by PET/CT weekly. Syngeneic NHPs treated with autologous NIS-expressing CAR-T cells were monitored for cytokine release syndrome (CRS), neurotoxicity, and CAR-T cell expansion in response to endogenous and autologous reinfusion of B cells. NHP recipients of NIS-expressing CAR-T cells undergo weekly PET/CT imaging. **Results**: Successful bicistronic lentiviral transduction of both human and NHP T cells demonstrated equivalent *in vitro* CD20 antigen-specific cytotoxicity regardless of NIS expression and demonstrated NIS-specific iodide and ^{18}F-TFB uptake. NIS-expressing CAR-T cells homed to Raji lymphoma in NSG mice with variable trafficking kinetics and *in vivo* tumor control depending on the costimulatory domain. CD20/41BB/NIS most quickly and effectively induced remission (max SUV_{mean} day 12; day 45 survival 83%, n=6) followed by CD20/CD27/NIS (max SUV_{mean} day 18; day 45 survival 67%, n=6) and CD20/CD28/NIS (max SUV_{mean} day 33+; day 45 survival 33%, n=6). An NHP (NHP01) was given 2.72x10^6/kg CAR+ T cells consisting of both CD20/41BB/EGFRt and CD20/4-1BB/NIS CAR-T cells. NHP01 developed CRS, B cell aplasia, CAR-T cell expansion (ddPCR analyses of PBMCs for EGFRt and NIS), and CAR-T cell-associated cytokine production. B cell reinfusion at day +17 did not induce substantial CAR re-expansion or cytokine elevation. No neurotoxicity was observed. Another NHP (NHP02) received CD20/41BB/NIS CAR+ T cells (5.49x10^6/kg) and will undergo weekly PET/CT imaging as well as combined IV and subcutaneous autologous B cell reinfusion. **Conclusions**: CD20 CAR-T cells that express NIS demonstrate unhindered *in vitro* and *in vivo* anti-tumor activity, allowing sensitive and specific visualization of CAR-T cells *in vivo* via PET/CT. In a syngeneic NHP model, 4-1BB-costimulated CAR-T cells expressing NIS expanded as well as those with EGFRt and induced CRS and B cell aplasia. Currently, PET imaging of an NHP treated with CD20/41BB/NIS (NHP02) is underway with plans for another treated with CD20/CD28/NIS (NHP03) in the near future.

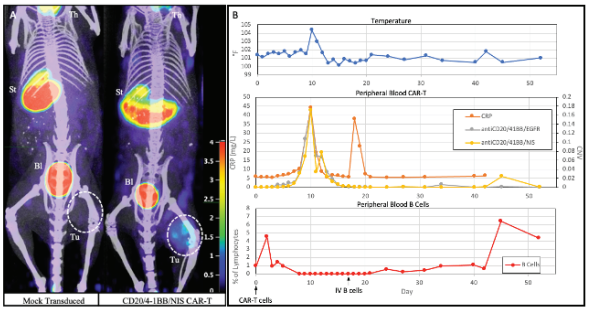

Figure 1. (A) Representative PET/CT image of tumor-bearing NSG mice 8 days after T cell administration. Day -4 subcutaneous challenge with 10^6 CD20+Raji lymphoma cells in the right thigh was followed by 2x10^6 T cells IV on day 0. Increased SUV is noted within the tumor (Tu) of mice treated with NIS-expressing CAR-T cells (right) but not mock CAR-T cells (left). Expected background uptake present in thyroid (Th), stomach (St), and bladder (Bl). (B) Evidence of CRS (top and middle), CAR expansion by ddPCR (middle), and B cell aplasia (lower) in NHP01 post-infusion of CD20/41BB/EGFRt and CD20/41BB/NIS CAR-T cells. Peak expansion and CRS occurred at day 10 with B cell aplasia noted from day 8 to 21.

94. Chimeric Cytokine Receptors Induce Antigen-Specific Activation in Natural Killer Cells Against Acute Myeloid Leukemia

Natalie J. Holl, Ruyan Rahnama, Jun Choe, Megan Zinsky, Danielle Grace Jones, Challice L. Bonifant

Pediatric Oncology, Johns Hopkins University School of Medicine, Baltimore, MD

Background: Chimeric antigen receptor (CAR) T cell therapies have revolutionized the standard of care treatment for B cell malignancies. However, CAR-T cell clinical trials for acute myeloid leukemia (AML) have had discouraging outcomes. As an alternative effector to T cells, natural killer (NK) cells are being investigated. NK cells are innately cytotoxic against cancer cells, are readily enhanced with CARs, and, unlike T cells, do not cause graft-versus-host disease. However, NK cells have exhibited a lack of persistence in multiple clinical trials, limiting their efficacy and the relapse-free survival of patients. In order to increase NK cell persistence, we have designed antigen-specific chimeric cytokine receptors (CCRs) based on the interleukin-15 receptor (IL-15R) to stimulate prolonged NK cell survival. **Methods:** Artificial receptors were designed with AlphaFold using sequences from either the native IL-15Rβ chain or the common gamma chain (γc) and single chain variable fragments to target CD123, an AML-associated antigen. Each CCR chain was subcloned into an expression vector with a fluorescent protein, GFP or mScarlet (mSc), to create various CCR-γc-GFP and CCR-IL-15Rβ-mSc constructs. Primary NK cells were expanded from peripheral blood mononuclear cells with irradiated K562.mbIL15.41BBL feeder cells following magnetic depletion of T cells. NK cells were then transduced with retroviral vectors. After testing constructs with promising predicted *in silico* folding, the optimal CCR pair was chosen for further testing based on

surface expression and antigen-binding. Antigen-specific signaling of CCRs was evaluated by stimulating CCR-NK cells with immobilized recombinant human CD123 (rhCD123) and detecting activation of STAT5 by phosphorylation (pSTAT5) using Western blot. Antigen-specific cytotoxicity was assessed in 18-hour bioluminescence assays with firefly luciferase-expressing target cell lines. Non-transduced NK cells were used as controls in all experiments. **Results:** CCR chains were expressed at similar levels individually (mean ± SD; CCR-γc-GFP, GFP+%: 61.7 ± 16.5%; CCR-IL-15Rβ-mSc, mSc+%: 63.3 ± 15.4%) and together (co-transduced, GFP+mSc+%: 53.2 ± 13.3%). CCR single chain pSTAT5 was not detectable with rhCD123 stimulation and while NK cells co-transduced with both receptors displayed low levels of tonic signaling, stimulation with rhCD123 resulted in a 2.1x fold increase in signal. Co-transduced NK cells displayed significantly higher cytotoxicity versus MOLM-13 (CD123+) at every effector-to-target ratio except the lowest compared to NKs expressing single CCRs and non-transduced cells (1:10 $p = 0.7935$, 1:5 $p = 0.0309$, 1:2 $p < 0.0001$, 1:1 < 0.0001 vs. non-transduced). NK cells did not show different cytotoxicity against Raji (CD123-) (all $p > 0.8145$ vs. non-transduced). **Conclusions and future directions:** NK cells expressing our IL-15R-based CCRs demonstrate antigen-specific signaling and cytotoxicity dependent on expression of both our chimeric IL-15Rβ and chimeric γc. We are actively evaluating the phenotype of NK cells expressing these receptors in long-term *in vitro* assays, specifically as relates to persistence and activation. These results will provide insights to the signaling biology of NK cells in the context of engineered cytokine-dependent activation. We next plan *in vivo* experiments in our established xenograft models of human AML to track NK cell persistence and disease clearance.

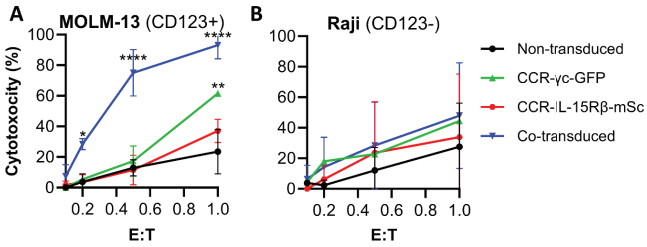

Figure 1. CCR-NK cells display antigen-specific cytotoxicity. **A)** NK cells were co-cultured with CD123+ and **B)** CD123- cell lines at various effector-to-target ratios (E:T). Cytotoxicity was quantified as the percentage of decreased bioluminescent signal after 18 hours of co-culture with firefly luciferase-expressing target cells compared to target cells not exposed to NK cells. * $p \leq 0.05$, ** $p \leq 0.01$, or **** $p \leq 0.0001$ vs. non-transduced. N = 2 unique NK cell donors, 3 technical replicates per donor.

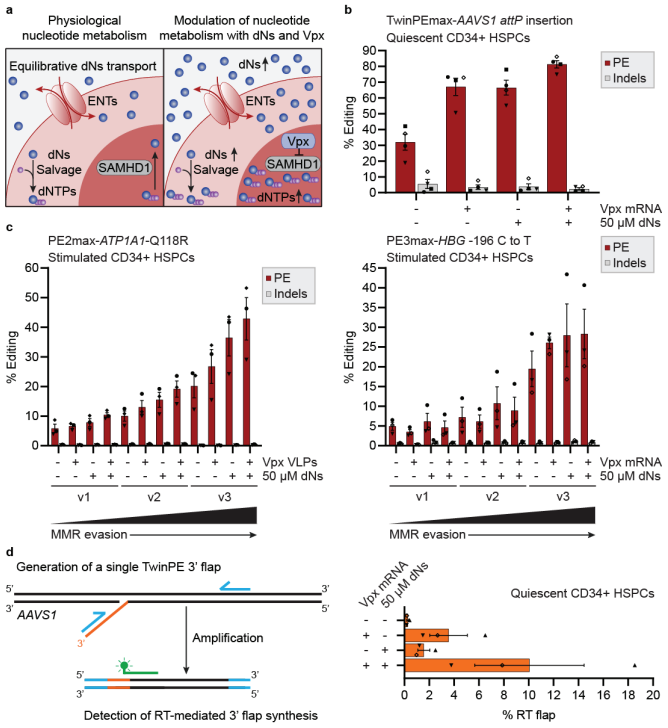


Base Editing and Prime Editing I

95. Nucleotide Metabolism Constrains Prime Editing in Hematopoietic Stem and Progenitor Cells

Sébastien Levesque[1,2,3,4,5], Andrea Cosentino[1,2,5,6], Archana Verma[1,2,3,4,5], Pietro Genovese[1,2,5], Daniel E. Bauer[1,2,3,4,5]

[1]Division of Hematology/Oncology, Boston Children's Hospital, Boston, MA,[2]Department of Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA,[3]Harvard Stem Cell Institute, Cambridge, MA,[4]Broad Institute, Cambridge, MA,[5]Harvard Medical School, Boston, MA,[6]Milano-Bicocca University, Milan, Italy

Therapeutic prime editing (PE) of hematopoietic stem and progenitor cells (HSPCs) holds great potential to correct pathogenic mutations causative of severe blood disorders. While recent advances have improved the technology, efficient prime editing remains challenging in primary hematopoietic cells. Since SAMHD1 has been identified as an antiviral factor restricting the nucleotide pool available for reverse transcription (RT) and virus replication, we hypothesized that modulating this metabolic pathway could enhance RT and thus prime editing in HSPCs. We devised strategies to modulate nucleotide metabolism by supplementing deoxynucleosides (dNs) and delivering the viral accessory protein Vpx using virus-like particles (VLPs) or mRNA. Exogenous dNs supplementation and Vpx-mediated proteasomal degradation of SAMHD1 markedly increased PE efficiency at seven loci in HSPCs from seven different healthy donors, achieving up to 68%, 77%, and 86% editing using the PE2, PE3, and TwinPE systems, respectively. Of importance, maximal enhancements were observed with epegRNAs designed to evade DNA mismatch repair. To substantiate our findings, we tested whether the limited level of dNTPs constrains RT in HSPCs. We installed the V223M mutation known to increase dNTP affinity to the M-MLV RT. This additional approach improved PE at three different loci, further expanding the toolkit available to overcome this metabolic constraint. We then developed a ddPCR assay to measure PE-mediated RT based on synthesis of a non-homologous 3' DNA flap that does not integrate to its target locus. Using this approach, we confirmed that modulating nucleotide metabolism increases PE flap synthesis by an average of 37-fold in quiescent HSPCs from three different donors. Altogether, modulation of nucleotide metabolism should enhance prime editing to facilitate the clinical translation of gene therapies for severe blood disorders through engineering quiescent cells. This work highlights a key metabolic restriction for therapeutic prime editing of primary cells and could help design future approaches to engineer HSCs in vivo.

Vpx and deoxynucleoside (dN) supplementation enhance prime editing in CD34⁺ HSPCs. (**a**) Schematic representation of the modulation of nucleotide metabolism. (**b**) PE and indel quantification as determined by CRISPResso2 analysis from amplicon sequencing. HSPCs were electroporated with Vpx and TwinPEmax RNAs targeting *AAVS1* and cultured in the presence or absence of 50 µM each dNs. Genomic DNA was harvested 3 days post-nucleofection. $n = 4$ independent biological replicates. (**c**) Same as in (**b**) with PE2max and PE3max RNAs targeting *ATP1A1* or the *HBG1/2* promoters using (e)pegRNAs designed to progressively evade DNA mismatch repair (MMR). $n = 3$ independent biological replicates. (**d**) Percentage of allele harboring the PE flap relative to a genomic reference as determined by ddPCR. $n = 3$ independent biological replicates.

96. Prime Editors Precisely Correct Pathogenic *RHO* Mutations and Preserve Photoreceptors *In Vivo*

Emily Brown, Abhishek Dass, Vanessa Yanez, Manuel N. Tapia, Bilva Burkule, Shreya Malhotra, Rafaela Mendes, Peter Jeffrey Chen, Billy Law, Jeff Jones, Yunchao Gai, Yi Pu, Jacob Stewart-Ornstein, Jia Tay, Vivian Choi, Deepak Reyon, Jeremy Duffield

Prime Medicine, Cambridge, MA

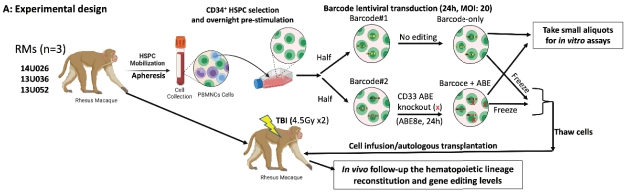
Mutations in the rhodopsin gene result in *RHO*-mediated Retinitis Pigmentosa (*RHO*-RP), characterized by progressive degeneration of rods and cones photoreceptors. Children or young adults develop loss of night and peripheral vision, ultimately losing central vision. Multiple gene therapy approaches have been investigated in treating patients with *RHO* p.P23H. However, due to the potential toxicity of overexpression of wildtype Rhodopsin (RHO) by gene transfer and limited options of gene correction by other gene editing (GE) mechanisms, there has only been incremental clinical success. Prime Editing is a next generation GE technology that can precisely correct more than 90% of all pathogenic human mutations without the need for DSB, with minimal byproducts at the edit site, minimal off-target activity, or risk of large chromosomal alterations or genotoxicity sometimes observed with CRISPR-Cas9. This approach potentially restores WT RHO expression in its endogenous locus and could address patients with mutations other than p.P23H. We developed a dual AAV system to deliver Prime Editor components (Dual AAV PEs) to photoreceptors via subretinal (SR) injection. Prime Editors (PEs) precisely correct prevalent disease-causing autosomal dominant (ad) mutations in *RHO* including p.P23H and a mutation hotspot located at the C-terminus of the protein that includes 18 pathogenic mutations, including *RHO* p.V345L and p.P347L, which could potentially benefit ~60% of *RHO*-mediated adRP patients. Comprehensive high throughput screening led to the identification of potent PEs to precisely correct either p.P23H or all 18 mutations in the mutational hotspot *in vitro*. Early PE candidates were tested in mutant or patient cell lines and human retinal explants using a Dual AAV PE, where we observed editing efficiencies as high as 40%. To test PE *in vivo*, we generated humanized mouse models with the mutant human *RHO* gene (with 5-point mutations) replacing the mouse *Rho* gene. Dual AAV PEs were injected subretinally to 6-8 weeks old humanized mice, resulted in >60% of photoreceptors with precise correction of p.P23H or p.V345L/p.P347L mutations within the transduced area. To assess if Prime Editors impacted disease progression, we generated humanized *RHO* p.P23H animals where photoreceptors degenerate rapidly after birth. Six- and 13-weeks post injection of Dual AAV PEs, animals were evaluated for mutational correction and for photoreceptor preservation. The transduced regions of the retina showed significant preservation by quantitative histological evaluation, without evidence of inflammation or toxicity while the untransduced area showed complete degeneration of the photoreceptor layer. Separately, Dual AAV PEs were tested in human retinal explants. Photoreceptor genomes were analyzed using Prime Medicine's comprehensive genome-wide off-target assays. Preliminary results have not identified any off-target edits or AAV genome integrations. The AAV Prime Editor platform effectively and safely delivers PE components to photoreceptors with high efficiency, precisely corrects pathogenic mutations that cause adRP and halts retinal degeneration in humanized mice. Genome-wide preliminary off-target analyses in human photoreceptors show no evidence of unintended edits. The AAV Prime Editor platform has the potential to be applied to additional retinal diseases by using other the Prime Editor guide RNA sequences.

97. In Utero and Postnatal Base Editing for a Metabolic Liver Disease in Mice and Nonhuman Primates

Ana Maria Dumitru[1], Marco Carpenter[1], Madelynn Whittaker[2], Cara Berkowitz[1], Valerie L. Luks[2], Nicole Kus[1], Rosa Choi[1], Nicholas F. Archer[1], William Johnston[3], Arjit Biswas[1], Julie Yeo Su Li[4], Yiping Fan[4], Xiao Wang[2], Mohamad Gabriel Alameh[1], Jerry Chan[5], Kiran Musunuru[2], William Peranteau[6]

[1]CHOP, Philadelphia, PA,[2]University of Pennsylvania, Philadelphia, PA,[3]Children's Hospital of Philadelphia, Philadelphia, PA,[4]NUS, Singapore, Singapore,[5]KK Women's and Children's Hospital / Duke NUS Medical School, Singapore, Singapore,[6]The Children's Hospital of Philadelphia, Philadelphia, PA

A number of genetic diseases amenable to therapeutic gene editing cause pathology before or shortly after birth. In utero gene editing has the potential to mitigate disease before the onset of this pathology. Moreover, normal developmental properties of the fetus including the small size, immature immune system, and abundant, accessible progenitor cell populations are hypothesized to facilitate efficient gene editing. Genetic diseases affecting the liver, including metabolic liver diseases, are some diseases that may benefit from in utero editing. As an example, we have chosen to evaluate a therapeutic base editing strategy for hereditary tyrosinemia type 1 (HT1) applied either before or after birth. HT1 is an autosomal recessive metabolic liver disease in which mutations in the *FAH* gene, the final step in the tyrosine catabolic pathway, result in accumulation of toxic metabolites and subsequent liver failure with an increased risk of hepatocellular carcinoma. The pathology can begin before birth. Current treatment for HT1 includes daily dosing of nitisinone which inhibits the HPD enzyme upstream in the tyrosine catabolic pathway and prevents the accumulation of toxic metabolites. We hypothesized that adenine base editing to disrupt a splice acceptor or donor site in the *HPD* gene could inactivate the gene as a therapeutic approach for HT1. To address this hypothesis, we screened a number of gRNAs together with ABE8.8 in HuH-7 cells, a human hepatoma cell line. A lead gRNA, HPD20, was chosen based on on-target editing efficiency and off-target editing profile. To assess the ability of this approach to rescue the disease phenotype, gestational day (E) 16 fetal HT1 mice or 8 week old HT1 mice were intravascularly dosed with an LNP containing ABE8.8 mRNA and a mouse gRNA orthologous to HPD20 gRNA. These studies demonstrated efficient on-target editing with survival, liver function and urine metabolites similar to that seen in HT1 mice maintained on nitisinone and significantly improved compared to HT1 mice in which nitisinone was removed, all of which died by 3 weeks off nitisinone. The target sequence of the human HPD20 gRNA is homologous to the sequence present in *Macaca fascicularis*. Thus, we next tested the feasibility of in utero base editing in the fetal nonhuman primate (NHP). LNP_ABE8.8_HPD20 was intravascularly delivered into midgestation *Macaca fascicularis* fetuses. Assessments at short time points after injection demonstrated efficient delivery of the LNP to the fetal liver and moderate editing throughout the liver. To assess a potential benefit of the fetal environment for in vivo editing, we dosed two 3 year old *Macaca fascicularis* NHPs with LNP_ABE8.8_HPD20 at a comparable dose to that given to the fetuses. On-target liver editing was noted although editing levels were approximately 2- to 4.5-fold lower compared to fetal recipients. This study supports a mutation-agnostic adenine base editing approach for HT1 and demonstrates the feasibility of *in utero* liver gene editing via LNP delivery in NHPs, highlighting potential advantages to editing during fetal development in this model.



98. The Impact of Base Editing on Rhesus Macaque Hematopoietic Stem Cell Engraftment and *In Vivo* Clonal Behavior

Ashley Gin[1], Chuanfeng Wu[1], Diana Abraham[1], Yifan Zhou[1], Taha B. Hayal[1], Richard Lozano[1], Gregory A. Newby[2], David R. Liu[2], Cynthia Dunbar[1]

[1]National Heart, Lung, and Blood Institute, Bethesda, MD,[2]Broad Institute of MIT and Harvard, Cambridge, MA

CRISPR/Cas9 editing has transformed hematopoietic stem and progenitor cell (HSPC) gene therapies; however, Cas9 generates double-stranded breaks (DSBs), enhancing off-target risks, p53 activation, and HSPC genotoxicity. Base editors (BEs) mitigate these concerns by facilitating single-nucleotide conversions without DSBs. Investigation into BE impact on long-term HSPC engraftment and clonality is necessary to evaluate BEs for clinical HSPC gene therapies. Depleting CD33, a myeloid differentiation marker, protects HSPCs from CD33-targeted immunotherapies without effecting functionality. We evaluated the clonal impact of HSPC CD33-targeted adenine BE (ABE, ABE8e variant) in a competitive rhesus macaque (RM) autologous HSPC transplantation (HSCT) model (n=3). Following total body irradiation, RMs were infused with two genetically barcoded $CD34^+$ HSPC populations: Lib#1 was unelectroporated (Barcode-only arm) and Lib#2 was electroporated for CD33-targeted ABE (Barcode+ABE arm) (Fig. 1A). ABE efficiency in the Barcode+ABE arm varied from 11.7-88.2% in the 3 RMs (Fig. 1B). *In vitro*, no significant differences were observed in cell growth, viability, CFU plating efficiency, or lineage distribution between both arms. Following HSCT, blood cells were collected weekly to track engraftment via GFP expression and ABE alleles and to follow clonal diversity via quantitative barcode retrieval. *In vivo,* GFP marking peaked earlier than the editing level in granulocytes (Gr), suggesting slower engraftment of Barcode+ABE cells (Fig. 1C). CD33 ABE levels peaked at expected levels 2-3 weeks post-HSCT, but markedly decreased over time, indicating deficient long-term ABE cell engraftment. Unexpectedly, in the 2 RMs receiving ABE cells with the highest editing frequencies (13U036 & 13U052), the overall GFP^+ population, consisting of Barcode+ABE and Barcode-only cells, declined in tandem with the decrease of edited cells. In contrast, GFP^+ cells in the less efficiently edited RM (14U026) maintained consistently high GFP^+% for up to 14 months (m) despite a significant decrease in edited cells. These findings suggest high ABE efficiency may induce toxicities that impact infused HSPC engraftment via niche effects or paracrine signals, requiring further investigation. In RM 13U036, 1m $CD33^{+/-}$ Gr and 3 and 5m $GFP^+CD33^{+/-}$ Gr were sorted for barcode clonal analysis. The majority of $CD33^-$ Gr showed expected CD33 ABE (Fig. 1D), and the high-contributing clones revealed distinct clonal patterns between $CD33^+$ and $CD33^-$ Gr (Fig. 1E). Initially, short-term engraftment was polyclonal with high diversity in both $CD33^+$ lib#1 (Barcode-only) and $CD33^-$ lib#2 (Barcode+ABE) Gr. However, clonal diversity decreased over time, with $CD33^-$ lib#2 Gr's diversity declining the most, exhibiting oligoclonality (Fig. 1E-F). Despite Barcode+ABE cells maintaining normal characteristics *in*

vitro, our preliminary findings indicate reduced long-term engraftment potential of Barcode+ABE cells *in vivo*. These findings suggest high ABE levels may enhance HSPC toxicity, increasing risk for HSPC loss and oligoclonal hematopoiesis. While the combination of lentiviral transduction and ABE8e may have added to HSPC stress, these findings provide relevant information for the optimization and safe clinical development of ABE-based gene and cell therapies.

B: *In vitro* transduction, gene editing efficiency and monkey transplantation parameters

Monkey ID	Barcode-only Library ID	Barcode+ABE Library ID	Barcode-only transduction efficiency (GFP+%)	Barcode+ABE transduction efficiency (GFP+%)	Barcode+ABE CD33 ABE editing efficiency (%)	Barcode-only infused cell number (million)	Barcode+ABE infused cell number (million)	Infusion product total cell number (million)	Infusion product GFP+%	Infusion product overall editing level(%)	Cell dose million/kg
14U026	Barcode lib#1	Barcode lib#2	37.9%	49.5%	11.7%	26.2	18.8	45	n/a*	4.8%	5.3

*n/a: Infusion product GFP level was not measured.

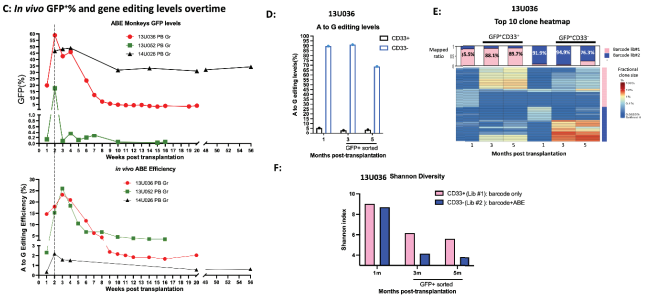

Figure 1: *In vivo* tracking of CD33 KO base edited and barcoded hematopoietic stem and progenitor cells (HSPCs) indicates poor engraftment and oligoclonality induced by adenine base editing (ABE) in rhesus macaque (RM) autologous transplantation model. (A) Experimental design of competitive Barcode-only and Barcode+ABE autologous RM transplantation model. **(B)** *In vitro* transduction, gene editing efficiency, and monkey transplantation parameters. **(C)** GFP+% levels (upper panel) and the ABE editing levels (lower panel) overtime post-transplantation. **(D)** Editing levels of CD33$^{+/-}$ Granulocytes (Gr) subsets overtime; the 1m Grs were sorted only based on CD33 expression, and the 3m and 5m GFP^{+} CD33$^{+/-}$ Grs were sorted. **(E)** Barcode clonal tracking of the CD33$^{+/-}$ Gr subsets overtime. The bar plots on top of the heatmap show the normalized proportion of the barcode libraries (lib) indicated by their percentage of mapping ratios. The pink bars show the lib#1 percent from the barcode sequencing reads in a sample; the blue bars show the lib#2 percent. In the CD33^{+} Gr samples, most of the barcode presented were from lib#1 (Barcode-only), and the majority barcodes in the CD33^{-} Gr samples are the lib#2 (Barcode+ABE). The lower barcode heatmap is the top 10 high contributing clones relative fractional clone size heatmap; each row is a barcoded clone, each column is a sample, the color scale shows the relative clonal size, redder indicates a bigger clone size. The pink/blue bar on the right of the heatmap indicated the barcodes in the heatmap belong to the corresponding lib. **(F)** Clonal diversity of Barcode+ABE and Barcode-only cells was calculated by the Shannon Diversity Index of the retrieved barcodes.

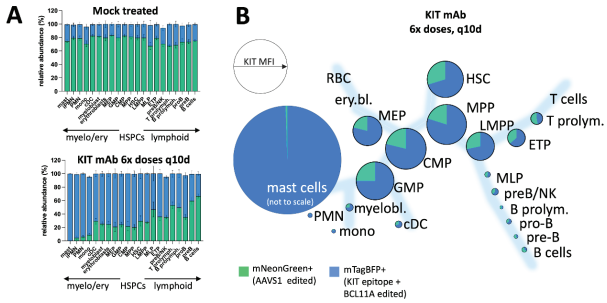
99. Base Editors Provoke Non-Predictable Chromosomal Translocations and Off-Target Editing

Manuel Rhiel[1], Kerstin Geiger[1], Masako Kaufmann[1], Julia Klermund[1], Melissa Whitehead[1], Viviane Dettmer-Monaco[1], Ala' Dibas[1], Carla Fuster-Garcia[1], Geoffroy Andrieux[1], Claudio Mussolino[1], Melanie Boerries[1], Tatjana Cornu[2], Toni Cathomen[1]

[1]Medical Center - University of Freiburg, Freiburg, Germany,[2]Medical Center – University of Freiburg, Freiburg, Germany

Base editing has emerged as a promising alternative to CRISPR-Cas nuclease-based genome editing, in part because of its promise of reduced genotoxicity. Here, we performed a comprehensive genome-wide analysis of base editing-induced off-target effects. Primary human T cells were edited at four genomic loci (CCR5, COL7A1, EMX1, FANCF) using side-by-side CRISPR-Cas9 nuclease, an adenine base editor (ABE8e), one of three cytosine base editors (CBEs), or Cas9 nickase. We used CAST-Seq to identify gross chromosomal aberrations and off-target sites (OTs), followed by rhAmp-Seq to evaluate on-target activity (44-84% modified alleles) and mutagenic effects at >100 nominated OTs. CAST-Seq revealed large (>200 bp) on-target aberrations ranging from 45% for Cas9 to 5% for ABE, 2-7% for CBEs, and 0% for nickase-edited cells. While ABE8e editing induced few translocations, more than 10% of the alleles were modified in 17 of the 40 identified OTs. In contrast, chromosomal translocation events in some CBE-treated cells exceeded that found in Cas9-edited T cells by 3-fold. Furthermore, extensive C-to-T conversion (≤99% of alleles) and mutagenesis (≤7% of alleles) were detected in T cells edited with a hyperactive CBE, whereas recently developed CBE variants (TadCBEd or CBE-T1.52) showed only marginal OT activity. In conclusion, our study revealed the genotoxic potential of ABE8e and the hyperactive evoCDA1-BE4max. These base editors induced mutagenic OT editing at sites that were not altered by CRISPR-Cas9 nucleases complexed with the same gRNA, suggesting that the mechanism of gRNA-dependent OT activity of base editors is different from that of CRISPR-Cas nucleases.



100. Epitope Editing Combined with Extended Schedule Anti-KIT Antibody Treatment Enhances Immune-Based *In Vivo* Selection of Multiplex Gene-Engineered Cells

Gabriele Casirati[1], Adele Mucci[2], Marta Freschi[1], Mohammed S. Mahmoud[1], Jan-Phillipp Gerhards[2], Andrea Cosentino[1], Jing Zeng[2], Christian Brendel[2], Daniel E. Bauer[3], Pietro Genovese[4]

[1]Hematology/Oncology, Boston Children's Hospital / Dana Farber Cancer Institute, Boston, MA,[2]Hematology/Oncology, Boston Children's Hospital, Boston, MA,[3]Boston Children's Hospital / Harvard Medical School, Boston, MA,[4]Hematology/Oncology, Boston Children's Hospital / Harvard Medical School, Boston, MA

Hematopoietic stem/progenitor cell (HSPC) transplantation (HSCT) offers curative options for conditions for which the substitution of endogenous hematopoiesis with gene-corrected cells can halt the pathogenic process. Yet, short and long-term effects of genotoxic conditioning remain a barrier to a wider application of HSCT and gene therapies. Whereas monoclonal antibodies (mAbs) targeting HSPCs have been proposed as alternative to chemo/radiotherapy, their pharmacokinetics hamper effective clinical use due to risk of on-target depletion of transplanted HSPCs, leading to increased risk of graft failure or incomplete myeloablation. We previously demonstrated that precise editing of the targeted epitope in HSPCs can endow hematopoietic cells with selective resistance to mAbs without affecting stem cell functionality. We identified amino-acid changes in the extracellular domain of KIT that abrogate the binding of a therapeutic mAb (Fab79D) without affecting surface expression, ligand affinity and downstream signaling. We exploited adenine base editing (BE) to efficiently (~80%) introduce these mutations in CD34+ HSPCs, which preserved long-term multilineage repopulation. As epitope-editing can be achieved through BE, it is well suited for combination with additional therapeutic genome modifications, such as the disruption of *BCL11A* erythroid enhancer to enforce fetal hemoglobin (HbF) expression, which can provide therapeutic benefit for patients affected by sickle cell disease. We multiplexed KIT and sgRNAs targeting the +55 and +58 BCL11A DHSs and obtained efficiencies comparable to single edits, while achieving upregulation of HbF proportional to the number of disrupted WGATAR motifs (up to 80%). Critically, we observed high degree of biallelic co-editing, with 60% HSPCs bearing biallelic KIT edits and at least 3 disrupted WGATAR motifs.

By performing a competitive transplant with co-injection of multiplex KIT+BCL11A BE and AAVS1 BE CD34+ cells in NBSGW mice. We observed progressive enrichment of both *KIT* and *BCL11A* edits (~2x) in mice treated with a standard dose-dense Ab regimen when compared to controls. We speculated that optimized Ab schedules with extended exposure to anti-KIT mAb may provide superior results. We performed a second competitive transplant with lentiviral fluorescent marking of the KIT+BCL11A BE (mTagBFP) and AAVS1 BE cells (mNeonGreen), to enable precise tracking by FACS. We treated mice with a dose-dense or extended Ab regimens (6 doses, either every 5 or 10 days). Extended regimens produced markedly improved in vivo selection with near complete replacement (>80%) within progenitor and myeloid/erythroid compartments (FIG.A), which translated to improved HbF increase. The selection was proportional to KIT surface levels (FIG.B) and lineage half-life. As epitope editing eliminates limitations due to Ab on-target toxicity, we can envision innovative, non-genotoxic gene therapy transplant regimens that will achieve therapeutic levels of corrected HSPCs with substantial advantages over alternatives in terms of safety and tolerability.

101. Development of a Prime Edited CD34+ Cell Drug Product for the Treatment of P47phox Chronic Granulomatous Disease

Jack M. Heath[1], Jacob Stewart-Ornstein[1], Christa E. Osuna[1], Ahmad S. Arabiyat[1], Justin G. Tedeschi[1], Maria Collier[1], Julia Kushakji[1], Allen C. Ng[1], Marina Lilieholm[1], Alan Wilhelm[1], Katie Green[1], Hari Prasanna Subramanian[1], Sarah Trusiak[1], Katya Kosheleva[1], Matthew J. Gori[1]

[1]Prime Medicine, Inc., Cambridge, MA,[2]National Institutes of Health, NIAID, Bethesda, MD,[3]NIH/NIAID Laboratory of Clinical Immunology and Microbiology, Bethesda, MD

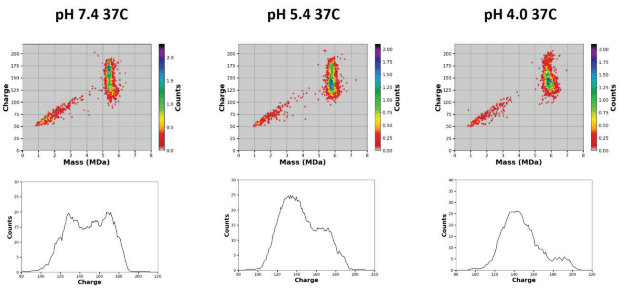
Chronic Granulomatous Disease (CGD) is an immunodeficiency caused by mutations in genes encoding proteins of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase enzyme complex. A primary function of the NADPH oxidase is to produce reactive oxygen species (ROS) that kill pathogens to control infection. CGD patients lack a functional NADPH oxidase, causing infections and inflammatory complications. CGD patients' symptoms are managed with antimicrobials, immunosuppression for inflammation, and interferon to boost immune responses. Allogeneic hematopoietic stem cell transplantation (HSCT) is currently the only potentially-curative treatment but is not available to many patients. P47phox CGD is typically caused by a two-nucleotide deletion (delGT) in the *NCF1* gene which encodes the p47 protein of NADPH oxidase. The *NCF1* gene is flanked by two nonfunctional pseudogenes that are homologous to *NCF1* and contain the delGT mutation in *NCF1* of CGD patients. Toward the development of a Prime Edited (PE) CD34+ cell therapy for p47phox CGD, an *in vivo* study was conducted with PE CGD patient CD34+ cells transplanted into immunodeficient mice. At week 16 post HSCT, 80% of bone marrow (BM) engrafted colony forming cells (CFCs) from PE CGD CD34+ cells had ≥ 1 delGT allele corrected and there were no significant differences in human hematopoietic reconstitution between mice engrafted with mock treated and PE CGD CD34+ cells. To determine whether Prime Editing of CGD patient CD34+ cells restored NADPH oxidase activity *in vivo*, BM CD15+ neutrophils were evaluated in an *ex vivo* dihydrorhodamine (DHR) assay which detects ROS. The percentage of DHR+ BM neutrophils from mice transplanted with PE CGD CD34+ cells was significantly increased compared to neutrophils from mice transplanted with mock treated CGD CD34+ cells (Mean ± S. D. % DHR+ of PE vs. mock cells: 67 ± 6% vs. 0.03 ± 0.02%; $p<0.0001$) and was closer to mock treated healthy donor (HD) controls (82 ± 5%). The median DHR fluorescence intensity was not statistically different between PE CGD and HD control cells ($p=0.145$). To evaluate the safety of Prime Editing, chromosomal, off-target, and transcriptional analyses were performed on BM engrafted mock treated and PE CGD CD34+ cells. Chromosomal and genomic analyses revealed no significant differences between mock treated and PE CGD CD34+ cells and no editing at potential off-target sites. Transcriptome analysis showed that engrafted mock treated CGD patient cells had elevated interferon signaling compared to HD and that this was restored to HD levels in PE CGD patient cells. A clinical scale manufacturing process with optimized PE components produced under Good Laboratory Practice was conducted to generate CD34+ cell drug product (DP) for IND-enabling studies. HD CD34+ cells were used for cell process development because they are readily available and have pseudogenes that contain the delGT mutation identical to the target mutation in *NCF1* of CGD patient cells. Four lots of HD CD34+ cell DPs showed similar CD34+ cell purity (98±1%), PE efficiency (74 ± 8% of CFCs with ≥ 1 allele corrected), and viability after editing and a freeze/thaw of the final product (78 ± 3%). These results show that correction of delGT in CGD patient CD34+ cells may provide a safe and efficacious curative treatment for CGD and that the clinical scale manufacturing process supports consistent production of a PE CD34+ cell DP.

AAV Analytical Methods

102. Three-Dimensional Linkage Analysis with Digital PCR for Recombinant Adeno-Associated Virus Characterization Beyond Genomic Titer: Integrity and Identity

Tam Duong[1], Michele Firmo[2], Bingnan Gu[1], Peng Wang[1]

[1]R&D, Lonza Houston Inc., Houston, TX,[2]Global Biologics Technical Development, Lonza Basel Inc., Basel, Switzerland



Recombinant adeno-associated virus (rAAV) has emerged as the vector of choice for *in vivo* gene delivery, with numerous clinical trials underway for the treatment of various human diseases. Utilizing rAAV in gene therapy requires a highly precise quantification method to determine the viral genome titer. This quantification process plays a pivotal role in establishing the optimal therapeutic dosage for a rAAV product, both in preclinical and clinical contexts. The conventional single-channel droplet digital PCR (ddPCR) method offers only partial information regarding the viral vector genome titer, lacking insights into its integrity, specifically whether it comprises a complete or partial genome. In our pursuit of further advancing rAAV analysis, we have developed a novel 3D ddPCR assay with advanced 3D linkage analysis. We have designed the three amplicon sites targeting both ends of the viral genome, as well as the center of key therapeutic gene of interest (GOI). This study aims to offer a more comprehensive and insightful assessment of rAAV products. Leveraging our 3D assay platform, we can determine not only the quantity of viral genome titer but also the quality, distinguishing between intact full-length viral genomes and partial ones, and even the identity of key GOI, therapeutic gene component. Importantly, we have developed algorithms to analyze 3D ddPCR linkage titer information. We rigorously tested our algorithms by conducting experiments involving the mixing of seven DNA fragments to represent various AAV viral genome populations, including 3 single partial, 3 double partial, and 1 full-length genomes. Across all 37 tested scenarios, we observed a significant correlation between the percentage of 3D linkage (representing full-length genomes) in the actual input and the model's output. Consequently, our comprehensive AAV analytical package not only offers insights into viral genome titer but also provides valuable information on its integrity and identity. This cost-effective approach, akin to the setup of traditional 1D or 2D dPCR, holds the potential to advance the application of rAAV in cell and gene therapy for the treatment of human diseases.

103. Quantification of pH Induced AAV9 Capsid Alterations and TLR9 Interactions by Charge Detection Mass Spectrometry

Li F. Lin[1], Zachary M. Miller[2], Evan R. Williams[2], David V. Schaffer[3]

[1]Chemical and Biomolecular Engineering, University of California Berkeley, Berkeley, CA,[2]Chemistry, University of California Berkeley, Berkeley, CA,[3]University of California Berkeley, Berkeley, CA

Vectors based on adeno-associated viruses (AAVs) are prevalently used in preclinical and clinical gene therapy, and their efficacy hinges on their delivery efficiency and subsequent transgene persistence following delivery. A recognized challenge for gene delivery is the activation of innate immune responses that trigger T-cell activation to target and eliminate cells expressing therapeutic proteins. In particular, the activation of toll-like receptor 9 (TLR9) is known to detect unmethylated CpG motifs and initiate T-cell activation signals. Acidification within endosomes, a necessary step for AAV transduction, could facilitate premature AAV genome release and subsequent exposure of AAV genomes to TLR9 recognition. Due to the heterogeneity of AAV capsids and the sensitivity of traditional assays, conventional methods fall short in elucidating individual AAV virion behaviors. In this study, we employed charge detection mass spectrometry (CDMS) to quantify the individual AAV9 virion's responses at selected pH points (7.4, 5.4 and 4.0), representing various endosomal stages. Through the analysis of over 1000 individual AAV9 virions per pH point, we observed a subpopulation of AAV9 capsids undergoing significant structural changes, indicated by the lower charge and increased mass, suggesting partial extrusion of viral genomes. Additional CDMS experimental results involving AAV9-TLR9 interactions that provide new insights into a vital aspect of AAV-mediated gene therapy and its immunological challenges will be presented.

104. Detection, Biophysical Characterization, and *In Vitro* Potency Impact of Distinct Empty/Light Capsid Populations in Recombinant AAV Preparations

Surya Simha Addepalli[1], Deepshika Gilbile[2], Wade Wang[2], Sergio Viedma Gonzalez[1], Daniel Barajas[1], John Muroski[2], Alexander Giaramita[1], Tu Nguyen[1], Kiernan Kringen[1], Laura Thacker[2], Ryan Liang[1], Leeann Alferness[1], Marissa Holmbeck[1], John Holtzinger[1], Abhigya Mookherjee[2], Vijay Raja[2], Wes Yonemoto[1], Vikas Bhat[2], Sreekanth Suravajjala[2], Terri Christianson[1], Pooja Agarwal[1], Bartlomiej Blus[1]

[1]Research and Early Development, BioMarin Pharmaceutical, San Rafael, CA,[2]Technical Development, BioMarin Pharmaceutical, Novato, CA

Recombinant Adeno-associated viruses (rAAVs) provide effective treatment for a variety of genetic diseases due to their broad tropism, favorable safety profile, and low immunogenicity. The commercial success of rAAV gene therapies has been, in part, driven by manufacturing advances, allowing for improved product yield, purity, and safety. The most common rAAV byproducts include extra-viral DNA and empty or light capsids that do not contain a copy

of a therapeutic transgene. The increased content of light capsids in rAAV preparations poses a manufacturing burden to meet often high dose requirements in the clinic and potentially elevates the risk of immunogenicity and toxicity. Therefore, pharmaceutical companies are actively optimizing manufacturing processes to reduce or eliminate light capsids from their products. In this study, we employed a combination of affinity and anion exchange chromatography (AEX) to purify light rAAV capsids from mammalian and insect cell harvests. During the AEX step, we observed distinct populations of light capsids for a subset of tested rAAV serotypes for both production systems. These species eluted at varying retention times and were collected separately for subsequent biophysical characterization. Our analyses on one such rAAV serotype produced from mammalian cells revealed significant differences in surface charge, viral protein composition, aggregation propensity, and impurity profiles. Notably, light capsid populations with longer AEX retention times had a higher content of VP1 and N-terminal, surface-externalized VP1 unique regions (VP1u), suggesting compromised capsid integrity. Finally, we evaluated the impact of the identified light capsid populations on the in vitro potency of purified full or heavy rAAVs using multiple cell lines. In summary, our results illustrate the need for in-depth characterization of rAAV light capsids to better assess their impact on product efficacy and safety as well as to inform product-specific manufacturing process development. As the viral gene therapy landscape continues to grow, such detailed impurity characterization may be particularly required for the successful expansion into next generation rAAV therapies.

105. Analytical Technologies in Development of Potency Assay for Gene Therapies

Shiqian Zhu, Jeff Patrick, Jessica Weaver, Andrew Taylor, Leigh Laundon, Bhoomi Jani, Bryan Thacker
BioAgilytix, Durham, NC

Purpose: Gene therapies - including AAVs, engineered viruses and polymer formulated oligonucleotides or plasmids - is among the highest growth area in biopharmaceuticals. They provide great promise as therapeutics but meanwhile present many development challenges due to their complex mechanisms of action (MOA). Potency assays play a pivotal role in the development of biologic therapeutics and face growing regulatory expectations from global regulatory agencies. The assay format depends on MOA of the product, and usually includes analysis of infectivity, expression, or function of the expressed protein. Therefore, it is critical to identify a suitable assay format and the associated analytical technology for potency assay development. Here case studies for representative gene therapies have been provided as examples of matrix approach and phase appropriate strategy for potency assay development, including the selection of analytical technologies, i.e. infectious titer, ELISA, MSD, Flow Cytometry, PCR, and LC-HRMS. We include discussion of phase appropriateness and the challenges and solutions for a variety of gene therapies. **Methods**: In all cases cells were cultured and maintained per vendor recommendation or established conditions. Flow cytometry was performed using a Cytoflex LX and plates were read using a BioTek Synergy Neo2 and Cytation. qPCR was performed on Quantstudio 7 and ddPCR was performed on QX200. LC-HRMS used to determine the expressed protein level was Orbitrap Exploris 240 coupled with Vanquich UHPLC system. Data was processed using Gen5, PLA, or Excel. Relative potency was determined by comparison to reference material. **Results**: Case 1 was an oncolytic Virus. One simple combined assay for infectivity and potency was developed in very early phase. The assay showed adaptable for formulation and dosing concentration changes. Continuous improvement of variation and sensitivity is required. Case 2 was about two AAV products. Each product contains a transgene for protein replacement treatment. However, due to the different MOAs, flow cytometry and In-cell ELISA were selected respectively. Western-Blot was used to screen knockout (KO) cell lines for flow cytometry assay. Upgraded software improved the data processing for In-Cell ELISA assay. Case 3 was a complicated nanoparticle containing plasmid DNA which encodes 3 transgenes. For early phase 3 methods (2 qPCR and 1 MSD) were developed to confirm the expression of 3 genes. When the product moved to Phase 2, two qPCR methods were upgraded to a duplex ddPCR method; MSD method was changed to ELISA method to improve the assay performance. Two additional cell-based assays were developed to test the function/activity of the transgene products. Drug substance (DS) transfection is procedurally different compared to DP transfection, which increased assay development workload, and the cytotoxicity at high dose levels limited the dose range so a linear curve fit was used for data analysis. Case 4 was a mRNA vaccine. This product was in early phase, no antibody available, so the potency assay was developed using LC-HRMS to test the expressed protein(s) as their peptide surrogates. The pilot study results showed promising does response curves. **Conclusions**: Our data and results demonstrated different approaches to the potency assay development for a variety of gene therapies at different phases. The selection of analytical technologies should base on the MOA of the product and should be phase appropriate. In addition to the traditional antibody-based technologies, e.g. MSD/ELISA and flow cytometry, molecular biology technologies, e.g. PCR, have been also playing an important role in potency assay for gene therapies. LC-HRMS provided an option for detection of expressed protein without the requirement of antibody, which could become a platform assay format for mRNA vaccines.

106. Quantification of Full and Empty Particles of Adeno-Associated Virus Vectors via a Novel Dual Fluorescence-Linked Immunosorbent Assay

Sereirath Soth, Mikako Takakura, Masahiro Suekawa, Takayuki Onishi, Takahiro Maruno, Mitsuko Fukuhara, Yasuo Tsunaka, Tetsuo Torisu, Susumu Uchiyama
Biotechnology, Osaka University, Suita, Japan

Background: The adeno-associated virus (AAV) vector is an attractive platform for gene therapy because of its low immunogenicity and non-pathogenicity. During the upstream process, both AAV vectors which do not contain DNA, empty particles (EPs), and AAV vector which contain DNA, full particles (FPs), are generated. It is difficult to completely remove EPs by purification because the physicochemical properties of EPs are only slightly different from those of FPs. Therefore, analysis and control of AAV vector purity are crucial for successful developments of AAV vector. Some analytical methods are available to assess the contents of FPs and EPs. Analytical ultracentrifugation (AUC) is the gold standard for characterizing AAV vectors and can quantify FPs, EPs with high precision. Mass photometry (MP) is a method that measures the mass of individual particles and provides

the percentage of each kind of particle against total counts (% counts). However, these analytical methods have limitations. For example, it is burdensome that prior purification is required before the analyses. A combination of enzyme-linked immunosorbent assay (ELISA) and polymerase chain reaction (PCR), which do not require purification before analysis, is a conventional method to quantify capsid and genome titers and to calculate EP/FP ratios. However, the combination of ELISA and PCR is subject to inherent drawbacks of error and variability because it relies on data from two independent quantitative analyses that use different mechanisms, and FPs and EPs must be quantified separately using non-identical samples. **Result:** In this study, we established a dual fluorescence-linked immunosorbent assay (dFLISA) that uses two different fluorescent dyes to quantify capsid and genome titers in a single analysis. After the addition of a secondary antibody conjugated to one fluorescent dye, the plate is subjected to heat treatment to release the genome from the capsid before addition of the second fluorescent dye. In dFLISA, capture of AAV particles, detection of capsid proteins, and release and detection of the viral genome are performed in the same well.Our study showed that the concentrations of EPs and FPs determined by dFLISA were comparable to those determined by AUC. The FP/EP ratios determined by dFLISA were consistent with the expected values. Furthermore, the concentrations of EPs and FPs in crude samples, which contain host cell DNA and proteins, were successfully obtained by dFLISA. Another advantage of dFLISA is that dFLISA can be readily adapted to measure other AAV serotypes and AAV vectors with different genome lengths. **Conclusion:** A novel analytical technique that allows the accurate and precise measurement of the abundance of both EPs and FPs, and the full/empty capsid ratio was developed in this study. The correlation between dFLISA and AUC indicated the reliability of the dFLISA results for both full and empty capsids. The dFLISA was also comparable or more accurate/precise compared with orthogonal techniques, including MP and a combination of dPCR and ELISA. In addition, dFLISA showed significant potential for evaluating the capsid and genome titers of unpurified samples and diverse AAV vector serotypes. These attributes render dFLISA an invaluable tool for developments of AAV-based gene therapies.

107. Analysis of Heterogeneous, Unpurified Gene Therapy Formulations by High Throughput Charge Detection Mass Spectrometry

Benjamin E. Draper, Lohra Mickelle Miller, Martin Jarrold

Megadalton Solutions, Inc., Bloomington, IN

Gene therapies produced in cells are expected to play an important role in emerging therapeutics. These biologics are generated using transfected cell lines with a major portion of the development cost associated with purifying the target drug from the host cell components. In the case of recombinant adeno associated virus (rAAV), typical purification strategies can involve a combination of ultracentrifugation, affinity capture and ion exchange chromatography to enrich and isolate the target drug. It is important to understand the quality of the product and the effects of different purification strategies at each stage. Charge detection mass spectrometry (CD-MS) has been shown to be a robust analytical method orthogonal to analytical ultracentrifugation for empty/partial/full quantification of AAV capsid heterogeneity for purified samples. In addition, intact mass measurements from CD-MS can identify the average viral protein ratio (VP1:VP2:VP3) and heterogeneity of the packaged DNA. Here, we show how advances in the throughput and dynamic range of CD-MS analysis have enabled the high resolution, multi-attribute analysis of purified rAAV to be applied to upstream, unpurified samples. The single particle analysis of mass and charge by CD-MS can be leveraged to characterize excess low molecular weight material, free DNA, and excess surfactant through the entire purification life cycle of rAAV.

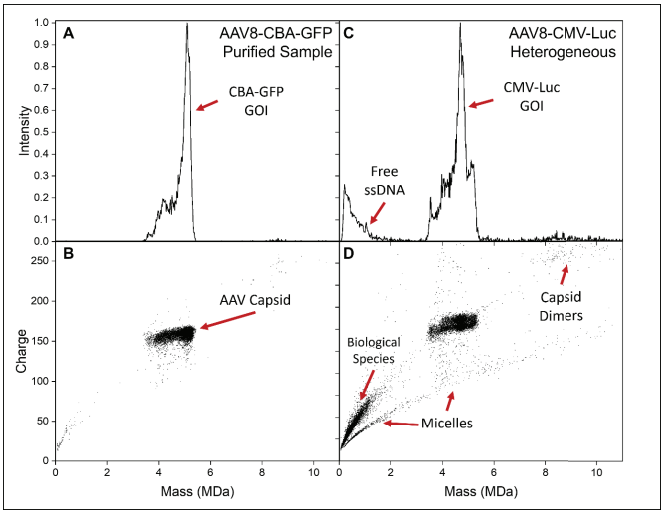


Figure 1 shows the CD-MS analysis of two samples, a well purified AAV8-CBA-GFP sample (a-b) and a representative in-process sample from AAV8-CMV-Luc (c-d). The mass histogram of the AAV8-CBA-GFP (Figure 1a) shows mostly full peak with some partial genomes and a small peak at residual empty capsid. The charge vs mass spectrum (Figure 1b) shows a well-defined charge population with small amounts of free protein aggregates at low molecular weight. The AAV8-CMV-Luc mass histogram (Figure 1c) has a much greater abundance of molecular weight smaller than the capsid with a resolved peak at the mass of the gene of interest (GOI). Even more information can be gleaned from the charge vs mass scatter plot (Figure 1d) where two separate charging bands can be seen with one attributed to biological species and one attributed to micelle species from non-ionic surfactant.

108. Rapid Optimization of AAV Production: Integrating Custom Design of Experiment, Cutting-Edge Production and Analytical Methods in Advancement of Gene Therapies

Tricia S. Jennings, Austin E. Smith, Gretchen Smith

Advanced Medicine Partners (AMP), Durham, NC

In the past decade adeno-associated viral vectors (AAV) have become a widely accepted therapeutic modality and a cornerstone of gene therapy. With continuous process improvements, optimized cell lines, and improved raw materials such as plasmids and transfection reagents, AAV production is evolving at a relentless pace. Amidst these impressive advancements, the pursuit of a repeatable process that yields high productivity and purity at scale remains a challenge. Transient transfection of HEK293 cells with three plasmids; including

the transgene flanked by ITRs, the packaging plasmid with the rep and cap genes, and helper plasmid for AAV lifecycle genes, not only offers a straightforward production method but also grants the flexibility to substitute plasmids. This production model provides significant advantages for rapidly assessing new genes of interest (GOI), AAV serotypes, and engineered capsid manufacturability. Nevertheless, differences in plasmid construct design and AAV serotype can result in diverse outcomes impacting productivity, product purity (such as capsid distribution), and unexpected losses in downstream purification steps. Given the unmet patient needs and the ongoing improvements in plasmid design, rapid and efficient screening and early optimization methods are critical at the current inflection point of gene therapy. Leveraging extensive expertise with a wide set of GOIs and serotypes, and utilizing the capabilities of our advanced production platform, we have developed a comprehensive Design of Experiment (DOE). For this customization, JMP®, Version 17 was utilized to design a mixture DOE with three mixture variables and two process variables. AAV production occurred in 24 single-use 250mL bioreactors using the automated Ambr® 250 High-Throughput platform bioreactor system. The implementation of the DOE and Ambr® approach ensures a high-quality experiment with a notable level of consistency and confidence, as indicated by statistical significance ($p < 0.0001$) and a high coefficient of determination ($RSq = 0.96$) for genomic titer by ddPCR (gTiter) at lysate. Additionally, the use of minibioreactors with analogous geometry and process controls to large-scale production bioreactors establishes a robust foundation for future scale-up. To further evaluate the DoE and Ambr® approach, selected bioreactors were processed through clarification and capture chromatography to assess productivity and de-risk downstream operations. Within a single DOE, plasmid screening and initial optimization for a GOI were performed, assessing feasibility and scalability, while notably enhancing both the product quantity and quality. The design, coupled with advanced analytical methods, allowed for analysis of lysate samples for genomic titer by ddPCR, total AAV by ELISA (tAAV), residual plasmid DNA by ddPCR, and capsid distribution. Rather than relying solely on the estimated full-to-total capsid ratio derived from the gTiter/tAAV ratio, our cutting-edge analytical methods enabled the incorporation of more robust capsid speciation data into our model. This experiment delivered rapid and meaningful data transfer to large-scale production within months. This approach can reduce drug product development timelines, costs of goods, and risk throughout the process, which are essential considerations for meeting current patient needs.

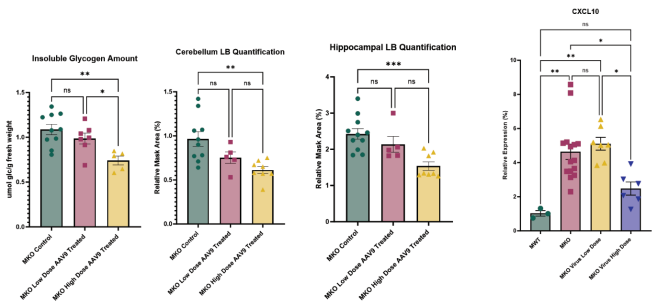
Neurologic Diseases II

109. Gene Replacement of Human EPM2A and EPM2B as a Potential Therapy for Fatal Childhood Neurodegenrative Disease, Lafora

Esther Alao

Pediatric Neurology, University of Texas Southwestern Medical Center, Dallas, TX

Background: Lafora Disease (LD) is a fatal progressive myoclonus epilepsy affecting otherwise healthy adolescents and leading to death within 10 years of onset, usually in a massive convulsion. LD is inherited in an autosomal recessive manner and caused by loss of function mutations in genes *EPM2A* encoding the glycogen phosphatase laforin or *EPM2B* encoding laforin's interacting ubiquitin E3 ligase partner malin. The absence of either protein results in a glycogen storage disorder driven by the accumulations of cytotoxic insoluble glycogen molecules called Lafora bodies (LBs), the driver of pathology in LD. LBs are present in all tissues with the brain being the severely affected organ. LBs form in both neurons and astrocytes and drive neurodegeneration and neuroinflammation respectively. Since LD is associated with mutations in either of two genes, it makes it an ideal candidate for gene replacement therapy whereby a functional copy of the mutated genes (*EPM2A* or *EPM2B*) can be delivered to make up for deficient proteins. **Hypothesis**: We **hypothesize** that delivering a functional copy of both *EPM2A* and *EPM2B* genes in brain tissue of respective LD Knockout mouse models would stop further formation of lafora bodies and reduce neuroinflammation. **Methods**: Non-pathogenic and neuronal trophic Adeno-associated virus serotype 9 (AAV9) was used as the vector of choice for delivering human *EPM2A* and *EPM2B* genes into the respective LD mouse model. To circumvent the blood-brain barrier (BBB), mice were treated with intrathecal injections of vectors at post-natal day 10. To evaluate the safety of gene therapies, a high titer of AAV9 delivering transgenes were injected into wild type mice and tissues were evaluated for any toxicity via H&E staining one month post treatment. The efficacy of both gene therapies was measured by injecting low and high titers of AAV9 in LD Knockout mice and evaluating outcome measures such as insoluble glycogen, lafora bodies, neuro-inflammatory markers three months post treatment. **Results**: The brain and other peripheral tissues revealed the expression of both laforin and malin following IHC and RNAscope respectively. Safety studies revealed that overexpressed human laforin (*EPM2A*) in wild type mice causes a dose dependent toxicity whereby lafora bodies form in tissues (DRG and Spinal Column) proximal to injection site and are absent in other tissues. Meanwhile, no toxicity was observed in safety study of human malin (*EPM2B*) expression. While both gene therapies presented with some efficacy, *EPM2B* gene replacement had a statistically significant effect wherein there was approximately 25% reduction in insoluble glycogen amounts, lafora bodies and about 50% reduction in the expression of *CXCL10*, a neuro-inflammatory marker upregulated at 3 months old (**Figure 1**). **Conclusions**: Preliminary results reveal a therapeutic potential for human *EPM2B* gene replacement in treating LD. However, to improve efficacy for potential clinical translation, focused ultrasound (FUS) technology would be used to increase the transduction efficiency of AAV9- delivered human *EPM2B*. Furthermore, to determine the mechanism underlying lafora body formation when human laforin is overexpressed in wild type mice, we would be investigating the role of excess laforin phosphatase activity in altering glycogen structure.



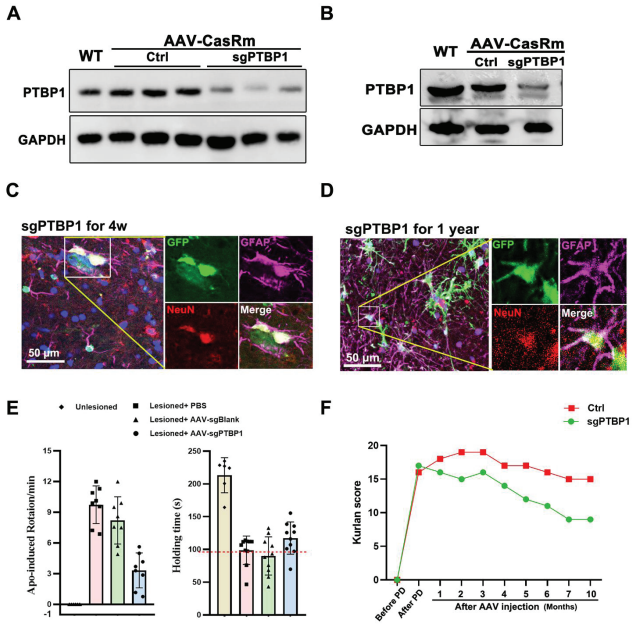


Figure 1: a) Insoluble Glycogen Measurement in EPM2B Knockout mice (MKO Control) and AAV9 treated mice at low and high viral titers b,c) LB quantification in control and AAV9 treated, and d) QPCR data showing MRNA levels of CXCL10 in control and AAV9 treated mice at 3 month of age.

110. CasRm-Mediated PTBP1 Knockdown Improves Motor Functions in Parkinson' Disease Mouse and Non-Human Primate Models

Shimin Wang[1], Piao Zhang[1], Huabao Liao[1], Xin Li[1], Hui Xu[1], Zhendong Xiao[2], Junjiu Huang[3], Junbin Liang[1]

[1]Reforgene Medicine, Guangzhou, China,[2]Biotherapy Center, The Third Affiliated Hospital, Sun Yat-Sen University, Guangzhou, China,[3]School of Life Sciences, Sun Yat-sen University, Guangzhou, China

Background: Parkinson's disease (PD) is a neurodegenerative disorder characterized by the loss of dopamine neurons in the midbrain and reduction of striatal dopamine level, leading to motor dysfunction. In situ induction of glial cells transdifferentiate into neurons has emerged as a promising treatment for PD. Polypyrimidine tract-binding protein 1 (PTBP1) is an RNA-binding protein that plays a key role in regulating nerve-specific splicing, however, its role in regulating the transdifferentiation of astrocytes into neurons remains to be studied. **Methods:** We developed an AAV-mediated PTBP1 RNA targeting therapy (RM-201) based on CasRm, a highly specific novel CRSIRP/Cas13 RNA targeting tool. The potential of RM-201 in treating PD was evaluated both in 6-OHDA-induced PD mouse model and MPTP-induced non-human primate (NHP) model. RM-201 was dosed by intra-nigra injection along with a GFP-expressing AAV that carries the same GFAP promoter as RM-201 (RM-201: AAV-GFP = 15:1). As negative controls, an AAV expressing CasRm and a control guide RNA was also given to mice and the monkey (control: AAV-GFP = 15:1). The performance of movement behaviors of animals were evaluated monthly following treatment. At the end of experiments, we detected the expression of PTBP1 in the midbrain of animals and the existence of GFP/GFAP/NeuN triple-positive intermediate neurons that transdifferentiated from AAV-infected astrocytes. **Results:** PTBP1 expression was significantly down-regulated in the midbrain of both PD mice (Fig. A) and the PD monkey (Fig. B) after a single dose of RM-201 treatment. GFP/GFAP/NeuN triple-positive cells can be captured in the midbrain of RM-201-treated mice (Fig.C) and treated side (right) of the monkey (Fig.D), but cannot be observed in control mice or control side (left). Both apomorphine (APO) induced rotation behavior and rotarod test showed that RM-201 treatment could significantly improve the motor function of PD mice (Fig. E). In PD monkey, Kurlan score of RM-201-treat side decreased significantly compared to the control side and the efficacy is durable (Fig. F), indicating that the motor function of PD monkey can be continuously improved by RM-201 treatment. **Conclusions:** Our results demonstrated that RM-201 can effectively suppress the expression of PTBP1 and induce astrocyte-to-neuron transdifferentiation, which could significantly improve the motor function of PD animals. This study provides direct evidence supporting RM-201 as a potential therapeutic gene editing for the treatment of patients with PD.

111. Unveiling the Therapeutic Potential of Targeted AAV-Mediated Glycogen Clearance in the Central Nervous System in a Glycogen Storage Disease IV Mouse Model

Su Jin Choi, Fiona E. Weaver, Rebecca A. Gibson, Rebecca L. Koch, Priya S. Kishnani, Jeong-A Lim

Duke University Medical Center, Durham, NC

Glycogen serves as the central nervous system (CNS)'s primary energy source required for proper brain functioning and is primarily stored in astrocytes under normal conditions, with dysregulation of this pathway causing a group of rare, inherited, disorders known as glycogen storage diseases. Specifically, glycogen storage disease IV (GSD IV) results from a deficiency of the glycogen-branching enzyme (GBE) which leads to widespread accumulation of poorly branched glycogen, known as polyglucosan. The adult-onset form of GSD IV is known as Adult Polyglucosan Body Disease (APBD) and is characterized by progressive neuromuscular dysfunction, neurogenic bladder, gait abnormalities, and poor motor coordination. The GSD IV mouse model (*Gbe1*$^{ys/ys}$), is a knock-in mouse model of the most common GBE1 mutation, p.Y329S, found in APBD patients of Ashkenazi Jewish ancestry and recapitulates many phenotypes observed in APBD patients. In this study, we utilized the *Gbe1*$^{ys/ys}$ mouse model to reveal the intricacies of CNS involvement during GSD IV progression. We report significant polyglucosan accumulations throughout the brain and spinal cord, initiating early in the disease progression. Furthermore, *Gbe1*$^{ys/ys}$ mice presented with severe, widespread astrogliosis in comparison to wildtype (WT) mice. At 3 months of age, *Gbe1*$^{ys/ys}$ mice performed

similarly to that of WT mice, however by 6 months, they showed a significant decline in the behavioral tests, exhibiting decreased muscle endurance and poor motor coordination. These data highlighted the significance of the CNS in GSD IV pathogenesis, and therefore, we targeted the CNS, using a neuron-specific promoter (Synapsin1; Syn1), for the treatment of GSD IV in the *Gbe1*$^{ys/ys}$ mouse model. At 6 weeks of age, two cohorts of mice received an intravenous injection of AAV9-Synapsin1-humanGBE (AAV9-Syn1-hGBE) and were subsequently sacrificed 2 weeks and 9 months post-injection. In the short-term (2 weeks) cohort, we observed an increase in GBE protein expression in the liver and brain of *Gbe1*$^{ys/ys}$ mice, and promisingly, the treatment led to preventing polyglucosan bodies accumulation in both tissues. Notably, the AAV treatment successfully rescued the behavioral defects in 6-month-old *Gbe1*$^{ys/ys}$ mice, who exhibited a significant improvement in motor coordination and neuromuscular function and performed comparably to age-matched WT mice. Interestingly, these effects persisted for approximately 6 months post-injection before we noted a dwindling of the performance improvements in AAV-treated *Gbe1*$^{ys/ys}$ mice, despite detectable GBE protein expression at that time. These data suggest that using the synapsin1 promoter to target the CNS for expressing glycogen branching enzyme in the APBD mouse model successfully prevented the early accumulation of polyglucosan. Furthermore, our vector restored GBE protein expression and rescued the neuromuscular phenotype in 6-month-old *Gbe1*$^{ys/ys}$ mice, revealing the therapeutic potential of neuron-directed gene therapy. Interestingly, our findings also alluded to non-neuronal CNS involvement in GSD IV pathology, thereby highlighting additional therapeutic avenues, which we are currently exploring for the treatment of GSD IV.

112. hfCas12Max-Mediated Gene Editing Therapy for Amyotrophic Lateral Sclerosis

Dong Yang[1], Aiguo Guo[1], Mengsi Duan[1], Meixian Wu[1], Shaoran Wang[1], Tong Li[1], Xuan Yao[1], Alvin Luk[1], Hui Yang[1,2], Linyu Shi[1]

[1]HuidaGene Therapeutics Co., Ltd., Shanghai, China,[2]Institute of Neuroscience, Center for Excellence in Brain Science and Intelligence Technology, Chinese Academy of Sciences, Shanghai, China

Background: 97% of amyotrophic lateral sclerosis (ALS) patients exhibit cytoplasmic aggregation of mutated TDP-43 protein, contributing to neuron death. Ataxin-2 is implicated in the formation of stress granules that contain TDP-43. Knockdown of Ataxin-2 has been shown to potentially prevent the aggregation of TDP-43 stress granules. Here, we developed a potential therapeutic strategy using a high-fidelity Cas12Max (hfCas12Max) system, an engineered Cas12i with high activity and specificity, to target *ATXN2* as a novel treatment for ALS. **Methods**: We generated a single AAV vector packaging hfCas12Max and gRNA targeting *ATXN2* (g*ATXN2*) capable of accessing neurons in the brain and spinal cord when administered through intracerebroventricular (ICV) injections in neonatal humanized *TDP-43*$^{Tg/Tg}$ mice, a mouse model of ALS displaying abnormal gait, severe tremors, and motor function decline and develop increasingly severe kyphosis, which typically begins manifesting at P14. We, therefore, monitored these phenotypes tri-daily between P15 and P21, as well as weight, which is also adversely affected in *TDP-43*$^{Tg/Tg}$ mice. The lifespan of mice injected with AAV-hfCas12Max-g*ATXN2* or PBS was observed daily. The editing efficiency of *Atxn2* DNA in the cortex and spinal cord of *TDP-43*$^{Tg/Tg}$ mice was detected by NGS analysis 21 days after the treatment. The Ataxin-2 and p-TDP43 protein levels within the cortex and spinal cord of these mice were also detected by western blot or immunofluorescence (IF). **Results**: Compared to *TDP-43*$^{Tg/Tg}$ mice with PBS injection, *TDP-43*$^{Tg/Tg}$ mice treated with different doses of AAV-hfCas12Max-g*ATXN2* had improved gait ($P<0.05$), decreased kyphosis ($P<0.05$), reduced tremors ($P<0.05$), and increased weight ($P<0.05$) in a dose-dependent manner (Fig.1a-d), suggesting that the *TDP-43*$^{Tg/Tg}$ mice treated with AAV-hfCas12Max-g*ATXN2* possessed improved motor coordination and neuromuscular function. Additionally, high-dose AAV-hfCas12Max-g*ATXN2* treatment dramatically extended the lifespan in *TDP-43*$^{Tg/Tg}$ mice. Median survival soared by ~77 days (101.5 vs. 24 days; $p < 0.05$)(Fig. 1e), with mean survival also extending by ~50 days (73.83 ± 10.80 vs. 23 ± 0.67 days; $p < 0.01$) (Fig. 1f). Remarkably, 50% (6 out of 12) of high-dose-treated mice surpassed 100 days of survival. NGS results at 21 days after dosing showed that the editing efficiency of *Atxn2* in the cortex and spinal cord of *TDP-43*$^{Tg/Tg}$ mice treated with low-, middle-, and high-dose was increased, with 12.73±2.01%, 22.13±3.97%, 35.60±6.93% in cortex and 3.13±0.19%, 8.50±1.86%, 9.60±1.35% in spinal cord, respectively. After treating *TDP-43*$^{Tg/Tg}$ mice with high-dose, the ATXN2 protein level in the cortex decreased to 59.37±17.32% compared to the control mice. IF results showed a significant knockdown of ATXN2 protein level in the cortex and spinal cord p-TDP43 level in the motor cortex was almost rescued to WT mice level. **Conclusions**: Our findings suggest a promising therapeutic strategy using AAV-mediated delivery of hfCas12Max-g*ATXN2* for precision genome editing of *ATXN2*, which has the potential to extend lifespan and improve motor function and neuromuscular performance in ALS.

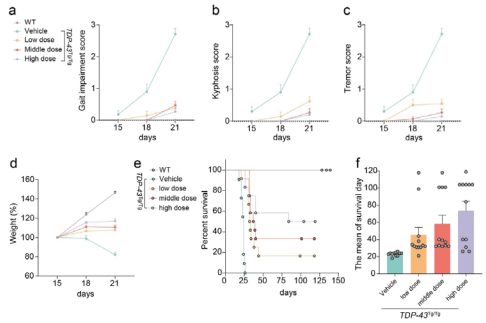

Figure 1. AAV-hfCas12Max-gATXN2 dosing improved the motor coordination, neuromuscular function, weight, and lifespan of *TDP-43*$^{Tg/Tg}$ mice.

113. All-in-One Adeno-Associated Virus Delivery for Therapeutic miR-21 Editing by saCas9 *In Vivo*

Lisa Nieland[1], Anne B. Vrijmoet[1], Isabelle W. Jetten[1], David Rufino-Ramos[1], Alexandra J. E. M. de Reus[1], Koen Breyne[2], Benjamin P. Kleinstiver[3], Casey A. Maguire[4], Marike L. D. Broekman[1], Xandra O. Breakefield[5], Erik R. Abels[6]

[1]Massachusetts General Hospital, Charlestown, MA,[2]Massachusetts General Hospital, Charleston, MA,[3]Massachusetts General Hospital, Boston, MA,[4]The Massachusetts General Hospital, Charlestown, MA,[5]Massachusetts General Hospital / HMS, Charlestown, MA,[6]Massachusetts General Hospital, Amsterdam, Netherlands

Glioma, the most aggressive tumor of the CNS has poor patient outcome with limited effective treatments available. CRISPR-Cas9 technology has opened a new avenue for gene therapy and has been previously used to target non-coding RNAs, including microRNA-21 (miR-21), a microRNA highly expressed in glioma cells responsible for tumor progression. In our previous research we showed that miR-21 is crucial for tumor growth and a complete knock out *in vitro* reduced its tumorigenesis potential. Here, we designed a single all-in-one recombinant adeno-associated vector (rAAV) containing *Staphylococcus aureus* Cas9 (saCas9) guided by a single-guide RNA (sgRNA) to target miR-21 coding sequences in the genome *in vivo*. We utilized a CRISPR delivery system using AAV-based gene therapy in a glioma mouse model. We showed that the AAV-8 serotype is capable in reaching the tumor cells in an orthotopic glioma model where it can deliver saCas9. We demonstrated that saCas9 is functionally expressed in glioma cells upon AAV-mediated delivery. This resulted in miR-21 downregulation in tumor cells leading to reduced tumor growth and improved overall survival. This all-in-one AAV-sgRNA-saCas9 approach specifically targeting microRNA coding sequences can be applied not only in the context of glioma, but for a range of genome editing purposes *in vivo*. Besides specifically targeting miR-21, this strategy could be used to target any microRNA by designing a sgRNA targeting the microRNA of interest. Applying CRISPR to microRNAs has the advantage that microRNA becomes non-functional based on a single cut, whereas the effect of CRISPR in genes could still result in a truncated protein to still be expressed with potential negative effects. Together, we show that engineering a single AAV can achieve therapeutic genome editing outcomes. We anticipate that successful *in vivo* delivery of this accurate and effective saCas9 can also advance therapeutic gene-editing in humans.

114. Chemogenetics for the Treatment of Spasticity

Nicholas Boulis, Kelly M. Poth, Michelle Zhang, Jareer Imran, Olivia Shi, Anthony Donsante

Neurosurgery, Emory University School of Medicine, Atlanta, GA

A consequence of many insults to the central nervous system, such as spinal cord injury and stroke, is the development of spasticity. The underpinnings of spasticity are not completely understood, but it involves the loss of descending innervation from the brain, increases in motor neuron sensitivity, and signaling through type Ia fibers. Ultimately, this results in the unrestrained activation of motor neurons, leading to unwanted muscle contractions. This can cause additional injuries, pain, and decreased quality of life for patients. Pharmacologic treatment with baclofen, alpha-2 agonists, and anticonvulsants can provide relief for some patients. However, these drugs can have significant side effects that lead patients to discontinue therapy, and tolerance can develop over time, requiring greater and greater doses. Therefore, there is a compelling need for better therapeutic approaches. Since the ultimate problem in spasticity is the aberrant activation of motor neurons, strategies that directly reduce the activity of these cells may be therapeutic. Chemogenetics is one such option. This approach involves two components: 1) an engineered receptor that suppresses neuronal activity, and 2) a biologically inert drug (ligand) to activate the receptor. For spasticity, the strategy would be to express the receptor in the motor neurons driving spasticity. Oral administration of the ligand would then reduce spasticity in a dose-dependent manner. However, the ability of chemogenetics approaches to regulate the activity of spinal motor neurons has not previously been evaluated. We hypothesized that an engineered chloride channel that opens upon binding of the ligand, bradanicline, could hyperpolarize motor neurons and inhibit their activity, resulting in changes in ambulation and grip strength. To test this hypothesis, we used an adeno-associated virus serotype 9 vector to deliver the cDNA for this channel to the lumbar spinal cord. Expression of the cDNA was driven by a human synapsin promoter to limit expression to neurons. In order to identify a maximum tolerated dose of the vector, three doses (10^9, 10^{10}, and 10^{11} vg) were injected unilaterally, spread over five injection sites. For eight weeks, motor function was quantified using hindlimb grip strength measurements and BBB scores. By two weeks post-delivery, the highest dose produced significant deficits on the treat side that worsened over time. These deficits were accompanied by a substantial increase in Iba1 staining, suggesting toxicity caused by the receptor. The lower two doses were better tolerated, and the 10^{10} vg dose was carried forward for further testing. To demonstrate ligand-dependent inhibition of motor neurons, a second cohort was again injected unilaterally with the vector. Animals receiving an empty vector served as a control. Five doses of ligand were tested (0, 1, 10, 30, and 100 mg/kg body weight), delivered by oral gavage. Animals receiving the control vector experience no change in motor function at any dose of the ligand. Animals receiving the receptor exhibited dose-dependent reduction in grip strength and gait on the ipsilateral side, demonstrating that the motor system can be modulated using chemogenetics. Further experiments in a rat spasticity model will demonstrate the utility of this approach to treat this disorder.

115. Delivery of scAAV9.co*GM2A* for Phenotypic Correction of GM2 Gangliosidosis AB-Variant, in the Newly Characterized *Gm2a/Neu3* Double Knockout Mouse Model

Camilyn S. Cheng[1], Natalie M. Deschenes[1], Melissa Mitchell[2], Jagdeep S. Walia[1,2,3]

[1]Centre for Neuroscience Studies, Queen's University, Kingston, ON, Canada,[2]Pediatrics, Queen's University School of Medicine, Kingston, ON, Canada,[3]Kingston Health Sciences Centre, Kingston, ON, Canada

GM2 Gangliosidoses AB-Variant (ABGM2) is an autosomal recessive lysosomal lipid storage disorder characterized by an overaccumulation of GM2 gangliosides in neuronal lysosomes, ultimately resulting in neuronal cell death. This disorder arises due to a mutation in the *GM2A* gene, which encodes for GM2 Activator Protein (GM2AP), an essential cofactor in the hydrolysis of GM2 gangliosides. Overaccumulation of GM2 gangliosides and eventual neuronal cell death present as phenotypic symptoms of sensory, motor, and cognitive decline and ultimately result in a shortened lifespan. In its most severe and common 'infantile' form, death can occur as early as 4 years of age. Currently, there are no curative treatments available for ABGM2; however, due to the monogenic nature of this disease, the delivery of a gene therapy using an Adeno-Associated Virus expressing a codon-optimized *GM2A* transgene holds great promise to treat ABGM2. Previous *GM2A* transgene administration in *Gm2a*$^{-/-}$ murine models showed reduction in GM2 ganglioside accumulation as well as widespread vector biodistribution to the central nervous system; however, that

model does not accurately mirror the severe human form due to its normal lifespan. This has led to the creation and characterization of a *Gm2a*$^{-/-}$/*Neu3*$^{-/-}$ murine model in the Walia lab, which more closely parallels the symptoms and lifespan of the severe human form of ABGM2 as these mice die at approximately 27 weeks of age. This study aims to investigate the dose-response of intrathecal delivery of scAAV9.co*GM2A* in the newly characterized *Gm2a*$^{-/-}$/*Neu3*$^{-/-}$ murine model for the first time. 5 cohorts each containing 6 mice received intrathecal administration at 6 weeks of age of either vehicle or three different doses of vector per mouse - low (0.5e^{11}vg), medium (1.0e^{11}vg) or high (2.0e^{11}vg). Monthly behavioural testing and blood collections were performed starting at 8-weeks of age and were continued until either short-term endpoint of 27-weeks of age, or humane endpoint. At each respective endpoint, serum, gross organs and tissues from the central nervous system were collected for biochemical analysis of GM2 ganglioside accumulation, GM2AP activity, vector biodistribution, immune response and histology. Data will be shown to support the hypothesis that there will be a dose-dependent response in GM2 ganglioside accumulation, GM2AP activity, vector biodistribution to the central nervous system and improvement in behavioural outcomes in short-term and added survival benefits in long-term. Furthermore, immune responses will be tested through immunological assays. These results will provide more clinically translatable results on the efficacy and safety of scAAV9.co*GM2A* in the treatment of ABGM2.

Breaking Barriers to the CNS via AAV Capsid Engineering

116. Human Blood-Brain Barrier Receptor-Guided Rapid Evolution of AAVs for Brain Gene Therapy

Changfan Lin[1], Xinhong Chen[1], Yujie Fan[1], Erin E. Sullivan[1], Tomasz Gawda[1], Alex Jin Hyung Chung[1], Xiaozhe Ding[1], Bill Kavvathas[1], Lillian J. Campos[2], Cameron R. Jackson[1], Jonathan Hoang[1], Sripriya Ravindra Kumar[1], Andrew S. Fox[2], Timothy Shay[3], Viviana Gradinaru[1]

[1]Caltech, Pasadena, CA,[2]University of California Davis, Davis, CA,[3]CLOVER Center, Caltech, Pasadena, CA

Despite substantial advancements in technologies to genetically modify cells, the systemic delivery of such gene therapies to cells in the brain continues to present significant challenges. Our research focuses on developing brain delivery tools, specifically harnessing adeno-associated viral vectors (AAVs). These non-pathogenic vectors show some ability to cross the blood-brain barrier (BBB), yet there is considerable room for improvement in their efficiency, specificity, and performance across mammalian species. In recent years, many engineered AAVs identified through directed evolution have shown greatly enhanced brain efficiency and specificity in mice and non-human primates (NHPs) with systemic delivery. The ultimate clinical utility of these vectors in humans, however, remains unproven. In vivo directed evolution of AAV capsids involves transduction of an animal with a library of AAV variants, followed by selective recovery of those variants that effectively reach, for example, the rodent or NHP brain. Notably, this method is resource-intensive and achieves only limited success in translating performance to other species, due to receptor differences across species, including between NHPs and humans. In response, we have developed a fast and efficient in vitro capsid engineering strategy that focuses on directed evolution of AAVs to target human BBB receptors such as carbonic anhydrase IV (CA4), recently identified by our group (Shay et al. Science Advances, 2023). Notably, CA4 expression is primarily concentrated in the primate brain, rather than other organs, unlike previously-characterized BBB transporters. CA4's expression profile offers the potential for AAVs targeting it to have fewer off-target effects. Employing a hybrid approach integrating both cell-free (resin-based) and cell-based selection methods, we successfully isolated AAVs exhibiting specific affinity for human CA4 (huCA4). We validated our approach using known receptor-binder pairs targeting the rodent BBB receptors LY6A (Huang et al., PLOS ONE, 2019) and CA4 (msCar4). Three rounds of selection yielded a set of AAVs with enhanced binding to huCA4 via a specific N-terminal surface loop of huCA4. These AAVs exhibit increased infectivity in cell culture, improved BBB penetration in an in-vitro human BBB model, and broad transduction of neurons in human brain organoids. Finally, testing in huCA4-expressing mice confirmed enhanced receptor-mediated delivery to mouse brain cells in vivo. Overall, our work presents an animal-free pipeline to engineer human receptor-targeting AAVs in a shortened development timeline. The AAVs identified by this mechanism-driven strategy show promise for enhancing gene delivery efficiency across species, including to the human brain, an improvement over current mechanism-agnostic AAV development methods.

117. Identification and Characterization of STAC-BBB, an Engineered AAV Capsid That Exhibits Widespread Transduction of the Central Nervous System in Cynomolgus Macaques

Matthew R. Tiffany, Stephanye Frias, Lori Andrews, Ankitha Nanjaraj, Russell Darst, Stephen Wist, Satria Sajuthi, Yuri Bendaña, Hung Tran, Sarah Mueller, Bryan Zeitler, Amy Pooler, David Ojala

Sangamo Therapeutics, Inc., Richmond, CA

The blood brain barrier (BBB) is a stringent biological barrier that severely restricts central nervous system (CNS) delivery with naturally occurring AAV serotypes. Previously we described our SIFTER (Selecting In vivo for Transduction and Expression of RNA) platform for in vivo selection of engineered AAV capsids that mediate improved CNS delivery. Here we applied this platform to identify STAC-BBB, a novel AAV capsid that exhibits robust and widespread CNS transduction in cynomolgus macaques after intravenous delivery. Three rounds of in vivo library screening were conducted in cynomolgus macaques using the SIFTER method. In the third round of screening, three macaques were dosed intravenously with a multiplexed library of 1,260 capsids, each linked to at least four unique barcodes driven by either a neuron-specific human synapsin 1 or ubiquitous CMV promoter. Nucleic acids were isolated from CNS and peripheral tissues and the level of mRNA expression and DNA delivery mediated by

each capsid was assessed. STAC-BBB was identified as the highest performing capsid for CNS delivery across all performance metrics, mediating a 700-fold improvement in neuronal expression compared to AAV9. Moreover, enrichment in both neuronal and ubiquitous transcript expression was highly consistent in all CNS tissues and across all animals on study. CNS delivery was robust in 150 brain punches collected from key brain regions, across six coronal brain slices spanning the rostro-caudal axis, and along the entire length of the spinal column. STAC-BBB also demonstrated de-targeting of dorsal root ganglia and peripheral tissues. We additionally analyzed capsid performance across barcode replicates and counted the number of unique molecular identifiers linked to each barcode. All four STAC-BBB barcode replicates performed equally well, and thousands of unique molecular identifiers were recovered from CNS tissues. An individual evaluation of STAC-BBB in cynomolgus macaques is underway with results expected shortly. Study readouts include vector genome biodistribution, transgene expression levels, and single cell analysis of transduction efficiency.

118. Antibody-Based AAV Retargeting to Transferrin Receptor Mediates Efficient Blood Brain Barrier Crossing and *In Vivo* Gene Delivery to the CNS in Mice and Non-Human Primates

Kalyani Nambiar, Kyle Plasterer, Ammar Tareen, Pascaline Aime-Wilson, Nicole Keating, Caryn Galligan, John Dugan, Tazeen Ishmam, Anthony LoMastro, Min Gao, Aishwarya Shevade, Zhe Zhang, Sheldon Mink, Andrew David Tustian, Lynn Macdonald, Christos Kyratsous, Leah Sabin

Regeneron Pharmaceuticals, Inc., Tarrytown, NY

Adeno-associated virus (AAV) is a leading viral vector used in gene therapy to treat human diseases. Although AAV has many advantages as a gene therapy vector, some of the limitations to its use for disorders of the central nervous system (CNS) are the inability of wild-type AAV serotypes to efficiently cross the blood-brain-barrier (BBB) when delivered systemically, as well as their tendency to preferentially transduce the liver. The high AAV doses required to effectively transduce extrahepatic tissues have led to severe adverse events in patients, including liver toxicity and death. While directed evolution-based selection approaches are a powerful method to identify novel capsids with desired properties, the translatability of such capsids for human treatment remains challenging. Thus, we sought to develop a species-agnostic, modular AAV retargeting platform that utilizes rational capsid engineering and monoclonal antibodies to redirect AAV particles to cross the BBB, while minimizing off-target tissue transduction. We are using a protein tagging system to covalently attach antibodies to surface-exposed variable loops on the viral capsid. The tropism of the conjugated capsid can be further modified through the introduction of mutations in the amino acid residues that serve as primary determinants of AAV tropism. This allows detargeting from the liver while enhancing on-target specificity. We have successfully used this approach to retarget multiple AAV serotypes to specific cell types *in vitro* and *in vivo,* using the cellular target of the retargeting antibodies to drive the specificity of transduction. Transferrin Receptor 1 (TfR) is a conserved receptor expressed on the apical surface of brain endothelial cells that is known to facilitate transcytosis of cargo across the BBB. We demonstrated that multiple AAV serotypes can efficiently cross the BBB following systemic administration when conjugated to anti-TfR antibodies, achieving comparable CNS transduction to wild-type AAV9 at lower doses. One of the key features of our antibody-mediated AAV retargeting platform is the cross-species translatability of the approach. By targeting surface-exposed cellular proteins with conserved expression patterns between mice, non-human primates (NHPs), and humans, we aim to develop AAV vectors with predictable tropism and potency across species. We screened a panel of anti-human TfR fabs for their ability to mediate BBB-crossing and transduction of the CNS following systemic delivery in mice expressing human TfR and identified multiple fabs with a range of binding properties that facilitated potent AAV delivery to the brain. To demonstrate translation of TfR-mediated BBB crossing in a large animal model, we evaluated the retargeted AAVs in cynomolgus macaques. Importantly, after intravenous delivery, TfR-retargeted AAVs were significantly enriched in multiple brain regions, including in cortical, subcortical, and cerebellar tissues. TfR-retargeted AAVs were also markedly detargeted from the liver, heart, and dorsal root ganglion. Thus, our novel TfR-targeted AAV vectors dramatically outperformed AAV9 in both efficiency and specificity of CNS transduction. This modular, antibody-based AAV retargeting system represents a robust method to enhance delivery of AAV to the CNS by targeting a conserved receptor, while simultaneously reducing off-target tissue transduction to mitigate safety risks. We aim to apply this technology to the development of therapies for diseases of the CNS.

119. Continued Directed Evolution of VCAP-101 and VCAP-102 Identifies Second Generation Capsid Variants with Increased Brain Tropism and in Non-Human Primates and Mice

Tyler Moyer, Kristin Graham, Jiachen Liu, Xiaoqin Ren, Joseph Clement, Alexis Bloedel, Rebecca Spellman, Camila Arce, Hamza Khalid, Anupriya Kulkarni, Alexandra Tsolias, Rong Zhao, Wenya Yang, Amy Bruce, Chiso Egbuchulam, Tatianna Knox, Brett Hoffman, Ishan Shah, Michael Grannan, Charlotte Chung, Alexander Kutchin, Johnson Amy, Kyle Grant, Nilesh Pande, Jeff Thompson, Johnny Yao, Chanchal Sadhu, Todd A. Carter, Mathieu E. Nonnenmacher

Voyager Therapeutics, Cambridge, MA

The treatment of central nervous system (CNS) diseases by Adeno-Associated Virus (AAV)-mediated gene therapy has been hindered by the availability of AAV capsid variants capable of efficiently crossing the blood-brain barrier (BBB). We recently applied our RNA-driven TRACER™ capsid evolution platform to identify VCAP-101 and VCAP-102, members of a family of capsids with peptide insertions in Variable Region IV (VR-IV) of AAV9. These capsid variants demonstrate significantly increased CNS-tropism and liver de-targeting relative to AAV9 in non-human primates (NHPs) and mice. Here, we perform two further rounds of directed evolution to VCAP-101 and VCAP-102 to generate second generation (Gen2) capsid variants.

In a pooled, next generation sequencing (NGS) based screen, these Gen2 capsid variants showed up to 7-fold improved BBB-penetrance across broad CNS regions relative to the parental VCAP-101 or VCAP-102 capsids in NHPs. Upon intravenous dosing of cynomolgus macaques (*Macaca fascicularis*) with these Gen2 capsids expressing a self-complementary histone transgene at 3E13 vector genomes per kilogram (VG/kg), we observed upwards of 9 vector genomes per cell across broad CNS regions and upwards of 60% of cells being targeted, including both neurons and astrocytes. Gen2 capsids demonstrated further liver de-targeting relative to both the parental VCAP-101 and VCAP-102 capsids. Additional studies in mice reinforce the dual cell-type targeting of these Gen2 capsids. Furthermore, we identify the receptor for this family of capsid variants and demonstrate that the capsid-receptor binding is both specific and direct. Given the high conservation of this receptor across mammals, our data collectively suggest a novel, highly CNS-specific capsid for use in the clinic.

120. Second Generation AAV Capsids Reprogrammed to Bind Human Transferrin Receptor are Targeted to the Brain and De-Targeted from the Liver in Human TFRC Knock-In Mice

Ken Y. Chan, Qin Huang, Shan Lou, Casey Keyes, Jason Wu, Nuria R. Botticello-Romero, Qingxia Zheng, Chin-Yen Lin, Jencilin Johnston, Allan Mills, Pamela Brauer, Gabrielle Clouse, Simon Pacouret, John W. Harvey, Thomas Beddow, Jenna K. Hurley, Isabelle G. Tobey, Megan Powell, Catherine P. Pirtle, Albert Chen, Andrew J. Barry, Fatma-Elzahraa Eid, Yujia A. Chan, Benjamin E. Deverman

Broad Institute of MIT and Harvard, Cambridge, MA

Developing vehicles that efficiently deliver genes throughout the human central nervous system (CNS) will broaden the range of treatable genetic diseases. We developed a high-throughput *in vitro* screening approach to reprogram AAV9 to bind the human Transferrin Receptor (TfR1), a protein expressed on the blood-brain barrier (BBB). We showed that one TfR1-targeted capsid, BI-hTFR1, was actively transported across a human brain endothelial cell layer and achieved 40-50 times greater reporter expression in the CNS of human *TFRC* knock-in mice compared to AAV9 in wild type mice after intravenous delivery. The enhanced tropism of BI-hTFR1 was CNS-specific and absent in wild type mice (Fig. 1A). Through sequence diversification, we identified a second generation capsid, BI-hTFR1.2, that was capable of transducing more than 60 percent of NeuN-positive neurons in the cortex of human *TFRC* knock-in mice when dosed at 5E10 vg/mouse, while also being de-targeted from the liver (Fig. 1B). Similar to BI-hTFR1, BI-hTFR1.2 exclusively binds to human but not macaque or mouse TfR1. Using amino acid swaps between species, we pinpointed human-specific residues of TfR1 that are critical for the species-specific binding by BI-hTFR1 and BI-hTFR1.2. Importantly, there are no common human polymorphisms that would be predicted to directly impact the ability of these capsids to bind TfR1 in patients. Our work establishes these TfR1-targeting capsids as promising vectors for human CNS gene therapy.

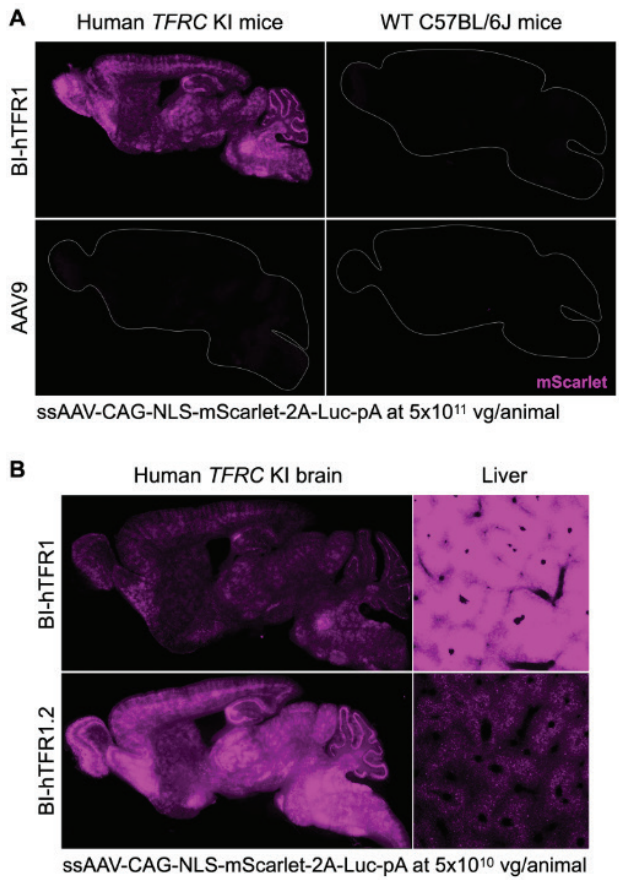

Figure 1. TfR1-targeted AAV capsids achieve efficient CNS-wide transgene expression in human *TFRC* knock-in mice. (A) BI-hTFR1 or AAV9 were intravenously injected into adult wild type C57BL/6J or *TFRC* knock-in mice at 5E11 vg/animal. Representative sagittal brain section images from three weeks post-injection are shown. **(B)** BI-hTFR1 or BI-hTFR1.2 were intravenously injected into adult *TFRC* knock-in mice at 5E10 vg/animal (~2.5E12 vg/kg). Representative sagittal brain and liver section images from three weeks post-injection are shown.

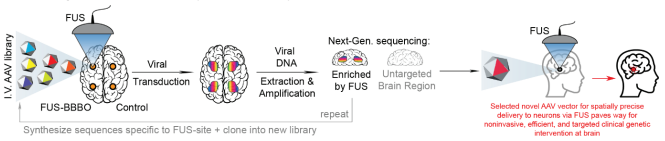

121. Engineering Viral Vectors for Acoustically Targeted Gene Delivery to the Brain across Species

Hongyi Richard Li[1], Jerzy Szablowski[2], Mikhail Shapiro[1]

[1]California Institute of Technology, Pasadena, CA,[2]Rice University, Houston, TX

Spatially targeted gene delivery to the brain has the potential to treat prevalent neurological and psychiatric diseases. However, the site-specific delivery of vectors such as adeno-associated viruses (AAVs) is typically performed via invasive injections, limiting scope of clinical applications. Over recent decades, focused ultrasound blood-brain-barrier opening (FUS-BBBO) has emerged as a noninvasive procedure enabling the site-specific entry of small viral vectors into the brain from systemic circulation. However, when used in conjunction with natural AAV serotypes, this approach has limited transduction efficiency, and results in undesirable transduction of peripheral

organs. In this project we employ in vivo evolution to develop new AAV serotypes with enhanced transduction at sites of FUS-BBBO and decreased transduction peripherally in rodents and nonhuman primates (NHPs). In our screening strategy, a library of AAVs with mutated capsids based on AAV9 is injected intravenously into hSyn1-Cre mouse and delivered via FUS-BBBO to one hemisphere. When a particular AAV variant transduces Cre-expressing neurons, its viral genome is modified, becoming detectable by a Cre-dependent PCR and next-generation sequencing (NGS). Repeated rounds of selection for vectors that uniquely appear in the targeted hemisphere led to desired novel AAV vectors (AAV.FUS) with 12.1-fold improvement in overall tissue specificity and above 56% improved neuronal tropism in brain. AAV.FUS's capability of improved FUS-mediated delivery to brain is validated across multiple murine strains. As a bonus, AAV.FUS has 2.5-fold improved transduction efficiency over AAV9 when delivered via intracranial injection. To develop improved viral vectors for FUS-BBBO in nonhuman primates (NHPs), we performed viral screening in macaques with a strategy similar to that of rodent model but introduced neuronal Cre expression through AAV9-hSyn1-Cre transduction due to lack of transgenic NHP. After two rounds of evolutions, 145 viral variants are selected for further screening based on their unique enrichment in acoustically targeted brain regions of NHP. Overall, this study shows that the molecular engineering of AAV capsids can lead to improved noninvasive, site-specific ultrasound-mediated gene delivery to the brain across different species, paving the way for large-scale disease model studies and potential future human clinical translation. Potential applications of noninvasive spatially targeted gene therapy include epilepsy, Parkinson's disease, chronic depression, obsessive compulsive disorder (OCD), and any other condition that is currently being treated with local ablation or DBS. By developing viral serotypes that more efficiently enter the brain at the site of FUS-BBBO, reducing the transduction of off-target organs, and reducing the required systemic dose, this work will greatly improve the safety profile and reduce the manufacturing cost of this class of therapies, making it more likely that they will benefit patients.

122. Directed Evolution of AAV9 Libraries in Non-Human Primates Identifies a Capsid Family with Enhanced Central Nervous System Tropism and Liver De-Targeting Following Systemic Delivery

Xiaojing Shi, Sean Gross, Michelle Ling, Reem Elteriefi, Zach Mason, Caden Holloway, Yixi Wang, Mark Chin, Kimberly McDowell, Brandon Wheeler, Nicholas Flytzanis, Nick Goeden, Susan Catalano

Capsida Biotherapeutics, Inc., Thousand Oaks, CA

Gene therapy for central nervous system (CNS) disorders has seen significant advancements, but achieving efficient and widespread CNS transduction by viral or non-viral vectors remains challenging. Local delivery of Adeno-Associated Virus (AAV) vectors to the CNS typically results in limited transduction, challenges in achieving therapeutic efficacy for diseases requiring systemic treatment and is associated with potential risks related to invasive delivery. Meanwhile, intravenous delivery of wild-type AAVs has limited brain tropism and toxicity risk due to off-target transduction in peripheral organs like the liver, presenting a significant opportunity for the development of engineered AAV capsids that can effectively cross the blood-brain barrier (BBB) while minimizing off-target transduction. We applied our high-throughput, non-human primate (NHP)-based AAV engineering platform for the directed evolution of an AAV9 capsid library and have generated capsids that overcome the limitations of these early gene therapy approaches. Following two rounds of intravenous dosing and screening, we identified several families of capsids with improved vector biodistribution across CNS regions compared to AAV9. Further evolution of these capsids, focusing on high CNS enrichment and liver de-targeting, led to the emergence of a capsid family with superior CNS tropism and liver de-targeting capabilities. One capsid was subsequently tested individually in cynomolgus monkeys by intravenous dosing. Compared to AAV9, this novel capsid showed a remarkable 137-fold improvement in transgene expression in the brain and a 16-fold decrease in vector biodistribution in the liver. Immunohistochemistry data confirmed that the novel capsid achieved extensive and neuron-specific transduction throughout CNS regions, including a 30% transduction in the frontal cortex, over 60% in the thalamus, and over 50% in the substantia nigra. Our work has identified a new family of CNS-tropic and neuron-specific AAV capsids with significantly decreased liver transduction, offering a promising avenue for effective and safe CNS-targeted gene therapies.

Strategies and Technologies for Advanced CMC

123. FDA and NIST Collaboration to Evaluate Assays and Control Materials for Characterizing Animal Biotechnology Products Generated by Genome Editing

Patricia Kiesler[1], Natalia Kolmakova[1], Sierra Miller[1], Sofiya Shevchenko[1], Stella Lee[2], Alexis Norris[2], Mayumi Miller[3], Adam Moyer[2], Samantha Maragh[1]

[1]Biosystems and Biomaterials Division, National Institute of Standards and Technology, Gaithersburg, MD,[2]Office of New Animal Drug Evaluation, US Food and Drug Administration, Center for Veterinary Medicine, Rockville, MD,[3]Office of Applied Science, US Food and Drug Administration, Center for Veterinary Medicine, Laurel, MD

Genome editing technology has revolutionized the ability to make targeted changes to an animal's genome (intentional genomic alterations or IGAs), offering exciting promise for the development of animal biotechnology products that address animal and public health needs. The U.S. Food and Drug Administration Center for Veterinary Medicine (FDA CVM) oversees regulation of such IGAs in animals that have been created using genome editing technologies. Characterization of these IGAs is an important part of the regulatory process to ensure that the edit to the animal is what it is intended to be and to

identify any unintended changes. However, there are currently no validated measurements and standards for characterizing unintended genomic alterations in animals. Most of the work to evaluate genome editing methods has been focused on human therapeutic use, and there is limited information available regarding their reliability and reproducibility for characterization of animal biotechnology products. To address these needs, FDA CVM has established a collaboration with the U.S. National Institute of Standards and Technology (NIST) that will generate resources including standardized measurements for characterizing both intended and unintended alterations in animal biotechnology products resulting from genome editing. These resources will provide animal biotechnology product developers and FDA regulators with example characterization approaches that they could use as part of the development and regulatory process for IGAs in animals as well as for validating methods, materials and/or data. Here, we present preliminary outcomes of this NIST-FDA CVM collaboration. NIST qualified commercially available swine and bovine cell lines and their DNA as potential control materials. The cell lines were characterized for genomic stability prior to editing, as well as for sequence by Sanger and NGS before and after genome editing. Multiple CRISPR/Cas9 editing assays, including two newly developed by NIST, were evaluated using purified animal DNA and the animal cell lines. Off-target sites identified from three in silico predictors and the biochemical assay CHANGE-seq were also compared. A subset of the off-target sites predicted by in silico tools were identified by CHANGE-seq and analyzed via targeted NGS for evidence of off-target editing in edited animal cells. Additionally, NIST onboarded the SITE-Seq off-target assay and did assay qualification and replicate analysis on human genomic DNA. SITE-Seq was found to perform similarly on animal genomic DNA as compared to human genomic DNA. Experimental design, protocols, datasets, and measurements that NIST generated will be published and made accessible to animal biotechnology product developers and the general public. Future work will focus on generating prototype DNA spike-in control materials to be used as controls for qualifying DNA sequencing methods that may be used for the detection of both intended and unintended genomic alterations in animal biotechnology products.

124. Purification Process Optimization of mRNA Lipid Nanoparticles via Microfluidic Platform to Improve Payload Distribution and Transfection

Xiang Liu, Fangchi Shao, Sixuan Li, Jinghan Lin, Yining Zhu, Tza-Huei Wang, Hai-Quan Mao

Johns Hopkins University, Baltimore, MD

Introduction Despite the extensive progress in lipid nanoparticle (LNP) composition optimization for tissue/organ targeting and therapeutic applications,[1] post-synthesis processing and purification have received limited attention. Commonly used LNP purification technologies include dialysis and tangential flow filtration (TFF); however, the composition stability during the purification process remains elusive and difficult to explore. Microfluidic technology has been successfully employed for the production of LNPs; the laminar flow within microfluidic channels facilitates integrated separation modules, enabling in-line purification, thus providing the unique opportunity to investigate the mechanism of LNP purification process in detail. By finetuning the flow rate and buffer conditions, and using the payload distribution detection method we previously developed,[2] we systematically studied LNP composition change during different purification programs, and aimed to ultimately optimize LNP purification process with improved payload distribution and transfection efficiency. **Materials and Methods** A widely used LNP formulation containing ionizable lipid SM-102, helper lipid 18:0 PC (DSPC), cholesterol, PEGylated lipid DMG-PEG2000, and fluorescently-labeled lipid TMR-PC (50:10:38.5:1.5:0.5, molar ratio) was formulated with Cy5-labeled mRNA using a T-junction at controlled flow rates according to our previously reported method.[2] The purification condition used in the microfluidic device was 1:24 volume ratio of LNP mixture to PBS buffer. Size and zeta-potential were determined by dynamic light scattering. Multi-color cylindrical illumination confocal spectroscopy (CICS) analyzed single-particle fluorescence burst quantification,[2] enabling particle classification and mRNA payload characterization. B16F10 cell line was used to assess the transfection efficiency of purified LNPs *in vitro*. **Results and Discussion** We utilized a microfluidic-based purification of LNPs via on-chip dialysis as illustrated in Figure 1A. We examined the effect of microfluidic dialysis flow rate from 0.5 to 50 mL/h on the quality of LNPs. As the flow rate increased, the polydispersity index (PDI) gradually decreased. The transfection efficiency peaks at 5 mL/h (Fig. 1B). Data from CICS analysis demonstrated that at 5 mL/h, the purified LNPs contained fewer empty particles and a higher average payload compared to those purified at 0.5 mL/h (Fig. 1E-G). These results suggest that a faster buffer exchange occurring at a higher flow rate may substantially reduce the composition drift and improve the uniformity of the payload distribution and transfection efficiency of LNPs.[2] This new microfluidic-based LNP purification platform and our results pave the way for further optimization of the LNP purification process and understanding of LNP structural features and their effect on transfection efficiency. **References** [1] X Hou, *et al.*, Lipid nanoparticles for mRNA delivery, *Nat. Rev. Mater.* 6: 1078 (2021). [2] S Li, *et al.*, Payload distribution and capacity of mRNA lipid nanoparticles, *Nat. Comm.* 13: 5561 (2022).

125. Recombinant Nuclease Cas9 for Therapeutic Genome-Editing - The GMP Manufacturer´s Point of View

Hans Huber
Biomay, Vienna, Austria

Genome editing with the CRISPR/Cas method has revolutionized molecular-biologic methods and the resulting therapeutic approaches. Nuclease Cas9 is an essential component of a recently market-approved therapy against sickle cell disease (SCD) and transfusion dependent beta-thalassemia (TDT). In this case study, we present an overview on the corresponding manufacturing campaign to supply those therapeutic programs with recombinant nuclease spCas9 under the requirements and conditions of current Good Manufacturing Practice (cGMP). Cas9 was expressed as a recombinant protein by using IPTG-induced *E. coli* culture as production system (pET/T7 promoter). A manufacturing process was developed and optimized, essentially consisting of fed-batch cultivation, high-pressure cell disruption, a three-step chromatography regime, formulation by ultra/diafiltration and final aseptic filling. Therapeutic nucleases for genome editing have to fulfill high and defined quality standards with respect of functionality/activity, homogeneity and purity. A set of analytical assays for routine in-process control and final quality control was developed and validated, and a respective list of specifications was defined. In addition, extended biochemical characterization of Cas9 was performed. Particular emphasis was put on the determination of the activity of Cas9 by application of an in-vitro potency assay. With respect to homogeneity, Cas9 aggregates and truncated variants thereof were characterized by high-performance size exclusion chromatography (HP-SEC). Long-term storage stability was shown to be sufficiently given by conducting multi-year stability studies. By performing forced degradation studies, the impact of extreme physico-chemical conditions on Cas9 potency was evaluated. For market submission, the performance of a manufacturing process is required to be validated. Exemplary data will be shown on critical quality attributes (CQA), down-scaled process characterization studies and their evaluation by statistical design of experiments (DOE). Finally, process validation was performed by conducting consecutive, full-scale and cGMP conform runs for process performance qualification (PPQ). In this comprehensive overview, the concepts, difficulties and results of late-stage clinical / pre-marketing manufacturing of GMP-grade recombinant Cas9 will be discussed.

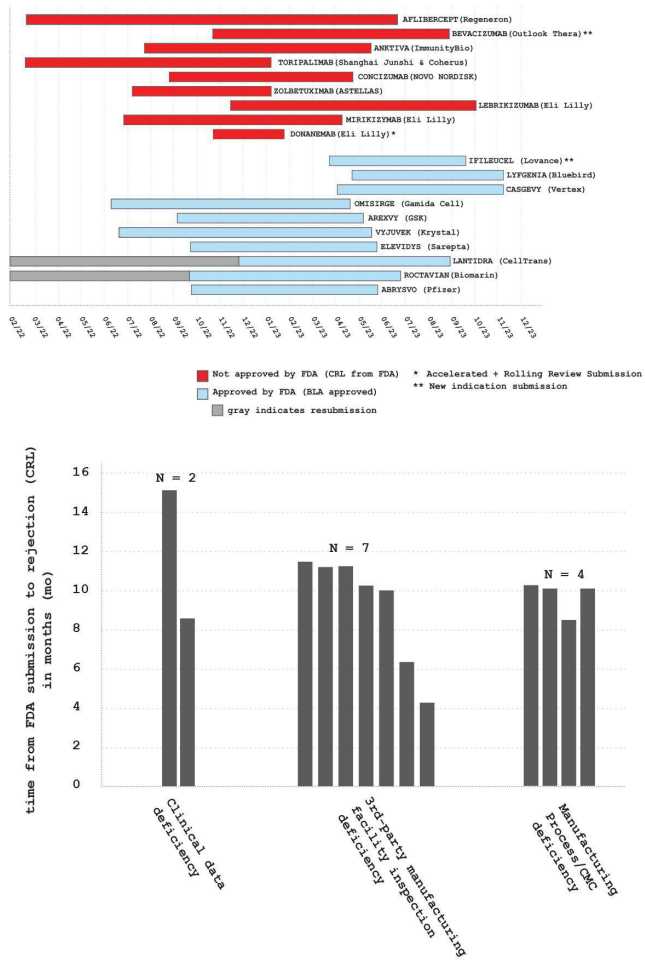
126. Addressing the Impact of RM Critical Quality Attributes and Variability on Complex Biologic Manufacturing

Nandu Deorkar
Avantor, Radnor, PA

The complex biologics such as gene therapy, cell therapy, multi-specific antibodies, oncolytic viruses, and fusion proteins are being pursued in clinical development to address various hard to treat diseases and conditions. The pipeline of these molecules is increasing significantly due to rapid understanding of underlying biology and new discovery tools. These therapies require efficient and cost-effective manufacturing processes to realize its benefits. There are many challenges that appear when scaling-up complex biologic products. The two most critical challenge includes (1) managing yield and quality and (2) addressing new impurities that are not seen during previous studies. The root cause of these includes limited understanding of the process, limitations of process steps due to properties of complex biologics and limited understanding of impact of raw material attributes on the process performance and product quality. Beyond attributes impacting the process, other impurities such nitrosamine, ethylene glycol, genotoxic impurities, and bioburden/adventitious agents, if not addressed in time, can delay the potential product entering into clinical/commercial phase. This presentation will discuss the critical quality attributes of various raw materials, impact of variability on the process and approaches to control variability and thereby improve complex biologic manufacturing processes. Specific case studies and lesson learned will be discussed by comparing and contrasting with traditional monoclonal antibody or recombinant protein manufacturing processes.

127. Validation of Rapid Microbial Testing in an Academic GMP Cell Therapy Facility

Kavya Hemmanur, Janaina Machado, Daniel J. Kota
Houston Methodist Research Institute, Houston, TX



The Ann Kimball and John Johnson Center for Cellular Therapeutics (KJCCT) is an academic GMP facility composed of ISO7 cleanrooms and a dedicated quality control laboratory. KJCCT focuses on the translation of cell therapy products from research to first in human trials. Overall, cell therapy products must undergo a series of testing protocols to ensure their safety, identity, quality, strength and purity before release for patient use. Rapid microbial methods are alternative methods that can detect microbial contamination faster than traditional testing methods and are easier to implement in-house and can provide quick turnaround time, lower sample volume requirements, and ability to be automated. Here we demonstrate the feasibility to validate 2 alternative rapid microbial methods for sterility and mycoplasma using a BioMerieux BACT/ALERT 3D Dual T - an automated microbial detection system, and the Biofire® Mycoplasma (NAT) system - a multiplex PCR-based system. Methods, Results & Conclusion: We used an Installation, Operation and Performance Qualification process to validate our rapid microbial methods. Briefly, we use microbial strains listed in USP <71> using the BACT/ALERT® 3D Microbial Detection System, and seven mycoplasma strains listed under USP <63>and performed the testing according to manufacturer's instructions. Results show that our validation efforts meet all the acceptance criteria related to the requirements for instrument qualification and growth promotion of all microbial and mycoplasma strains down to 10 and 2 CFUs respectively with detection times below 5 days and 2 hours respectively. In addition, we have successfully performed two product-specific matrix inhibitory interference testing for suitability. Therefore, our center is confident in only adopting the suitability qualification to confirm the Limit of Detection and Specificity for each product before using the alternative methods for cellular products, reducing testing time and significantly reducing cost.

128. Systematic Analysis of Primary Field Data from Biologics Therapy Regulatory Non-Approvals: Why Aren't We Talking About FDA Rejections?

Limin Wang[1], Andreia Domingues[2], Angela Johnson[3,4]

[1]Cytiva Global Regulatory Strategy, Marlborough, MA,[2]Cytiva Global Regulatory Strategy, Eysins, Switzerland,[3]Cytiva Global Regulatory and Compliance, Marlborough, MA,[4]Department of Professional Studies, Regulatory Science, Northeastern University, Boston, MA

Background While drug approvals are transparent and widely analyzed, comprehensive analysis of non-approval in complex biologics and cell and gene therapy (CGT) is lacking, in part, because unlike approvals no readily accessible public databases exist for non-approval actions. Non-approval trends, however, can inform future CGT development, offering a unique perspective to both drug developers and regulators in how to accelerate these, often complex, therapeutics to market. **Methods** Data were extracted by a single researcher and confirmed by a second independent researcher from primary sources for 2023 biologic drug approvals vs non-approvals, defined as Food and Drug Administration (FDA) Biologics License Application (BLA) 'Complete Response Letter' (CRL). Sources included public drug sponsor and regulatory websites (FDA.gov), and nonpublic data (i.e. news aggregators) were excluded for reliability. Resulting non-approvals (CRL) dates, manufacturer, candidate info, and codified (NVivo, QRS) CRL content were analyzed with SAS/GRAPH Proc GPLOT. **Results** Of 19 drug submissions (Fig.1) for approval (FDA BLA submissions), 10/19 (53%) received regulatory non-approval (FDA CRL). Heuristic coding on primary source data revealed that the basis for non-approval (Fig.2) were clinical (N = 2), 3rd party facility issues (N = 7), and manufacturing process (CMC) deficiencies (N = 4), with 1 non-approval reporting both CMC and clinical deficiencies, and 2 non-approvals reporting both CMC and facility inspection issues; with most facility and CMC non-approvals received as 10-11 months after filing, and clinical non-approval issues significantly later (up to 15 months after filing). Mean approval time to receive approval from FDA was 8.6±1.6 months vs non-approval (CRL) mean time was 9±2.5 months, excluding accelerated approval/rolling review cases which received non-approval approximately 6 months sooner than non-approval in conventional review. **Conclusions** Manufacturing site inspection issues and deficiencies in documentation (CMC) regarding manufacturing processes remain the leading cause of non-approval of novel biologics and CGT products, received 10 to 12 months after filing. To accelerate drug development in this space, earlier manufacturing review processed are needed, through collaboration between regulatory agencies, drug developers, and manufacturing equipment suppliers for novel biologic and CGT products. It remains to be seen if new FDA programs recently announced (Advanced Therapy manufacturing (AMT) and rare disease and gene therapy pilot programs modeled on Covid Operation Warp Speed and oncology Project Orbis successes) can accelerate these timelines and move the needle on time-consuming roadblocks for novel therapeutics.

Lipid Nanoparticles

129. PET Imaging of *In Situ*-Engineered CAR-T Cells in B Cell Lymphoma with ^{68}Ga-PSMA-11

Nisi Zhang, Jai Woong Seo, Elise Robinson, Angelie Rivera-Rodriguez, James Wang, Yutong Guo, Bo Wu, Spencer K. Tumbale, Marina N. Raie, Mohammed Inayathullah, Debra K. Czerwinski, Ronald Levy, Katherine W. Ferrara

Stanford University, Palo Alto, CA

Chimeric antigen receptor (CAR)-T cell therapy offers promising outcomes in the management of hematological malignancies. Current CAR-T cell *in vitro* manufacturing routes are complex, and the process duration and cost present significant barriers. While *in situ* engineering of T cells is being explored to include viral and non-viral vectors to modify ligands for T cell targeting, lipid nanoparticles (LNPs) offer a safe alternative with tunable particle size, surface chemistry, and ease of cargo loading. However, the effectiveness of LNP *in situ* CAR T cell engineering has not been extensively explored *in vivo*. Positron emission tomography (PET) is a molecular imaging

technique to depict biochemical processes in patients. Combined with a radiotracer specifically for CAR-T cells, PET monitors the activity and spatial distribution in the body. Herein, we use prostate-specific membrane antigen (PSMA) as the PET reporter transgene, with restricted expression in normal tissues, and the PET reporter gene-probe pair of PSMA and ^{68}Ga-PSMA-11. We developed aCD5 mPSMA/mCAR19 LNPs that encapsulate PSMA mRNA and anti-CD19 CAR-mRNA encoded with a flag tag. To evaluate the feasibility of CAR-T cell radiolabeling, we first treated an immortalized mouse T cell line (EL4) with LNPs, followed by ^{68}Ga-PSMA-11 incubation and measured radioactivity. The cells treated with aCD5 mPSMA/mCAR19 LNPs had significantly higher ^{68}Ga counts per minute (CPM) (p=0.016), compared to cells without treatment or treated with IgG mPSMA/mCAR19 LNPs. In *ex vivo* studies with mouse T cells, we found with flow cytometry that PSMA and CAR19 were co-expressed on T cells (5.6%), while PSMA and CAR19 single positive populations were 8.9% and 12.1%, respectively. For initial *in vivo* imaging studies, we encapsulated firefly luciferase mRNA (mFluc) in place of PSMA mRNA along with CAR19 mRNA into LNPs (aCD5 mFLuc/mCAR19 LNPs) and tracked the bioluminescence signals using *in vivo* and *ex vivo* imaging. We observed positive FLuc expression in lymphoid organs, particularly in the spleen. Additionally, we treated the mice with aCD5 mCAR19 LNPs and performed immunophenotyping analysis of the organs for CAR19 using spectral flow cytometry. We showed enhanced LNP binding (65.2%) and CAR19 expression (11.64%) in the CD3$^+$ T cell population in the spleen, as compared with non-treated controls or IgG mCAR19 LNPs (0%) at 24 h post treatment. Meanwhile, CD11c$^+$ dendritic cells and F4/80$^+$ macrophages had low levels of LNP binding (<5%) and CAR19 expression (<2%), and other immune cells remained unaffected. Furthermore, in CD19$^+$ A20 tumor-bearing mice (a B cell lymphoma mouse model), treatment with aCD5 mCAR19 LNPs resulted in a significant increase in chemoattractant and pro-inflammatory cytokines in blood, and infiltration of T cells and other immune cells in tumors, compared to the non-treated group, demonstrating potential efficacy of *in situ*-engineered CAR-T cells. In conclusion, our studies have shown an LNP transfection system that can load mRNA for imaging with different modalities and CAR19 mRNA for co-expression in T cells. While we have demonstrated in vivo imaging to track T cells based on the expression of Fluc, our initial in vitro studies showed the potential to quantitatively track T cells with 68Ga-PSMA-11 paired with PSMA mRNA. This strategy allows for active surveillance of the level of CAR-T cells (Fig. 1).

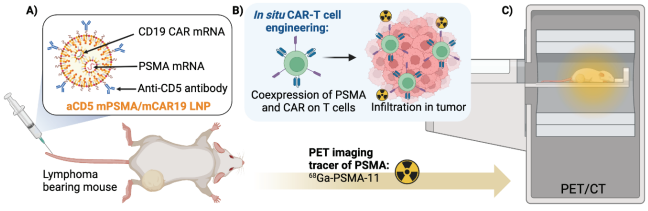


Fig 1. Schematic graph illustrates PET imaging of *in situ* engineered CAR-T cells. A) LNP vehicle is composed of DSPC, DSPE-PEG2000, Lipid 8, cholesterol and DSPE-PEG5000 conjugated with anti-CD5 antibody. The aCD5 mPSMA/mCAR19 LNP encapsulates PSMA mRNA and CAR19 mRNA encoded with a flag tag. We also prepare IgG mPSMA/mCAR19 LNP as the control with no T cell targeting. **B)** In a B cell lymphoma mouse model, we administer aCD5 mPSMA/mCAR19 LNPs to *in situ* engineer T cells expressing CAR19 and PSMA. **C)** Combined with CT scanning, PET imaging with ^{68}Ga-PSMA-11 monitors CAR-T cell spatial distribution in the body.

130. COATSOME® SS Series: Highly Versatile Ionizable Lipid as Vital Component of Lipid Nanoparticle for Gene Therapy and Vaccine Application

Ryosuke Fukuda[1], Shinya Tamagawa[1], Yuta Nakai[1], Hiroki Tanaka[2], Hidetaka Akita[2]

[1]NOF Corporation, Kasawaki, Japan,[2]Graduate School of Pharmaceutical Sciences, Tohoku University, Sendai, Japan

BACKGROUND: Nucleic acid vaccines, DNA and messenger RNA (mRNA), have emerged as promising modalities for infectious disease and for cancer immunotherapy due, in part, to shortened manufacturing cycles and high potency. Lipid nanoparticles (LNP) composed of ionizable lipids are important components of such vaccines as they can convey and present the nucleic acid effectively to the immune system. However, toxicity of ionizable lipids and the challenges of cold chain logistics of LNP have limited their clinical use. Further development of LNP requires 1) a reduction in the systemic toxicity, 2) improved endosomal escape, 3) potent and cytotoxic T-cell specific adjuvating function, 4) improved stability at room temperature. *RESULTS:* We have previously demonstrated that LNPs composed of our biodegradable ionizable lipids (COATSOME® SS series), can deliver pDNA or mRNA in mice to the liver or the solid tumor via intravenous injection and achieve high levels of expression with less toxicity. Here, we describe their potential applications for tissue-specific gene therapy and mRNA-based vaccines. First, we finely tuned the LNPs formulation to achieve liver or spleen delivery and tissue-specific mRNA expression via intravenous injection. In addition, subcutaneous administration of ovalbumin (OVA)-encoding mRNA encapsulating LNPs composed of ssPalm-O-Phe (COATSOME® SS-OP) induced higher anti-OVA antibody production than a counterpart of globally-marketed ionizable lipid. This result implies high vaccination effects for infectious disease. Furthermore, addition of ssPalm E-P4C2 (COATSOME® SS-EC), another type of our ionizable lipids, significantly improved cytotoxic T-cell activity as a cancer vaccine. Next, we demonstrated that our SS-lipid formulation clearly suppressed the tumor growth in a mouse model of disseminated malignant diseases. In addition, we successfully delivered LNPs containing SS-EC to the spleen efficiently, and they induced high levels of cytotoxic T-cell activity. Thus, SS-EC would be used as a promising material for spleen-targeted cancer vaccines. Importantly, our LNPs with attractive functions were found to be stable as a freeze-dried formulation at room temperature for at least 3 months. *CONCLUSION:* We here demonstrate that SS-lipid bearing LNPs stimulate humoral or cellular immune responses, in particular, remarkably high cytotoxic T-cell responses and the spleen-selective cytotoxic T-cell responses. These responses were shown to be effective in limiting growth of tumor cells in a disseminated disease model. Furthermore, we achieved the development of freeze-dried LNPs which were stable for at least 3 months at room temperature, potentially leading to avoiding the cold-chain limitation of conventional mRNA vaccines.

131. Map the Formulation Space of Lipid Nanoparticles (LNPs) Using Microfluidic Assembly in the Intraperitoneal (IP) Administration of RNA Therapeutics

Farhana Islam[1], Ling Ding[2], David Oupicky[2]

[1]Biochemistry and Molecular Biology, University of Nebraska Medical Center, Omaha, NE,[2]Department of Pharmaceutical Sciences, University of Nebraska Medical Center, Omaha, NE

Purpose: Pancreatic cancer (PC) is a challenging disease with limited treatment options and a poor prognosis. Despite progress in chemotherapy and targeted therapies, treatment remains difficult. A promising approach is utilizing lipid nanoparticle (LNP) technology for delivering therapeutic mRNA to pancreatic cancer cells. This technology enables specific mRNA delivery to cancer cells, enhancing effectiveness with fewer side effects than traditional therapies. Our goal is to synthesize and characterize LNPs optimized for mRNA delivery to pancreatic cancer cells, aiming to advance the development of mRNA-LNP as a potential therapeutic approach for PC. *Methods:* A microfluidic system was utilized in the development of the library of mRNA-LNP formulations, where various parameters were modified to optimize the formulations. To characterize the formulations, their size, polydispersity index (PDI), encapsulation efficiency (EE%), and stability were assessed using DLS and ribogreen assay. Additionally, the cytotoxicity of the formulations was evaluated by CTB assay on KPC8060 cell lines. Cellular uptake was investigated by luciferase assay and *in vitro* tumor spheroid penetration was observed under confocal microscopy by delivering GFP mRNA. *In vivo* biodistribution of mRNA-LNP formulation was examined in both healthy and tumor-bearing c57BL/6 mice and tracking performed using in vivo imaging system (IVIS). Luciferase mRNA was employed to assess mRNA delivery and expression in various organs. In the tumor mice model, orthotopic pancreatic tumor implantation was performed, and LNP formulations were administered upon reaching a specific tumor size. We also conjugated a peptide as a targeting moiety to one of the lipids used in the LNP synthesis. *Results:* The modification of process parameters had a notable impact on the size, PDI, and EE%. The resulting LNP formulations have demonstrated stability and reproducibility in terms of size, PDI, and EE%. LNP formulations exhibited significant cellular uptake when compared to free mRNA uptake. Both formulations showed efficient penetration of tumor spheroids, ensuring successful delivery of the mRNA payload *in vitro* (Fig 1). *In vivo* experiments conducted on healthy and tumor-bearing mice reveal that both LNP3 and LNP4 formulations exhibited distribution to the pancreas. Additionally, LNP4 demonstrated a significant presence in the liver, while LNP3 showed distribution to the tumor (Fig 2). The peptide-lipid conjugation was initially confirmed by thin layer chromatography. *Conclusion:* The utilization of a microfluidic system for the mRNA-LNP formulation development, coupled with the optimization of process parameters, has yielded promising outcomes concerning their physicochemical attributes, cellular uptake, tumor spheroid penetration and *in vivo* biodistribution to pancreatic tumors. As part of our future work, we aim to incorporate the peptide conjugated lipid into the LNPs to enhance their specificity for pancreatic tumor delivery.

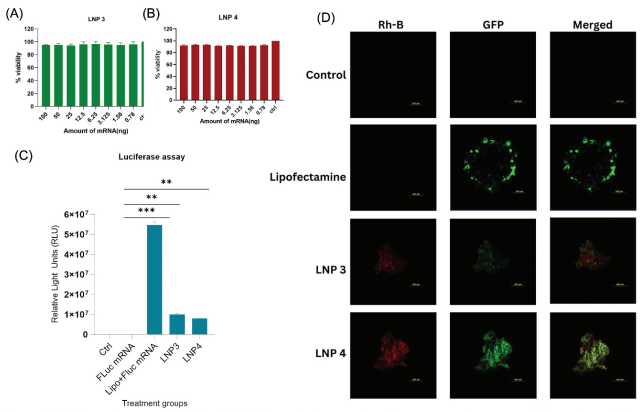

Figure 1: Cell-based assays of LNP3 and LNP4 formulations conducted on pancreatic cancer cell line. Cytotoxicity assessment, as determined by the CTB assay on KPC8060 cell line, indicates the impact of LNP3 (Fig. A) and LNP4 (Fig. B) formulations compared to untreated (control) cells. The study involves a range of mRNA concentrations from 0.78 ng to 100 ng (C). Furthermore, the cellular uptake of LNP formulations is explored through luciferase assay, comparing it with lipofectamine-treated mRNA uptake and free mRNA uptake. (D) The *in vitro* tumor spheroid penetration capacity of LNP formulations is also evaluated, and the level of penetration is compared with lipofectamine-treated mRNA using post-treatment confocal imaging and z-stacking. N=3 biological replicates, scale: 100 μm.

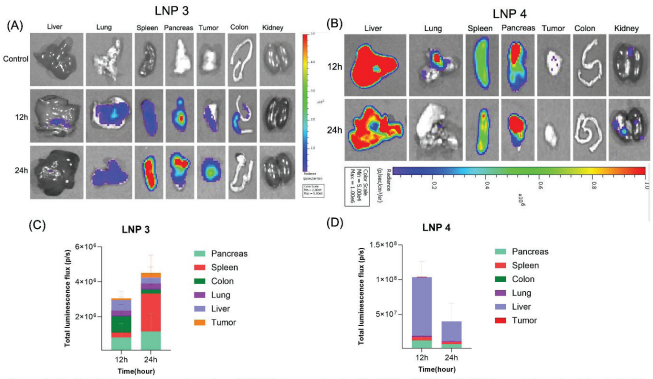

Figure 2: Biodistribution assay conducted on C57BL/6 tumor mice (n=3) utilizing LNP3 and LNP4 formulations, both loaded with fLuc mRNA. Orthotopic tumor implantation in pancreas was done and ultrasound was used to detect tumor size. When the tumor reached to a specific size, the mice treated with fLuc mRNA LNP formulations. Following post-treatment incubation, the animals were euthanized, and their organs such as pancreas, spleen, colon, lung, liver and tumor were collected for imaging. The expression of mRNA in various organs was assessed using an in vivo imaging system to track the biodistribution of LNP3 (Fig. A) and LNP4 (Fig. B) formulations. The total luminescence flux in different organs was quantified and is presented in Fig. C and Fig. D for LNP3 and LNP4 formulations respectively, with analysis conducted using living image software.

132. *In Vivo* RNA Delivery to T Cells and Hematopoietic Stem Cells in Humanized Mice and Non-Human Primates Using Targeting Lipid Nanoparticles

Rahul Palchaudhuri[1], Mohit Gupta[1], Michael T. Monte[1], Lorenzo Tozzi[1], Yu Cao[1], Han Gu[1], Rebecca Levy[1], Apiwat Wangweerawong[1], Lei Liu[1], Laura Saunders[1], Rebecca L. [1]Tessera Therapeutics, Somerville, MA,[2]DFCI, Boston, MA,[3]Boston Children's Hospital, Boston, MA

Non-viral *in vivo* delivery of genetic medicines could unlock new therapeutic areas and provide broader patient access. However, the success of *in vivo* delivery is dependent on the development of safe delivery vehicles capable of transporting the genetic medicines to their intended target tissues and cells. In recent years, lipid nanoparticles (LNPs) have emerged as a powerful *in vivo* delivery platform for RNA therapeutics to reach the liver, but efficient delivery to extrahepatic tissues remains a challenge. Tessera Therapeutics is developing novel LNPs designed to deliver RNA-based gene-modifying payloads to both T cells and HSCs *in vivo.* We have taken a multi-pronged approach to design our LNPs to target a desired tissue type. First, we optimized lipid chemistry and composition to skew biodistribution and facilitate endosomal escape. Second, we added specific cell targeting moieties to enable cell-specific delivery. By combining passive and active targeting strategies, we have observed efficient delivery to T cells and HSCs in preclinical mouse and non-human primate (NHP) models. *In vivo* delivery was assessed with LNPs containing Green Fluorescent Protein (GFP) reporter mRNA. Using our novel T cell-targeting LNPs, we demonstrated successful single-dose *in vivo* delivery of GFP in humanized mouse models generated from immunodeficient NSG mice. In NSG mice pre-engrafted with human HSCs for 12-weeks, GFP expression was observed in 34% of splenic T cells with minimal expression in both monocytes and B cells. In NSG mice pre-infused with human T cells for 14-days, GFP expression was observed in ~80% of splenic T cells. We also demonstrated successful GFP delivery in rhesus macaque, with a single dose leading to ~40% expression in peripheral T cells with negligible GFP expression in B cells. We also evaluated our Gene Writer in combination with a beta-2 microglobulin (*B2M)* template in a single dose of LNP and observed a ~30% knockout of *B2M* in T cells through a specific rewrite. Separately, we are developing HSC-targeting LNPs. In humanized NBSGW mice, HSC-targeting LNPs with a single dose led to dose-dependent delivery with GFP expression observed in over 90% of long-term HSCs (LT-HSCs defined as Lin-CD34+CD38-CD90+CD45RA- cells). With further improvements to the LNP, we also achieved over 90% GFP expression in long-term HSCs in NHPs. We then evaluated our Gene Writer in combination with B2M template in a single dose of LNP, where we observed ~15% *B2M* knockout in LT-HSCs of humanized mice after a single dose. **Together**, we believe these *in vivo* delivery results demonstrate our LNP delivery platform may be capable of efficiently delivering RNA payloads to T cells and HSCs, providing a potential delivery platform for *in vivo* genome engineering.

133. Machine Learning-Guided Optimization of Lipid Nanoparticle Composition for B Cell Transfection

Wu Han Toh, Leonardo Cheng, Gene Weng, Charles Shin, Ataes Aggarwal, Hai-Quan Mao
Johns Hopkins University, Baltimore, MD

Statement of Purpose: B lymphocytes (B cells) play a critical role in adaptive immunity, making them an important target for gene therapies. Despite this, efficient delivery systems for B cell transfection have yet to be developed. Lipid nanoparticles (LNPs) have emerged as promising non-viral vectors for immune cell delivery; however, they require extensive optimization across a complex design space - a task where manually directed approaches have proven insufficient[1]. Here, we build and deploy an iterative machine learning (ML)-guided screening platform to rapidly and exhaustively optimize LNP composition for B cell transfection *in vitro*. From a base library screening, we select, train, and refine high performing ML algorithms that predict transfection outcomes as a function of LNP design features[2]. Then, based on these predictions, we leverage Bayesian optimization to search for new test formulations, focusing on areas with the greatest transfection potential. We evaluate whether an *in silico* guided approach can uncover LNP formulations with improved experimental transfection. **Methods:** To generate a diverse LNP library for ML training, we used DLin-MC3-DMA as the ionizable lipid, cholesterol, DMG-PEG2000, and one of six helper phospholipids with varying charge. We varied four parameters, as previously described[1]. In total, 486 LNP formulations were screened for *in vitro* transfection efficiency in Ramos B cells using luciferase reporter mRNA. The sci-kit learn package (1.2.2) was used to conduct model training and prediction on a panel of tree-based, linear, and least squares regression models. Helper lipids were parameterized using select chemical features, and the data underwent 5-fold cross-validation with an 80-20 train-test split, optimized through randomized grid search to minimize mean absolute error. Gaussian process-based Bayesian Optimization via Scikit-Optimize (0.9.0) was used to suggest 15 *de novo* LNP formulations to test per helper lipid, using expected improvement (EI) to trade-off exploration and exploitation. **Results:** A total of 486 LNP formulations were screened for *in vitro* transfection in Ramos B cells, yielding a diverse library for robust ML model training (Fig. 1A, B). Of models tested, XGBoost (XGB) demonstrated the best predictive ability, achieving impressive Pearson's correlations (r = 0.91), and Spearman's rank (r = 0.89) on hold-out datasets (Fig. 1C). Feature importance analysis, using Shapley Additive Explanations, reveals structure-function relationships successfully learned by our model (Fig. 1D). Side-by-side experimental validation of ML-optimized test formulations yielded higher overall transfection efficiency compared to grid-screened formulations (Fig. 1E), with the top ML-optimized formulation achieving a 1.36-fold increase in RLU, 500% of the transfection signal benchmarked against the top-grid-searched formulation (Fig. 1F). Our platform efficiently tunes LNP formulation composition (Fig. 1G), achieving significant improvement over conventional screening.

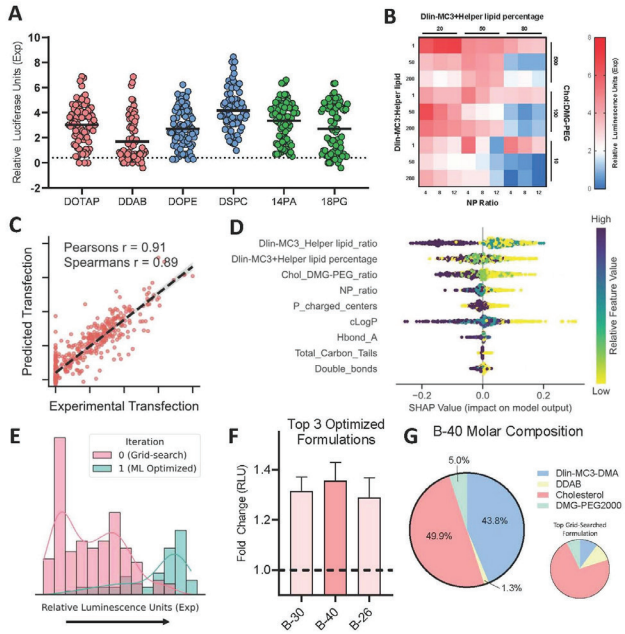

Figure 1. (A–B) Initial grid-based library screen of *in-vitro* Ramos transfection. (C–D) Model training and evaluation. (C) Experimental ground-truth vs. optimized XGB model-predictions on hold out set. (D) SHAPley feature importance beeswarm plot. (E–G) Experimental validation of ML-optimized test formulations. (E) Overall RLU distribution of optimized vs. grid-screened formulations. (F) Fold change in RLU of top 3 optimized LNPs over top grid-screened formulation. (G) Molar composition of top optimized LNP.

Conclusion: This platform is the first to use an ML-guided approach for screening LNP compositional ratios. This platform can be iterated to further increase transfection and can be adapted to optimize delivery to other historically hard-to-transfect cell-types. **References:** 1. Zhu Y, *et al.* **Nature Commun**. 2022;13:4282. 2. Cheng L, *et al.* **bioRxiv**. 2023. [Preprint]. Available from: https://doi.org/2023.12.07.570602

134. Formulation Optimized Circular RNA-LNP Vaccines Elicit Enhanced Immune Responses Against SARS-CoV-2

Edo Kon[1], Niv Cohen[1], Maya Shlosberg[1], Sofiya Pashko[1], Roi Mashiach[1], Bo Hu[2], Xiaowen Zou[2], Mengyao Zheng[2], Siqi Li[2], Emma Pan[2], Weiyi Zhang[2]

mRNA Lipid Nanoparticles (LNPs) have emerged as an essential vaccine platform due to their success in the recent COVID-19 pandemic. The RNA-LNP platform is effective and, among other advantages, is modular regarding the ability to encapsulate different antigen encoding RNA sequences in the same LNP formulation. LNPs comprise a lipid formulation typically containing a phospholipid, cholesterol, PEG-lipid and an ionizable lipid, in varying molar ratios. Beyond mRNA, the covalently-closed structure of circular RNA (circRNA) prevents the degradation by exoribonucleases, therefore, leading to an intrinsic stability. This stability results in a more robust protein expression which, in a vaccine context, can correlate with improved immune responses. Furthermore, the circRNA structure may require formulation optimization that differs from optimal formulations for linear mRNA payloads. To optimize a circRNA-LNP vaccine formulation, a Design of Experiment (DoE) approach was used to maximize vaccine immunogenicity. The optimization was performed by altering the LNPs' lipid molar ratios without altering the lipid component identities. To determine the prophylactic vaccine efficacy, circRNA-LNPs coding for the SARS-CoV-2 receptor-binding domain fused to an Fc sequence (RBD-Fc) were utilized. Animals were intramuscularly administered with the circRNA-LNP vaccines and probed for serum IgG and antigen-specific cellular responses against the SARS-CoV-2 Spike glycoprotein as well as live-virus neutralizing titers. We demonstrate increased anti-Spike IgG titers in circRBD-Fc-LNP vaccinated animals compared to linear modified mRNA RBD-Fc-LNPs (Fig B). Furthermore, we show that by optimizing the LNP formulation we substantially enhanced both the virus neutralizing titers and antigen-specific cellular responses (Fig D, E). In conclusion, we have optimized a vaccine formulation capable of substantially enhancing the immunogenicity of circRNA-LNP vaccines. The optimized formulation enables a significant reduction in the administered dose while maintaining the circRNA-LNP vaccine efficacy. This advantage can mitigate vaccine related-reactogenicity and toxicities and may enable the development of vaccines against antigens that require a more profound expression profile.

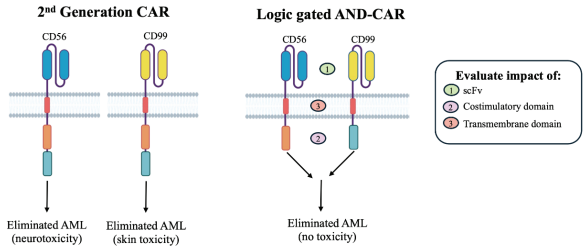
135. Development of a Novel "CLAMP" Platform for Scalable Preparation of Antibody-Conjugated Lipid Nanoparticles for T Cell-Targeted mRNA Delivery

Xi Zhu, Hong Chen, Jiaming Ren, Dalang Li, Chenxi Hou, Shin-Shay Tian, Xiaoping Zhao
Shanghai Vitalgen Biopharma, Shanghai, China

The advent of antibody-conjugated lipid nanoparticles (LNPs) for targeted delivery of nucleic acids has emerged as a compelling strategy for developing immuno and genomic therapies. This approach combines the robustness of LNPs as nucleic acid carriers with the specificity afforded by the conjugated antibodies, enabling precise and targeted delivery to the extrahepatic tissues. This approach has in particular, been validated by the encouraging proof-of-concept results of the T cell targeted LNPs (tLNPs) encapsulating CAR encoding mRNAs, resulting in the in-situ generation of functional CAR-T cells. However, the technical challenges associated with the reported tLNPs preparation methods, such as maleimide conjugation and post-insertion, have hindered the scale-up of LNP production and translational development. In response to these challenges, we developed a Controllable Ligand Attachment Modification and Purification (CLAMP) platform, an innovative technology tailored for the manufacturing of tLNPs. CLAMP integrates the processes for surface conjugation and purification of tLNPs, by incorporating systematically optimized components such as chemical linkers, surface anchors, site-specific residues engineered onto antibodies, coupling reactions, and purification processes. This platform simplifies complex conjugation procedures, ensuring compatibility with the standard LNP manufacturing processes. Applying the CLAMP technique, we successfully prepared anti-human CD5 antibody-conjugated LNPs (CD5-tLNPs) for T cell-targeted mRNA delivery. In the *in vitro* transfection studies, CD5-tLNPs exhibited high transduction efficiency in CD5-expressing Jurkat cells, with positivity exceeding 95%, while positivity for the human hepatic cell line HepG2 remained below 7%. Studies with unstimulated human peripheral blood mononuclear cells (PBMCs) demonstrated remarkable T cell specificity, with approximately 30% positivity in T cells and less than 1% in other evaluated immune cell types. To assess the robustness of the CLAMP technique, multiple independent batches of CD5-tLNPs were produced and tested. The high quality and consistencies of the different batches were confirmed by the physicochemical parameters evaluated and the consistent results from the *in vitro* transfection studies. In a stark contrast, the CD5-tLNPs prepared using the conventional maleimide conjugation method exhibited significantly greater batch-to-batch variations. To further demonstrate the T cell targeting efficiency of the CD5-tLNPS prepared by CLAMP, *in vivo* studies were conducted in hPBMC-engrafted NSG mice and CD5 humanized transgenic (hCD5) mice, employing tdTomato mRNA as a reporter. Expressions of tdTomato in subsets of cells in the peripheral blood and various tissues were assessed with flow cytometry 24 hours post-intravenous administration. In the hPBMC mouse study, 27.5% of the peripheral blood T cells expressed the tdTomato, contrasting with 0.23% in the CD5 antibody-negative LNP control group. In the hCD5 mouse study, tdTomato expression were observed in 32.9%, 10.3%, and 7.0% of the T cells isolated from the peripheral blood, spleen, and liver, respectively. In contrast, only 2.1%, 0.4%, and 0.9% of the T cells from the corresponding tissues did so. Notably, in the liver of the CD5-tLNP treated group, we observed a significant decrease in CD3 off-target cell positivity (7.7%) compared to the CD5 Ab negative LNP group (36.1%). In summary, we have shown that the novel CLAMP platform consistently produced fully functional and scalable antibody-conjugated tLNP preparations that could be adapted to clinical applications.



Genetically Modified Immune Cells for AML and Solid Tumors

136. Logic Gated CAR T Cells Targeting Acute Myeloid Leukemia Effectively Clear Leukemia While Mitigating Skin and Neuronal Toxicity

Phoebe Duong, Mark E. Kohler
University of Colorado, Anschutz Medical Campus, Aurora, CO

Chimeric antigen receptor (CAR) expressing T-cells have demonstrated remarkable efficacy in inducing minimal residual disease (MRD)-negative remissions in pediatric patients with relapsed and/or chemotherapy refractory acute lymphocytic leukemia (ALL). CAR T cell therapy for myeloid leukemias, however, has not demonstrated the same level of clinical success. There are multiple factors that may limit the effectiveness of CAR T cells in AML, such as clonal heterogeneity, a more suppressive cytokine milieu, and increased toxicity when targeting lineage restricted antigens. Furthermore, there is mounting evidence that leukemia stem cells (LSC) are drivers of relapse and chemotherapy refractoriness in AML patients, making this an essential population to target. However, many of the putative antigens that define LSCs are expressed on non-malignant cells of vital tissues, making them unsuitable for current CAR T cell strategies. Logic gated CAR T cells have the potential to overcome the lack of tumor-specific antigens through the targeting of unique combinations of antigens that are restricted to malignant cells and absent from healthy tissues. To this end, we evaluated an AND-CAR design to target AML antigens while mitigating on-target/off-tumor toxicity. Preclinical testing of logic gating strategies is limited by a paucity of syngeneic CAR T cell models where targeted antigens are present on normal tissues. Furthermore, testing of logic gating in xenograft models frequently evaluates responses to tumors engineered to express a single antigen, however, the continuous growth of tumors makes it unlikely for these models to fully capture the impact of off-target leakiness of logic gated CAR on normal tissues. To interrogate the efficacy of our AND-CAR strategy, we took advantage of two scFv's that targeted human AML antigens and cross-react with murine antigens expressed in normal tissues. We first generated a 2nd generation CAR using a cross-reactive scFv targeting CD56, which eliminated human AML from xenograft models, but led to lethal neurotoxicity in mice. Similarly, a 2nd generation CD99 CAR with a cross-reactive scFv was effective at eradicating AML but caused an inflammatory infiltrate in the skin of the paws of mice. Using an AND-CAR targeting CD56 and CD99, in which costimulatory domain and CD3z domain were expressed on two separate CAR molecules, we were able to clear human AML from mice without the off-tumor toxicity to the brain or skin. We further

investigated the factors important to the function of our AND-CAR and found enhanced in vitro and in vivo function when incorporating a 4-1BB costimulatory domain but no differences when examining combinations of transmembrane domains. Unexpectedly, we found the combination of scFv and signaling domain had a large impact on AND-CAR function. In conclusion, we have developed a model to leveraged cross-reactive scFv's to interrogate logic gating strategies for efficacy and on-target/off-tumor toxicity to healthy tissues and have begun to define the key aspects of CAR design which impact the success of logic gating.

137. Development of Extracellularly Linked Concatemeric Trivalent Cytokine (ELeCTriC) Chimeric Antigen Receptor (CAR) T-Cells as Dual Conditioning and Immunotherapeutic Agents

Quenton R. Bubb[1], Mohammad Balood[2], Gabe E. Seir[2], Leah Swartzrock[3], Ethan Haslett[2], Katie Ho[2], Saida G. Wiltz[3], Elena Sotillo[2], Rebecca M. Richards[4], Tanja A. Gruber[2], Crystal L. Mackall[2], Agnieszka Czechowicz[3]

[1]Stem Cell Biology and Regenerative Medicine, Stanford University, Stanford, CA,[2]Pediatrics, Stanford University, Stanford, CA,[3]Stanford University, Stanford, CA,[4]Pediatrics, University of Wisconsin-Madison, Madison, WI

Pediatric acute myeloid leukemia (AML) is a heterogenous disease of the hematopoietic system in which hematopoietic stem and progenitor cells (HSPCs) acquire genetic or epigenetic lesions that bias them toward a self-renewing, immature differentiation state at the cost of healthy, balanced hematopoiesis. Significant progress has been made toward improving outcomes in pediatric AML in part through advances in Hematopoietic Stem Cell Transplantation (HSCT); however, nearly 40% of children with AML relapse, and in the relapse setting, approximately 50% die due to refractory disease or treatment related morbidities within 5 years. Powerful immunotherapeutic modalities, such as chimeric antigen receptor (CAR) T-Cells, have reached impressive clinical milestones in the treatment of certain hematologic malignancies including acute lymphoblastic leukemia. However, extension of these approaches to AML has been difficult due to immense heterogeneity of target expression in AML and shared antigen expression between AML cells and healthy hematopoietic tissues. This is a unique and significant challenge in AML, as sparing HSPCs can also potentially spare leukemic or pre-leukemic stem cells (LSCs) that can reinitiate disease and cause relapse even after HSCT. Here, we propose that the signaling overlap between HSPCs, LSCs, and leukemic blasts can be exploited as a therapeutic strategy. It is well known that engagement of receptor tyrosine kinases (RTK) KIT, MPL, and FLT3 by their cognate ligands, stem cell factor (SCF), thrombopoietin (TPO), and FLT3 ligand (FLT3LG) and downstream signaling are essential to both healthy and malignant hematopoiesis. By interrogating a large pediatric AML cohort (n=453), we found that despite significant transcriptional heterogeneity among AML subtypes, expression of KIT, MPL, or FLT3 was a feature shared by nearly all pediatric AMLs. Further, after identifying pediatric AML subtypes with high and low interpatient transcriptomic heterogeneity, we found that pediatric AML subtypes with high transcriptional heterogeneity had higher diversity of KIT, MPL, and FLT3 expression and increased expression of stemness-related genes. To bridge this heterogeneity and provide a means of non-genotoxic conditioning for consolidation with an allogeneic HSCT, we have developed a novel, first-in-class Extracellularly Linked Concatemeric Trivalent Cytokine (ELECTRIC) CAR, in which the binding domains of SCF, TPO, and FLT3LG are attached via a flexible linker to enable simultaneous targeting of KIT, MPL, and FLT3 through a single CAR. CD4 or CD8 T-cells endowed with an ELECTRIC CAR specifically target cognate RTKs and effectively killed a panel of diverse AML cell lines and healthy HSPCs *in vitro*. ELECTRIC CARs also exhibited *in vitro* cytoxicity against primary pediatric AML LSCs and leukemic blasts, including CBFA2T3-GLIS2+ leukemias, a dangerous subtype of AML that is not cured with chemotherapy in combination with HSCT. Guided by pre-clinical models of targeted HSC conditioning to enable allogeneic HSCT, we propose that the ELECTRIC CAR system can be applied in the bridge-to-transplant setting to achieve the dual goal of eliminating residual leukemia and effectively providing non-toxic conditioning. Subsequently, the ELECTRIC CARs and the patients' immune compartment could be cleared using FDA-approved immune-depleting agents, thereby enabling a safe and effective allogeneic transplant with potential to effectively cure all AMLs with minimal toxicity.

138. Developing Adoptive Cell Therapy Strategies to Leverage Myeloid Immunity Against AML

Shannon Oda[1,2], Ryma Toumi[1], Simonne Guenette[2], Edison Chiu[1], Aitong Ruan[1], Sofia Nguyen[1]

[1]Seattle Children's Research Institute, Seattle, WA,[2]University of Washington, Seattle, WA

Acute myeloid leukemia (AML) is a rapidly progressing and highly fatal disease, with a 5-year survival rate of 32% (NCI). AML cells alter the programming of immune cells, supporting conversion of anti- to pro-tumorigenic cell types. In particular, AML tumor cells induce pro-tumor macrophages that promote resistance to therapy and phagocytosis. This subset of inhibitory, $CD206^{+}$ macrophages is significantly associated with worse outcomes for AML patients ($^{**}P<0.01$). However, pro-tumor macrophages show significant plasticity and can be polarized to antitumor programming with costimulatory signals, increasing phagocytosis of tumor cells and recruitment of other antitumor immune cells. One such costimulatory signal, CD40, has been explored to induce antitumor myeloid immunity and agonist CD40 antibodies have been tested in clinical trials. However, enthusiasm for agonist antibody therapies has been dampened by dose-limiting toxicities, inadequate pharmacokinetics and tissue penetration, and the non-tumor targeted delivery of the

antibody modality. Another promising approach, adoptive cell therapy (ACT), utilizes living, genetically-engineered T cells that actively localize to sites of tumor and specifically attack tumor cells. ACT is particularly attractive for AML therapy, as ACT is a first-line therapy for other hematological cancers and T cells naturally home to the sites of AML (e.g. blood, bone marrow). We sought to develop a T cell engineering strategy to deliver CD40 costimulatory signals to the AML-BM and reprogram inhibitory macrophages. We engineered membrane-bound fusion proteins, CD40L Dual Costimulatory Receptors (DCR), that pair the CD40L ectodomain with a panel of costimulatory endodomains. We developed both human and murine CD40L DCRs and showed increased T cell antitumor function in *in vitro* studies. We advanced leading CD40L DCRs to proof-of-concept *in vivo* testing in an immunocompetent AML mouse model and found that CD40L DCR-T cell therapy significantly enhanced therapeutic outcomes (***P<0.001). We observed a significant increase in antitumor macrophages (>40%, **P<0.01) as compared to control T cells, suggesting that CD40L DCR expression indeed induced macrophage conversion. Our long-term objective is to develop strategies and define mechanisms to employ both innate and adaptive immunity to provide a diverse and durable antitumor immune response against AML, and support clinical translation.

139. *Ex Vivo* and *In Vivo* Generation of Dual Specific CAR T Cells for Combination CAR T/ Oncolytic Virus Therapy

Olivia Liseth[1], Benjamin Kendall[1], Elizabeth Appleton[1], Thomas Kottke[2], Rosa Diaz[1], Jason M. Tonne[2], Soha Rizk[1], Masahiro Ono[3], Metko Muriel[2], Matthew Coffey[4], Houra Loghmani[5], Ian Parney[2], Webb Mason[2], Alan Melcher[6], Richard G. Vile[2]

[1]Mayo Clinic Minnesota, Rochester, MN,[2]Mayo Clinic, Rochester, MN,[3]Imperial College London, London, United Kingdom,[4]Oncolytics Biotech Incorporated, Calgary, AB,[5]Oncolytics Biotech, Calgary, AB, Canada,[6]The Institute of Cancer Research, London, United Kingdom

We hypothesized that the inflammation induced by oncolytic virus (OV) infection of tumours would enhance the trafficking, activation and cytotoxicity of CAR T cell therapy. However, we showed that a Type I IFN-rich tumour microenvironment induced by OV infection resulted in the attrition of CAR T cells infiltrating the tumour. We also observed that treatment with both OV and CAR T cells generated a population of dual specific (DS) CAR T cells in which the DS CAR T recognised viral epitopes through their T Cell Receptors. These DS CAR T cells were significantly more cytotoxic against tumour and persisted for much longer in vivo than conventional CAR T cells. Moreover, DS CAR T cells could be re-activated *in vivo* by subsequent boosts with the OV. By pre-loading CAR T cells with OV and administering boosts with virus we have shown that it is possible to cure tumours without prior lymphodepletion in pre-clinical models of melanoma and glioma where conventional CAR T therapy is completely ineffective. We show that these DS CAR T cells exhibit a hyper-functional anti-tumor activity associated with a $CD73^{lo}$, $CD62L^{lo}$, $CD127^{lo}$, and $KLRG1^{hi}$ phenotype, suggesting a highly differentiated effector T cell phenotype. Additionally, upon *ex vivo* splenocyte stimulation with EGFRviii CAR targets or viral peptide, DS CAR T produced higher levels of Granzyme B and IFNγ compared to conventional CAR T. Using the Tocky-Nr4a3 transgenic reporter mouse that expresses a blue protein ($t_{1/2}$ ~ 7h) upon Nr4a3 transcription (downstream of the TCR) that then decays to red ($t_{1/2}$ ~ 20h), we found differential TCR activation dynamics between DS CAR T and conventional CAR T cells, with the more potent DS CAR T cells exhibiting shorter, "fast-off" target interactions with a stronger blue protein positive population. Increased prevalence of blue protein positive T cells in the tumor significantly correlated with decreased tumor weight. We are now developing this approach for clinical trials which necessitates the determination of optimal loading of virus onto the CAR T cells to ensure that the CAR T cells are not cleared by anti-viral effectors *in vivo*. Finally we have also developed novel methods to generate a full range of memory and effector DS CAR T cells directly from naive T cells *in vivo* which are also highly active against tumour following *in vivo* boosting.

140. ROR1 CAR Armored with Dominant Negative TGF-Beta Receptor II Demonstrates Enhanced Efficacy in Xenograft Models of Pancreatic Cancer

Bal Krishna Chand Thakuri, Tri Tran, Saule Nurmukhambetova, Jia-Jye Lee, Peirong Hu, Ngoc Tran, Brittany Steimle, Pradyot Dash, Dina Schneider

Lentigen Technology, Inc., a Miltenyi Biotec Company, Gaithersburg, MD

Introduction. The receptor tyrosine kinase-like Orphan Receptor 1 (ROR1) is a membrane receptor highly expressed at the early embryonic stage and rarely expressed in normal adult tissues. ROR1 is broadly expressed in hematologic and solid tumors making it one of the most promising targets for cancer treatment. To date clinically characterized ROR1-CAR T-cells failed to induce durable remissions, in part due to the immunosuppressive nature of tumor microenvironment (TME). Here we report the development of a fully human ROR1-CAR armored with a dominant negative TGFβ receptor II (TGFβRIIDN) which is protective against TGFβ1, one of the major immunosuppressive components of TME. **Methods.** Enriched primary $CD4^+$ and $CD8^+$ T-cells were used for the generation of CAR T-cells by lentiviral transduction. *In vitro*, flow cytometry was used to assess the expression of ROR1-CAR, TGFβRIIDN armor and its effect on TGFβ1 signaling (via pSmad2/3; canonical signaling pathway) in CAR T cells. The xCelligence method was used to measure CAR cytotoxic activity, and elaboration of cytokines IFNγ, TNFα and IL-2 was measured by ELISA. *In vivo* CAR efficacy was evaluated in pancreatic adenocarcinoma (PDAC) NSG xenograft models AsPC-1, and AsPC-1 over-expressing TGFβ1. Cytokines in peripheral blood were assessed by MSD U-plex assay. Immunophenotype of infused T cells were assessed by flow cytometry. Tumor tissues harvested at day 7 post T-cell dosing and at termination of the study were analyzed by immunohistochemistry (IHC) and immunofluorescence MACSima Imaging Cyclic Staining (MICS) methods for biomarkers. **Results.** ROR1 CAR-T cells armored with TGFβ1-protective TGFβRIIDN element attenuated TGFβ1-mediated Smad2/3 phosphorylation in CAR-transduced primary T cells compared to ROR1 CAR alone. When co-cultured with ROR1+ AsPC-1 pancreatic cancer cells in the presence of TGFβ1, armored ROR1 CAR-T cells showed better killing activity and cytokine IFNγ, TNFα and IL-2 secretion. Similarly, armored CAR -T cells co-cultured with AsPC-1 cells overexpressing TGFβ1 maintained high level of cytotoxicity and cytokine response, in contrast

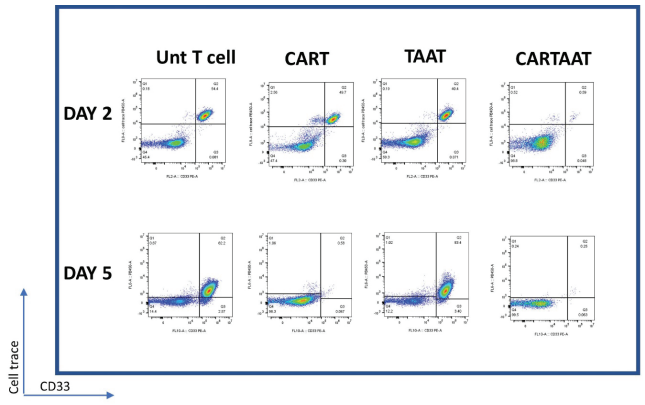
to the CAR alone. *In vivo,* in mice bearing AsPC-1 pancreatic tumor xenografts overexpressing TGFβ1, armored ROR1 CAR treatment achieved complete tumor remissions, higher expansion of CAR$^+$T-cells, prevented elevation of TGFβ1 level in the peripheral blood, with no noticeable toxicity or weight loss, as compared to CAR alone. MICS analysis demonstrated advanced tumor clearance by armored ROR1 CAR T cells at day 7 post T cell infusion. Unexpectedly, in mouse AsPC-1 pancreatic tumor xenografts without TGFβ1 overexpression, IHC and MICS analysis of tumor tissues harvested at day 7 post T cell infusion revealed marked induction of TGFβ1 upon antigen-dependent interaction of ROR1 CAR T cells with ROR1 positive tumor cells. Furthermore, armored ROR1 CAR treatment achieved enhanced tumor clearance in this model. **Conclusion.** The novel ROR1 CAR$^+$T-cells armored with TGFβRIIDN confer resistance to inhibition by TGFβ1 both *in vitro* and *in vivo*. In addition, TGFβ1 induction by CAR T cells represents a novel, CAR-induced checkpoint signaling in the solid TME, which can be overcome by armoring the CAR-T cells with TGβRIIDN, thus enhancing CAR-T therapeutic potential for the treatment of solid cancers.

141. A Phase 1 Dose Escalation Study of a Novel Coupled CAR T Cell Therapy, GCC19CART, for Patients with Metastatic Colorectal Cancer

Bridget P Keenan[1], Christopher H Lieu[2], Marwan Fakih[3], Dongqi Chen[4], Lucy Lu[5], Eric Rowinsky[5], Victor Lu[5], Lei Xiao[5], Alan P Venook[1], Benjamin L Schlechter[6]

[1]Helen Diller Family Comprehensive Cancer Center, San Francisco, CA,[2]University of Colorado Cancer Center, Aurora, CO,[3]City of Hope Comprehensive Cancer Center, Duarte, CO,[4]Innovative Cellular Therapeutics, Shanghai, China,[5]Innovative Cellular Therapeutics, Rockville, MD,[6]Dana Farber Cancer Institute, Boston, ME

Background: GCC19CART, our lead candidate from the CoupledCAR solid tumor platform, aims to overcome limitations of conventional CAR T-cells in solid tumor malignancies by pairing solid tumor CAR T-cells with CD19-targeting CAR T-cells to amplify the proliferation and activation of the solid tumor CAR T component. GCC19CART targets guanylate cyclase-C (GCC), which is reported to be expressed in the metastatic lesions of 70%-80% of subjects with colorectal cancers and largely restricted to the intestinal tract. A Phase 1 investigator-initiated clinical trial conducted in China showed preliminary efficacy with an overall response rate (ORR) at dose level 1 (1x10^6 CAR T-cells/kg) of 15.4% ORR (2/13) and 50% ORR (4/8) in dose level 2 (2x10^6 CAR T-cells/kg). Common side effects included cytokine release syndrome (CRS) and diarrhea/colitis. Immune effector cell-associated neurotoxicity syndrome (ICANS) occurred in a smaller subset of patients. Building on these encouraging findings, we initiated a US Phase 1 study in August 2022 for patients with metastatic colorectal cancer refractory to standard chemotherapy. As of November 1, 2023, four subjects have received treatment at the initial dose level. Methods: Subjects were initially screened for GCC expression; this requirement was later discontinued when immunohistochemistry studies revealed that the frequency of positive GCC expression exceeded 95%. Eligible subjects underwent leukapheresis, a single dose of lymphodepleting chemotherapy (fludarabine 30mg/m2 and cyclophosphamide 300mg/m2) 3 days prior to infusion, and then administration of a single infusion of GCC19CART. Responses were assessed by RECIST v1.1 by site investigator review and an independent third-party imaging contract research organization. Results: 4 subjects have been dosed at level 1 (1x10^6 cells/kg) and completed the DLT period at the time of data cutoff. The most common adverse events were CRS in 4/4 subjects (Grade 1: 2/4 (50%) or Grade 2: 2/4 (50%)) and diarrhea in 3/4 subjects (Grade 1: 1/4 (25%), Grade 2: 1/4 (25%), or Grade 3: 1/4 (25%)). Three out of four patients had a mild tremor (Grade 1) that resolved with corticosteroids and no other evidence of neurotoxicity. The combined overall response rate (ORR) was 50% (2/4) by independent review. Two subjects demonstrated a partial response (PR) while 1 additional subject had partial metabolic response (PMR) on PET/CT with stable disease (SD) and 1 patient had progressive disease per RECIST 1.1. Per site investigator review, the ORR was 25%, with 1 confirmed PR and 3 SD assessed as best response. The median PFS was 3.8 months in the dose level 1 group. Conclusions: Preliminary results from the US study corroborate our finds from the Chinee trial, demonstrating that GCC19CART has meaningful clinical activity and an acceptable safety profile in refractory metastatic colorectal cancer. This trial is ongoing and updated data will be presented, including from patients treated at dose level 2 (2x10^6 CAR T-cells/kg). Clinical trial information: NCT05319314.



142. Targeting AML with Multi-Antigen Specific T Cells Engineered to Express a CAR Specific for SSX2 Peptide 41-49

Gloria Pezzella[1], Achouak Achour[1], Eric S. Yvon[2], Catherine M. Bollard[1,2], Keri Toner[1,2]

[1]Childrens National Hospital, Washington, DC,[2]The George Washington University, Washington, DC

Background: Acute myeloid leukemia (AML) is the second most common pediatric leukemia, comprising 15-20% of acute hematological malignancies in children. While prognoses have improved due to optimization of chemotherapy and advancements in transplantation, around 30% of patients with AML relapse, and outcomes are poor due to limited treatment options. Targeted therapies, including cellular therapies, are necessary for AML patients. Our group as well as John's Hopkins University (JHU) have shown that tumor-associated antigen specific T cells (TAA-T) can safely prolong event free survival in high-risk patients with solid tumors and leukemia/lymphoma. However, responses in patients with active disease were modest. Therefore, we sought to determine whether CAR-engineering could enhance the potency of the TAA-T platform. Our group has developed a T cell receptor (TCR) like chimeric antigen receptor (CAR) targeting SSX2 peptide (41-49) in the context of HLA-A-0201. We hypothesized that by combining these two cellular therapy modalities-we can enhance the anti-leukemia activity of TAA-T in vitro. **Objectives:** To assess whether PRAME-specific TAA-T expressing $SSX2_{41-49}$ CAR enhanced cytotoxic effects against AML compared to CAR-T cells or unmodified TAA-T cells alone. **Methods:** Mononuclear cells isolated from peripheral blood mononuclear (PBMCs) of healthy donors were co-cultured with antigen presenting cells (APCs) pulsed with PRAME pepmix in the setting of exogenous cytokines. After two weekly stimulations with PRAME pepmix pulsed dendritic cells as APCs, TAA-T cells were transduced with $SSX2_{41-49}$ CAR and stimulated once more the

following week with the same APCs. TAA- T products were analyzed for antigen specificity using IFN-γ ELISpot assay by reintroducing PRAME or T2 cells loaded with $SSX2_{41-49}$ peptide. Immunophenotype and transduction efficiency was determined by flow cytometry. Cytotoxicity of TAA-Ts was determined by flow based coculture with cell trace violet and CD33 staining used to identify the THP1 tumor cells. $SSX2_{41-49}$ CAR TAA-T, $SSX2_{41-49}$ CAR-T, and unmodified PRAME-specific TAA-T cells were cocultured with THP1 tumor cells at 1:5 target to effector ratio. Cells cultures were analyzed by flow cytometry at 0, 24 hours, 48 hours, and 120 hours. **Results:** TAA-T targeting PRAME elicited the following responses on ELISPOT (means measured in SFC/100,000 cells): PRAME=298 and T2+SSX2=35. TAA-T from the same healthy donors (n=5) transduced and stimulated with PRAME elicited: PRAME=62 and T2+SSX2=219. Flow cytometry analysis showed that mean 71.6% (1.53-71.6%) of TAA-T were CD3+CD8+ T cells and mean 79.9% (1.83-90.0%) of $SSX2_{41-49}$ CAR transduced TAA-Ts were CD3+CD8+ T cells. The mean transduction efficiency of TAA-T was 83.9% (range 48.7-93.5%). At 120 hours, 35.4% (0.25-80.9%), 45.4% (0.58-98.2%), and 57.1% (2.82-83.4%) of the original THP1 tumor cells were still present in culture for transduced TAA-T, CAR-T, and unmodified TAA-T respectively. In conclusion, our novel cellular therapeutic of TAA-T transduced with $SSX2_{41-49}$ CAR display enhanced potency against AML tumor cells than unmodified TAA-T or CAR-T cells. Future studies are needed to optimize the expansion of $SSX2_{41-49}$ CAR transduced TAA-T and evaluate the potency of this novel cell therapy approach in an *in vivo* mouse model and ultimately in the clinic.

SSX2 CAR TAA-T demonstrate cytolytic activity after 5 days of coculture with THP1. Unmodified T cells, SSX2 CAR-T, TAA-T and SSX2 CAR TAAT were co-cultured with THP1 tumor cell line at 1:5 to target effector ratio. After 5 days, SSX2 CAR TAA-T showed effective tumor clearance by flow cytometry.

In Vivo Gene Therapy Clinical Trials

143. Long-Term Efficacy and Safety in Adults with Glycogen Storage Disease Type IA (GSD IA) from a Phase 1/2 Clinical Trial and Long-Term Follow-Up Study of DTX401, an AAV8-Mediated, Liver-Directed Gene Therapy

Background*:** Glycogen storage disease type Ia (GSD Ia) results from a deficiency of glucose 6-phosphatase (G6Pase) which is essential for glycogenolysis and gluconeogenesis. DTX401 is an investigational adeno-associated virus serotype 8 (AAV8) vector expressing the human *G6PC* gene. ***Methods*:** An open-label, phase 1/2, dose escalation gene therapy trial (NCT03517085) evaluated the safety and efficacy of a single DTX401 intravenous infusion in 12 adults with GSD Ia for 52 weeks. Three participants in Cohort 1 received DTX401 2.0 x 10^{12} genome copies (GC)/kg, and three participants each in Cohorts 2, 3, and 4 received 6.0 x 10^{12} GC/kg. Participants in Cohorts 1 through 3 received reactive steroids, and participants in Cohort 4 received a prophylactic steroid regimen to prevent transaminase elevations. All participants entered a long-term follow-up study (NCT03970278) to monitor safety and efficacy for up to 312 weeks after DTX401 administration. The data cutoff for this analysis was 21-Dec-2023. ***Efficacy Results*:** From baseline to Week 52, mean (SD [range]) change in actual total daily cornstarch intake was -68.1% (19.5 [-100 to -42%]), p<0.0001 among 10 participants with a cornstarch assessment within the ±14-day analysis window for the Week 52 visit. From baseline to last available timepoint in the follow-up study (including to Year 5 for three participants in Cohort 1 and to earlier timepoints for subsequently enrolled Cohorts 2 through 4), mean (SD [range]) change in actual total daily cornstarch intake was -74.1% (21.8 [-100 to -36%]), p<0.0001 for all 12 participants. ***Safety Results: All participants experienced a treatment-emergent adverse event (TEAE) and a related TEAE; however, no infusion-related or treatment-related serious adverse events (SAEs) were reported. There were three participants with five related TEAEs of hypertriglyceridemia and one participant with two related TEAEs of proteinuria. All SAEs were Grade ≤3 in severity except for one Grade 4 SAE of multisystem organ failure in the setting of cholecystitis. All SAEs were determined to be unrelated to study drug by both the investigator and study sponsor. ***Conclusions*:** DTX401 showed efficacy and an acceptable safety profile in all treated participants at Week 52 that was durable and sustained for up to five years. Participants in all cohorts showed a significant reduction in cornstarch needs from baseline to both Week 52 and to the last available timepoint. Participants treated with DTX401 should continue to be

monitored long-term for overall metabolic control. All participants remain in the follow-up study and updated efficacy and safety results will be reported.

144. AAV1-hOTOF Gene Therapy for Children with Autosomal Recessive Deafness 9

Yilai Shu[1], Jun Lv[1], Hui Wang[1], Xiaoting Cheng[1], Yuxin Chen[1], Daqi Wang[1], Longlong Zhang[1], Qi Cao[1], Honghai Tang[1], Shaowei Hu[1], Kaiyu Gao[2], Mengzhao Xun[1], Jinghan Wang[1], Zijing Wang[1], Biyun Zhu[1], Chong Cui[1], Ziwen Gao[1], Luo Guo[1], Sha Yu[1], Luoying Jiang[1], Yanbo Yin[1], Jiajia Zhang[1], Bing Chen[1], Wuqing Wang[1], Renjie Chai[3], Zheng-Yi Chen[4], Huawei Li[1]

[1]Eye & ENT Hospital of Fudan University, Shanghai, China,[2]Shanghai Refreshgene Therapeutics, Shanghai, China,[3]Southeast University, Nanjing, China,[4]Harvard Medical School, Eaton-Peabody Laboratory, Massachusetts Eye and Ear, Boston, MA

Background Autosomal recessive deafness 9 (DFNB9), caused by mutations of the *OTOF* gene, is characterized by congenital or prelingual, severe-to-complete bilateral hearing loss. However, no drug treatment is available for hereditary deafness. AAV1-hOTOF, adeno-associated virus (AAV) serotype 1 carrying a human *OTOF* transgene, was designed to treat patients with DFNB9. Here, we report the safety and efficacy of AAV1-hOTOF gene therapy as the treatment of children with DFNB9 via unilateral or binaural injection. **Methods** In this single-arm trial, patients (1-18 years of age) with severe-to-complete hearing loss were eligible. AAV1-hOTOF was administered into one or two cochleas through the round window. The primary outcome was dose-limiting toxicity (DLT). Adverse events (AEs), immune response, auditory function and speech perception were evaluated. **Results** From December 2022 to September 2023, 9 patients with 95 dB of average auditory brainstem response (ABR) thresholds at 0.5-4 kHz were enrolled. Six patients received unilateral injections, of which patient #1 received a 9×10^{11} vg dose and patients #2-6 received a 1.5×10^{11} vg dose. Subsequently, patients #7-9 received a binaural injection at a dose of 1.5×10^{11} vg. Follow-up visits ranged from 6 to 26 weeks. No DLT was observed. 61 adverse events were observed, with 97% (59/61) being grade 1 or 2, and 3% (2/61) being grade 3. In patient #1, the average ABR threshold was recovered to 68 dB at 4 weeks, 53 dB at 13 weeks, and 45 dB at 26 weeks. In patients #2-5, the average ABR thresholds were >95, 48, 38, and 40 dB at 26 weeks, respectively, while the average ABR threshold was 60 dB in patient #6 at 13 weeks. In patients #7-8, the average ABR thresholds of the left (right) ear was reduced to 63 (63), 88 (83) at 13 weeks. In patients #9, the average ABR thresholds of left (right) ear was reduced to 60 (63) at 13 weeks. Speech perception was improved in 5 patients who had hearing recovery. The ability of sound source localization was improved in all patients who received binaural injection. **Conclusions** The AAV1-hOTOF gene therapy is safe and efficacious as a novel treatment for patients with DFNB9.

145. VGN-R08b Gene Therapy for Neuronopathic Gaucher Disease

Huiwen Zhang[1], Yueniu Zhu[1], Weiwei Mao[1], Xiaoqiang Wang[1], Dake He[1], Xia Zhan[1], Yi Yang[1], Mengni Yi[1], Xiaodong Zhu[1], Hua LV[2], Shan Ding[2], Xiaoping Zhao[2]

[1]Xinhua Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, China,[2]Shanghai Vitalgen BioPharma Co., Ltd., Shanghai, China

Objective: Gaucher disease is caused by biallelic mutations in the GBA1 gene, with severe mutations leading to neurological manifestations (nGD). The GBA1 encoded enzyme GCase is a key lysosomal enzyme required for normal metabolism of glycolipids. GCase deficiency causes the accumulation of glycolipid substrates, resulting in lysosomal dysfunction that leads to inflammation and other pathological changes. Acute nGD (GD2) is of the most severe type, which is characterized by hepatosplenomegaly and central nervous system involvement within first year of life. And the disease progresses rapidly leading to death by the age of 2 years. The most significant signs, including hyperextension of the neck, myoclonic seizures and swallowing impairment, followed by prolonged spontaneous apneas and chronic/subacute pulmonary disease, would be the main reasons of death. Here we present the preliminary results from an early dose escalation trial to evaluate tolerability and safety of VGN-R08b, AAV9-GBA1, delivered into the central nervous system via ICV injection. **Methods**: Six infants (4F, 2M; 3-26 months) were diagnosed as GD2, 4 on invasive ventilator and ERT, 1 with ERT, and 1 without specific treatment. They were implanted with Ommaya reservoir for drug delivery prior to the single dose injection. The first patient received 6.0×10^{10} Vg/g and other 5 patients received 2.0×10^{10}Vg/g accompanied with prophylactic glucocorticoid. The GCase activity and Lyso-GL1 levels in CSF were analyzed, and neurologic symptoms were assessed. **Results**: Results were analyzed for the 6 subjects who were followed not less than 4 weeks (4-26 weeks). The injections were well tolerated, without any AE related to the procedure or VGN-R08b. GCase activity in CSF of the subject dosed 6.0×10^{10}Vg/g increased to 4~8 folds of normal upper limits during follow-up (baseline 0.3 increased up to 68.3 μmol/d/L); GCase activity in subjects dosed 2.0×10^{10}Vg/g increased to 2~5 folds of normal upper limits (baseline 0.3~1.6 increased up to 17.6~43.7 μmol/d/L). The Lyso-GL1 levels in CSF decreased dramatically, and during a longer follow-up in the first two subjects, it maintained below 26.6pg/mL (Lyso-GL1 levels in CSF of GD patients range 26.6~2000 pg/mL). In further, their neurological symptoms, including neck hyperextension, peripheral hypertonia and myoclonic seizures, improved in severity or disappeared soon within a 6-month's follow-up. Additional improvements were also noticed. The upper level of body temperature on episodes of fever dropped by one degree in 3 patients who's on invasive ventilator. The frequency of fever decreased from 2.25 to 0.75 times per month in one subject who's on invasive ventilator. Of the 4 subjects whose protein quantifications in CSF were abnormally decreased at baseline, the levels in 3 subjects increased to the normal range 4 or 8 weeks after treatment, indicating an increased neuronal activity. The dosages of Ambroxol in the 4 subjects, as for controlling neurological symptoms at enrollment, has been discontinued 4 weeks to 6 months after VGN-R08b treatment. We are also grateful to observe that the brain MRIs keep stable in morphology when checked on the 12 weeks'follow-up in 4 of 5 patients. **Conclusions**: VGN-R08b gene

delivery via ICV has now been performed in total of 6 patients. To our knowledge, this is the first time in the world to report changes of GCase and its metabolite Lyso-GL1 levels in CSF after gene therapy in GD. The procedure is safe and the expression of GCase in CSF increased significantly. Furthermore, Lyso-GL1 levels in CSF decreased significantly during the follow-up period, accompanying continuous improvements of neurological symptoms in GD2 infants that had never been achieved before.

146. Interim Review of Safety, Tolerability, and Efficacy From a First-In-Human Phase 1/2a Clinical Study of ICM-203, an Intra-Articular, AAV Gene Therapy for Osteoarthritis

Alison E. Heald[1,2], Bogdan Solomon[3], Richard Page[4,5], Yoenhee Ahn[1], Young Na Yum[1], Jayhyuk Myung[1], Jamie E. Collins[6], Ali Guermazi[7], Dae-Won Kim[1,8]

[1]ICM Co., LTD, Seoul, Korea, Republic of,[2]University of Washington School of Medicine, Seattle, WA,[3]Royal Adelaide Hospital, Adelaide, SA, Australia,[4]Barwon Health, University Hospital Geelong, Geelong, VIC, Australia,[5]Deakin University, Geelong, VIC, Australia,[6]Brigham and Women's Hospital, Boston, MA,[7]Boston University School of Medicine, Boston, MA,[8]Yonsei University, Seoul, Korea, Republic of

Introduction: This first-in-human phase 1/2a study is being conducted to assess the safety, tolerability, and activity of ICM-203, a recombinant AAV vector designed to express a truncated form of human Nkx3.2, a transcription factor which plays an important role in both chondrocyte and synoviocyte activity. **Methods:** In this double-blind, placebo-controlled, dose escalation study (NCT04875754), subjects with Kellgren-Lawrence grade 2 or grade 3 knee osteoarthritis and minimum Joint Space Width (mJSW) > 1mm receive a single intra-articular injection of ICM-203 or placebo in a 3:1 ratio, with planned dose escalation of ICM-203 from $6x10^{12}$ vector genomes (vg) to $2x10^{13}$ vg and then $6x10^{13}$ vg. The primary safety endpoint is safety and tolerability through assessment of treatment-emergent adverse events. The primary efficacy endpoints are changes in knee pain as assessed on a numerical rating scale (NRS); changes in knee function as measured using the Knee Injury and Osteoarthritis Outcome Score (KOOS) activities of daily living (ADL) subscore, as well as structural knee changes, including change in mJSW on knee radiograph and changes in Magnetic Resonance Imaging (MRI) Osteoarthritis Knee Score (MOAKS). Here, 12-month blinded follow-up data from 8 subjects in the low-dose cohort treated with ICM-203 (n=6) or placebo (n=2) are reported. **Results:** No significant concerns about safety and tolerability arose, although transient increases in injected knee pain 6-12 days after study drug administration were observed in 4 of 8 subjects. Knee pain (NRS) decreased in 6 of 8 subjects and knee function (KOOS ADL) improved in 4 of 8 subjects between Day 1 and Week 52. Improvement in medial mJSW was observed at Week 52 in 3 of 5 subjects with predominantly medial space disease and medial mJSW > 1mm. Cartilage thickness was preserved or improved in 5 of 8 subjects and bone marrow lesions (BML) improved in 3 of 8 subjects at Week 52 (Fig. 1). Osteophytes were unchanged in 7 of 8 subjects and only worsened minimally in 1 of 8 subjects at Week 52. Synovitis (Hoffa + effusion) improved at Week 52 in 2 of 2 subjects with more inflammation (synovitis score >4) at baseline (Fig. 2). **Conclusions:** Intra-articular injections of ICM-203 $6x10^{12}$ vg or placebo were safe and well tolerated. Improvement in joint pain and/or function were observed in 6 of 8 subjects. Favorable structural changes were observed on MRI, such as preservation of cartilage thickness, decrease in BML, and improvement in synovitis in subjects with more inflammation at baseline. Changes in osteophytes were minimal, suggesting no adverse impact on bone remodeling. Investigation of higher doses of ICM-203 is in underway.

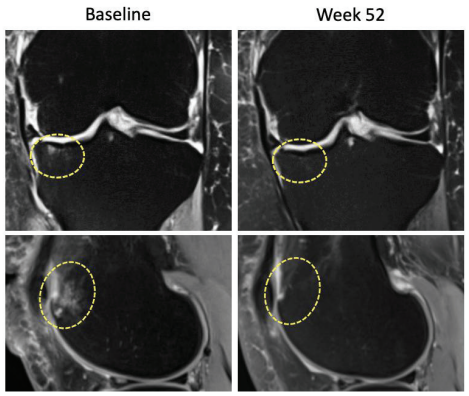

Fig. 1: Reduction in BML (yellow circles) in representative 2D IW MR images of subject R1007.

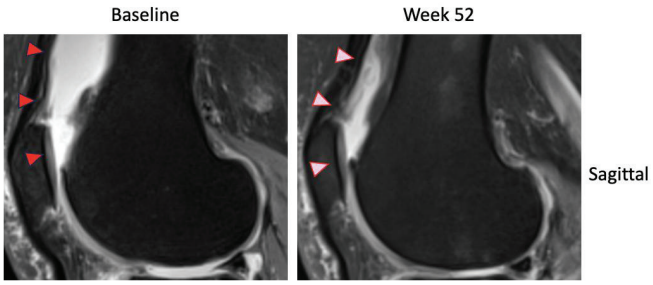

Fig. 2: Reduction in synovitis (red arrowheads) in representative 2D IW MR images of subject R1008.

147. Demonstration of Nuclease-Free Genome Editing (GeneRide™) in Pediatric Patients with Methylmalonic Acidemia

Marie Payton[1], Thomas Morgan[2], Jirair K. Bedoyan[3], Angela Sun[4], Hong Li[5], Daniel Gruskin[6], Mark A. Kay[6], Frederic Chereau[1], Jerry Vockley[3]

[1]Alexion AstraZeneca Rare Disease, Lexington, MA,[2]Vanderbilt Children's Hospital, Nashville, TN,[3]UPMC Children's Hospital of Pittsburgh, Pittsburgh, PA,[4]Seattle Children's Hospital, Seattle, WA,[5]Emory University, Atlanta, GA,[6]LogicBio Therapeutics, Lexington, MA

Methylmalonic acidemia (MMA) is an autosomal recessive inborn error of metabolism where certain amino acids and fats are not properly processed due to deficient activity of the mitochondrial enzyme methylmalonyl CoA mutase (MMUT). Therapeutic options include strict dietary management or liver transplantation. A phase 1/2 dose escalation trial (NCT04581785) evaluated the safety and efficacy of a single hLB-001 intravenous infusion in pediatric MMA patients. Liver-targeted hLB-001 utilizes the AAV-LK03 capsid to deliver a functional copy of the human *MMUT* coding sequence for homologous-recombination induced, non-disruptive integration

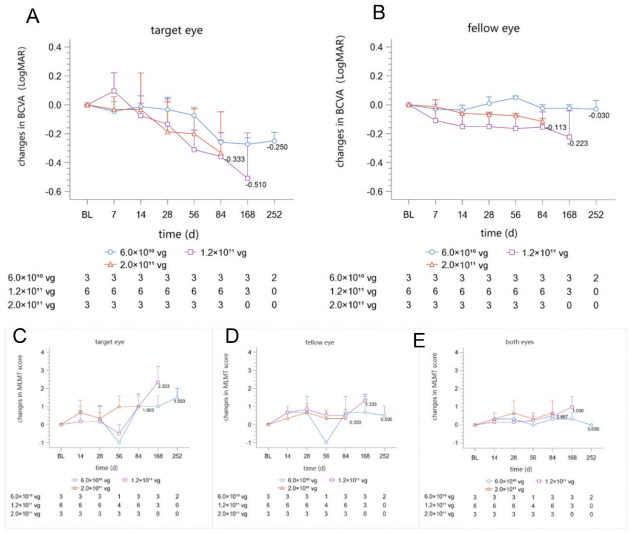
into the 3' end of the albumin (*ALB*) locus of hepatocytes. Using the GeneRide gene editing technology, LB-001 introduces a P2A ribosome skipping sequence peptide allowing edited alleles to produce ALB and MMUT as two separate proteins, and in doing so tags the C-terminus of ALB with the P2A peptide, which becomes a technology-dependent circulating biomarker for target-site integration events, albumin-2A (ALB2A). The hLB-001-edited hepatocytes express functional MMUT protein. Over time, the MMUT expressing hepatocytes selectively survive and progressively repopulate the MMA-diseased liver. This is observable by detecting increasing amounts of circulating ALB2A, a surrogate for the edited hepatocytes expressing mitochondrial MMUT protein. The clinical trial enrolled patients between 6 months and 12 years of age. Four patients enrolled in the study and received hLB-001 at a dose of $5x10^{13}$ vg/kg along with prophylactic corticosteroids. All patients entered a long-term follow-up study (NCT05506254); two years of post-treatment data are presented here. Two patients in the younger age group experienced thrombotic microangiopathy, with one case being life-threatening. All patients experienced transient increases in transaminases with hLB-001 administration. Although there is a theoretical risk of steroids leading to a catabolic episode in these patients, only one mild case of hyperglycemia was experienced. All patients recovered from these events. All patients showed evidence of targeted integration via measurable serum ALB2A. Persistently increasing levels of ALB2A throughout the study were observed in 2 patients, suggesting continued expansion of the edited hepatocytes. However, at the 2-year timepoint, serum ALB2A had not yet reached levels that would be predicted to reflect the expected necessary number of MMUT-producing cells required to provide a therapeutic benefit. Of the 2 patients without sustained increases in ALB2A, one patient's loss of expression may have been associated with an increase in liver enzymes that occurred immediately prior to the elimination of ALB2A levels. While the reason for the lack of sustained increase in ALB2A in the other patient is unclear, it is possible that this patient's disease was sufficiently mild and controlled to reduce the selective pressure for edited hepatocytes. This study was the first to demonstrate successful *in vivo* homologous recombination genome editing without the use of nucleases or promotors in a pediatric population. Future efforts will focus on methods to increase the integration rate of a corrective gene to accelerate time to efficacy with increased safety.

148. Phase 1/2 Trial of Combined Intrathalamic/Intracisternal/Intrathecal Gene Therapy for Tay-Sachs and Sandhoff Diseases

Terence R. Flotte[1], Allison M. Keeler-Klunk[2], Meghan Blackwood[2], Rebecca Artinian[2], Heather L. Gray-Edwards[2], Toloo Taghian[2], Oguz Cataltepe[3], Miguel Sena-Esteves[2], Florian Eichler[4]

[1]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[2]UMass Chan Medical School, Worcester, MA,[3]University of Massachusetts Medical School, Worcester, MA,[4]Neurology, Massachusetts General Hospital, Boston, MA

The GM2 gangliosidoses, Tay-Sachs and Sandhoff diseases, are caused by deficiency of lysosomal hexosaminidase A activity due to mutations in either the alpha subunit (encoded by HEXA) in Tay-Sachs or the beta subunit (encoded by HEXB) in Sandhoff. Severe deficiency states ($\leq$ 0.1% activity) result in infantile forms of these diseases in which infants begin to show normal neurodevelopmental progress, but then begin to relentlessly regress around 5 to 6 months of age leading to global neurological deficits, seizures and ultimately death around 3 to 4 years old. Our group has developed rAAVrh8 vectors encoding HEXA and HEXB, which when injected simultaneously into the thalami bilaterally and into the CSF of deficient animals (Sandhoff mice and cats and Tay-Sachs sheep) can restore CNS Hexosaminidase enzyme activity, decrease GM2 levels in CSF, and rescue most or all of the phenotypic consequences of the disease. Following upon a small (N of 2) expanded access (EA) trial, we initiated a phase 1/2, single-dose, dose-escalation of combined biThalamic (BiT), intra-cisterna magna (CM), and intrathecal (IT) infusion of rAAVrh8-HexA/HexB at four dosage levels ranging from 5.87E+12 vg/kg per patient to 4.08E+13vg/kg. Most importantly, the BiT injection volume (and vector dose) were doubled between each cohort (starting dose (SD) 180mcl, low dose (LD) 360mcl, mid dose (MD) 720 mcl, and high dose (HD) 1250 mcl) with the SD matching the dose used in the prior EA trial. Patients were immune suppressed with rituximab, sirolimus, and corticosteroids (10mg/kg solumedrol). Post-dose, patients continued with sirolimus for 6 months followed by a taper and prednisolone (1 to 2 mg/kg/day) for 3 months followed by a taper. All 9 subjects have been enrolled in this trial. Interim results of CSF HexA enzyme activity and GM2 levels show a dose-related, partial biochemical correction of the disease. Positive clinical findings in treated infantile subjects indicate prolonged oral feeding without aspiration until age 3 to 3.5 years. The data on dose-response effects on the CSF biomarkers and clinical outcomes will support later development. Multiple aspects of the immune response were evaluated in these subjects, including cytokine responses, anti-capsid antibodies, anti-capsid and anti-transgene ELISPOT responses, and development of vector-specific Tregs. The timing of these responses and their treatment will be discussed in the context of broader application to other rAAV clinical trials.



149. Subretinal Gene Therapy in Patients with Bietti Crystalline Dystrophy: Preliminary Results of a Phase 1/2 Clinical Trial

Shiyi Yin[1], Haihan Zhang[1], Jieqiong Chen[2], Jinyuan Wang[1,3], Yang Li[1], Qiong Yang[1], Ying Sha[1], Hua Lv[4], Xiaoping Zhao[4], Ning Guan[4], Ruixue Chen[4], Hongxia Mao[4], Xiaodong Sun[2], Wenbin Wei[1]

[1]Beijing Tongren Hospital, Capital Medical University, Beijing, China,[2]Shanghai General Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China,[3]School of Clinical Medicine, Tsinghua University, Beijing, China,[4]Shanghai Vitalgen BioPharma Corporation Limited, Shanghai, China

Introduction: Bietti crystalline dystrophy (BCD) caused by CYP4V2 biallelic mutation is a severe and visually threatening genetic disorder with no effective treatment. This study aimed to show the preliminary results of BCD patients received a single unilateral subretinal injection of VGR-R01, an AAV8 mediated CYP4V2 gene therapy. **Methods:** An open-label, phase1/2, dose-escalation clinical trial (NCT05694598) evaluated the safety and efficacy of a single VGR-R01 subretinal injection in 12 patients with BCD. Three patients each in Cohort 1 and 3 received VGR-R01 6.0×10^{10} and 2.0×10^{11} vg/ege, and six patients in Cohort 2 received 1.2×10^{11} vg/eye. All patients received prophylactic glucocorticoid to reduce the risk of vector-related immune responses.

The data cutoff for this analysis was Dec. 20, 2023. **Results:** 12 patients (mean age,42 years; range, 32~52 years; 7 [58%] male) were included in the study. The median observation period was 128 days (range, 78 ~ 247 days). Compared with the baseline (range, hand move to 0.61 LogMAR) , 58.3% (7/12) of patients had a significant improvement in visual acuity of the injected eyes (decrease of ≥ 0.3 LogMAR in BCVA). 3 patients in the Cohort 1 had a mean change from baseline in BCVA in the target eyes of −0.270 logMAR at D168 visit. 6 patients in the Corhort 2 had a mean change in BCVA of −0.345 logMAR at D84 visit, 3 of whom completed D168 visit with a mean change from the baseline of −0.510 logMAR. Cohort 3 (at D84 visit) had a mean change of −0.333 logMAR (Figure A, B). All patients had an average increase in Multi-luminance mobility testing (MLMT) of 1-2 points (-1 to +4), with 33% (4/12) of patients having an improvement two weeks after injection of VGR-R01(Figure C~E). There was no significant anatomical change or mean foveal thickness in the both eyes. All patients experienced a treatment-emergent adverse event (TEAE) but just one eye inflammation was related to VGR-R01. Most common AEs were related to administration procedure. **Conclusions:** VGR-R01 is safe and well tolerated, and efficacy is observed. More importantly, for some subjects with extremely low vision, the VGR-R01 administration also significantly improved their visual function.

Gene Disruption and Excision

150. Identification and Engineering of ABR-004, a Compact, High-Fidelity Nuclease for Therapeutic Gene Editing

Jeffrey R. Haswell, Michael S. Kuefner, Tanya Jain, Anthony J. Garrity, Linh B. Truong, Sneha Halwasia, Kyle Rehberger, Lauren E. Alfonse, Alexa Ornstein, Erin Doherty, Jenna M. Rachman, Gabrielle Z. Munoz, Gillian A. Mehigan, Tomoaki Sasaki, Zachary Maben, Blake D. McMahon, Carl Co, Gregory R. Hoffman, John E. Murphy, Tia DiTommaso

Arbor Biotechnologies, Cambridge, MA

Achieving widespread therapeutic gene editing will require a broad toolbox of editing enzymes. Here we describe an end-to-end pipeline for optimization of CRISPR gene editing nucleases towards greater efficiency and specificity in therapeutic applications, demonstrated through the development of ABR-004, a highly active <750 amino acid nuclease guided by a small (<60) nucleotide guide RNA. Through a metagenomic search, we initially identified a family of miniature CRISPR-Cas type V-L systems capable of RNA-guided double-stranded DNA target cleavage without requiring a tracrRNA. Focusing on one ortholog, we solved the cryo-EM structure in complex with its guide RNA and target DNA, and then combined structure-guided design and unbiased mutational scanning to rationally engineer a variant, ABR-004, for increased activity, achieving >70% indels at a number of targets within the *PCSK9* gene in primary human hepatocytes when delivered as an RNP. We further optimized additional parameters, using information from the cryo-EM structure, including guide length and chemical modifications, to increase editing specificity. To demonstrate potency in an *in vivo* model, ABR-004 mRNA and guide were formulated in an LNP and delivered at a low dose (0.5 mg/kg) to transgenic mice expressing a human *PCSK9* transgene, resulting in a >80% reduction in PCSK9 serum protein levels two weeks after treatment. Next, ABR-004 LNPs targeting *PCSK9* were delivered to cynomolgus macaques, resulting in a 65% reduction of serum PCSK9 and a 66% reduction in serum LDL-C after 4 weeks. This work demonstrates the feasibility of developing new gene editing tools, starting from computational identification, through molecular and structural characterization, engineering, and ending with *in vivo* application in non-human primates. Given its small size (<2.3kb combined size of guide + nuclease), specificity, and potency, ABR-004 is an attractive option for therapeutic applications, particularly those relying on AAV delivery.

151. Toward an *In Vivo* Approach to Knock-Out the HIV Co-Receptor CCR5 in Hematopoietic Stem Cells Using HDAd Vectors Expressing Base Editors

Anna K. Anderson[1], Aphrodite Georgakopoulou[1], Karthik Karuppusamy[1], Anne-Sophie Kuhlmann[2], Andrew Riker[3], Hans-Peter Kiem[2], Andre Lieber[1], Chang Li[1]

[1]University of Washington, Seattle, WA,[2]Fred Hutch, Seattle, WA,[3]Fred Hutchinson, Seattle, WA

We have developed an *in vivo* HSC transduction strategy that allows for efficient and stable gene transfer into mobilized HSCs. Our approach utilizes helper-dependent adenovirus (HDAd) vectors that target therapeutic gene delivery to HCSs. Here, we employ this approach using base editors to knock-out the HIV co-receptor CCR5 in HSCs and their progeny. Base editors can introduce precise cytidine (CBE) or adenine (ABE) substitutions with minimal occurrence of undesired DNA changes at the genomic target site. We screened a panel of single guide RNAs paired with base editors in TZM-bl cells to achieve CCR5 knockout. TZM-bl cells are susceptible to HIV infection (through CD4 and CCR5) and HIV infection can be measured as a function of Tat-induced luciferase reporter gene expression. In these screening studies, we found that a sgRNA targeting the CCR5 start codon (referred to as SILENCE2) combined with an ABE (ABE8e) and a sgRNA that creates a premature stop codon (referred to as STOP1) combined with a CBE (BE4max) or a laboratory-evolved CBE (TadCBE) exhibited the highest on-target editing rates as well as CCR5 down-regulation. Notably, editing rates were significantly higher with the TadCBE than with the BE4max. We then produced all-in-one base editor HDAd vectors containing the sgSTOP1 and sgSILENCE2 alone or in combination with a Dual editor (TadDE). In addition to the editing machinery, the vectors contained an expression cassette for $mgmt^{P140K}$, which allows for enrichment of edited cells by selection with low doses of O^6BG/BCNU. Downregulation of CCR5 (measured by flow cytometry) was highest for vectors containing the STOP1 guide (HDAd-STOP1-TadCBE and HDAd-STOP1-SILENCE2-TadDE) indicating that editing using this guide blocks CCR5 expression more efficiently. HDAd-transduced/edited TZM-bl cells were challenged with the HIV-BaL strain. CCR5 base editing by the HDAd-SILENCE2-ABE8e vector conferred 64% inhibition and both HDAd-STOP1-TadCBE, and HDAd-STOP1-SILENCE2-TadDE vectors conferred 98% inhibition of HIV-BaL infection/replication based on luciferase expression levels. Next, we transduced human $CD34^+$ cells from three healthy donors with HDAd-STOP1-SILENCE2-TadDE or HDAd-STOP1-TadCBE followed by treatment with O^6BG/35 μM BCNU. On average, target site editing rates were 25% for HDAd-STOP1-TadCBE and 13% for HDAd-STOP1-SILENCE2-TadDE. To allow for infection studies with HIV, we subjected transduced/edited $CD34^+$ cells (cord blood derived) to *in vitro* differentiation over 42 days resulting in $CD4^+CCR5^+$ T-cells. At the end of differentiation, cells were exposed to HIV. Three days after HIV infection, HIV genome titers in supernatants of T-cells derived from HDAd-STOP1-TadCBE and HDAd-STOP1-SILENCE2-TadDE-transduced $CD34^+$ cells were 21-fold and 4-fold lower, respectively, compared to T-cells derived from untransduced $CD34^+$ cells (which had titers of $>2x10^9$ copies/ml, based on qRT-PCR). Based on HIV-Gag flow cytometry of T-cells, inhibition of HIV replication was 84% and 70%, respectively. For *in vivo* studies, we are generating humanized mice with human $CD34^+$ cells that can differentiate into $CD4^+/CCR5^+$ T-cells. We plan to mobilize these mice, transduce human HSCs with HDAd-sgR5-1 *in vivo* and challenge the animals with HIV. We are also preparing *in vivo* HSC transduction studies in non-human primates by selecting appropriate sgRNAs for CCR5 knock-out in rhesus cell lines. In addition, we are generating an HDAd vector with two functional modules, e.g. the HIV decoy receptor eCD4Ig and the CCR5-knockout base editor to minimize the development of HIV escape mutants.

152. Targeting the Hepatitis B Virus cccDNA via the LNP-Delivered hfCas12Max Nuclease to Eliminate Hepatitis B Virus *In Vitro* and *In Vivo*

Yinghui Wei[1], Zikang Wang[1], Weiya Bai[1], Haosha Tang[1], Tong Li[1], Shaoran Wang[1], Xuan Yao[1], Alvin Luk[1], Yingsi Zhou[1], Hui Yang[1,2], Linyu Shi[1]

Background: The hepatotropic, non-cytopathic DNA virus, Hepatitis B virus (HBV) generates a covalently-closed-circular-DNA (cccDNA) intermediate in the nucleus of infected cells, as well as integrated sequences that act as templates for viral transcription and protein production. Although current antiviral therapies with nucleoside analogues inhibit replication of HBV DNA in capsids present in the cytoplasm of infected cells, they fail to reduce or eliminate nuclear cccDNA as well as cure chronic hepatitis B. Here, we present a potential curative strategy employing high-fidelity Cas12Max (hfCas12Max), an engineered Cas12i variant with high activity and specificity, delivered by lipid nanoparticle (LNP) which targets the HBV genome. **Methods**: Effective guide RNAs (gRNAs) were initially selected and screened within the PiggyBac(PB)-HBV-HEK293 system. Furthermore, a functional gRNAs screen was performed in HBV-integrated cell lines and primary human hepatocytes (PHHs) infected with HBV. To evaluate the *in vivo* efficacy of the hfCas12Max nuclease, we developed an episomal adeno-associated virus (AAV) mouse model harboring a 1.3-fold HBV genome, which serves as a surrogate for cccDNA. Clinically relevant delivery was achieved through the systemic administration of LNPs encapsulating hfCas12Max mRNA and gRNAs. **Results**: Leading gRNAs targeting the hepatitis B surface antigen (HBsAg) and associated genes were identified within HBV-integrated hepatic cell lines. Upon delivery via the LNPs, the hfCas12Max targeting led to a substantial decrease in cccDNA, HBV-DNA, and HBsAg levels in HBV-infected PHHs (Fig. 1A-E). In the AAV-HBV mouse model, we observed sustained reductions in HBsAg expression (up to 2.5 log) and serum HBV DNA (~3log) following systemic delivery of varying doses of the CRISPR-hfCas12Max system mediated by LNP (Fig. 2A-D). **Conclusions**: Our findings suggest that the CRISPR- hfCas12Max system could disrupt the HBV-expressing templates both *in vitro* and *in vivo*, which underscores its potential for the eradication of cccDNA, paving the way toward a potential cure for HBV.

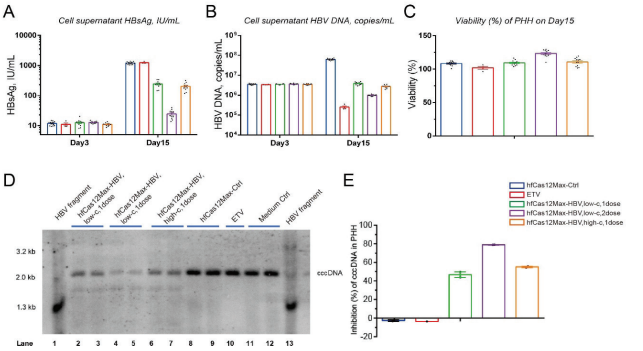

Figure 1. LNP-mediated delivery of hfCas12Max mRNA and gRNAs reduces HBV viral parameters in primary human hepatocytes (PHH). (A, B) HBV replication was assessed by HBsAg and HBV DNA in PHH supernatant. hfCas12Max targeting leads to efficient reduction of HBsAg (A) and HBV DNA (B). (C) The viability of PHH cells in each group was unaffected on day 15. (D) Hirt DNA samples were isolated from each sample and then subjected to Southern blot (n=2). Lanes 1 and 13 were loaded with HBV DNA fragments of 25 pg for each fragment (3.2kb, 2.0kb) and 12.5 pg for the 1.3kb fragment. Lanes 2 to 12 were loaded with 20 µL of Hirt DNA samples for each lane. (E) hfCas12Max nuclease treatment results in a significant reduction in cccDNA at day 15 post-transduction in PHH.

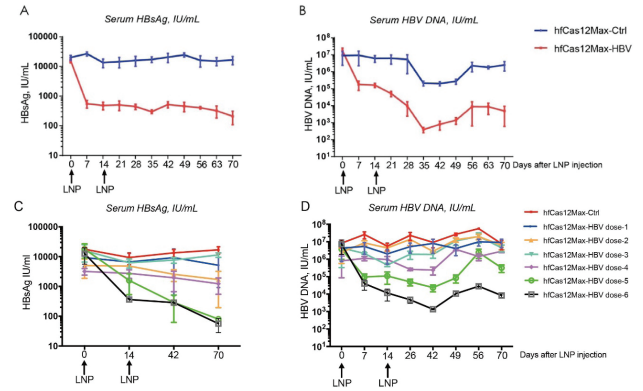

Figure 2. LNP-mediated delivery of hfCas12Max mRNA and gRNAs leads to sustained reduction of viral markers in AAV-HBV mouse model. (A, B) The AAV-HBV mouse model was used in the in-vivo pilot study. 4 weeks after hydrodynamic injection with AAV8-1.3-fold HBV genome, mice received two doses (2x) of the hfCas12Max-targeting reagents (mRNA & gRNA formulated into LNP). hfCas12Max nuclease treatment resulted in sustained reductions in HBsAg expression (~2 log) (A) and HBV DNA (~3 log) (B) in serum. (C, D) The antiviral activity was explored in the AAV-HBV mouse model by assessing serum HBsAg (C) and HBV DNA levels (D) following the administration of escalating doses of LNP, ranging from dose-1 to dose-6.

153. Non-Viral Gene Editing with Dual Guide RNAs for Chronic Hepatitis B Infection

Samuel Slattery, Sujeewa Sampath Lellupitiyage Don, TJ Cradick, Jennifer Gordon, Ryo Takeuchi

Excision BioTherapeutics, Watertown, MA

Hepatitis B virus (HBV) infection is one of the most prevalent infectious diseases worldwide. In hepatocytes with chronic HBV infection, a subset of HBV DNA is present as covalently closed circular DNA (cccDNA) and serves as the template for a series of viral transcripts. Currently approved treatment with antivirals and immunomodulators reduces the viral load to slow down the progress of liver injury but fails to eliminate the cccDNA that enables persistent viral infection. Gene editing holds the great potential to target all forms of viral DNA, including cccDNA, and may offer a new option for functional cure or even better clinical outcomes. We have developed multiple candidate therapeutics with paired guide RNAs, because we hypothesize that DNA strand breaks generated at multiple sites can lead to large deletions (excisions) that eliminate a large region of the viral genome, effectively inactivating and preventing the emergence of escape variants. Here, we evaluated a dual guide RNA-mediated editing strategy against HBV in cell-based assays and in vivo. Building on a proprietary computational approach, we identified multiple nucleases and guide pairs to target well-conserved sites within the HBV genome. We then cross referenced these selected guide target sites against human reference genomes to select sites that shared the least sequence identity with human genetic sequences, thereby minimizing the chance for off-target editing. Using reporter cell lines with the partial HBV genome integrated in the chromosomal DNA, we identified pairs of guide RNAs that efficiently deleted sequences between target sites found in a wide range of HBV isolates. We next examined a representative combination of editing nucleases and paired guide RNAs in HBV-infected cells and verified that it decreased copies of total HBV DNA. To demonstrate proof-of-concept in vivo, we intravenously administered a lipid nanoparticle (LNP) that encapsulated an editing nuclease-encoding mRNA and a pair of guide RNAs in the HBV mouse model established with AAV-HBV. A single LNP administration significantly lowered HBV biomarkers in serum. Consistent with that observation, we detected reduced levels of intrahepatic HBV, suggesting that cutting of HBV DNA facilitated its degradation in vivo. These results laid the foundation for advancing a potential curative CRISPR-Cas HBV treatment into IND enabling studies and human clinical studies.

154. A Comparison Study Between Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR) Guide RNAs and Discovery of LgRNA-33 as an Anti-HBV Agent of Multiple Mechanisms of Action (MOA)

Qiong Zhao[1], Xiaoyun Lin[2], Ju-tao Guo[1], Minghong Zhong[2]

[1]Baruch S Blumberg Institute, Doylestown, PA,[2]GeneLancet Biosciences, Inc., Doylestown, PA

Cure of chronic hepatitis B requires elimination or inactivation of HBV cccDNA and integrated DNA. Several CRISPR/Cas DNA editing-based therapeutics are currently under preclinical development to achieve this therapeutic goal. To improve the gene editing efficiency and accuracy, we optimize guide RNAs through chemical ligation of short RNA segments via non-phosphoramidite chemistry, i.e., ligated guide RNA (LgRNA) and chemical modifications. Compared to the linear chemical synthesis of a classical single guide RNA (sgRNA), our proprietary LgRNA technology provides high-quality products (>99% purity by HPLC) containing a single spacer sequence and enables cost-effective scaleup production (potentially multiple kilograms), diverse chemical modifications, targeted delivery by conjugations and various formulation technologies. We have shown that LgRNAs more efficiently cleave/edit target integrated HBV DNA and HBV cccDNA at multiple sites in hepatocytes (Fig. 1 (A)). To our surprise, in addition to the on-target editing of 50 to 80% of integrated HBV DNA in HepAD38 cell culture in the presence of tetracycline (tet) to suppress HBV pgRNA transcription as determined by next-generation sequencing (NGS), the LgRNAs targeting different regions of HBV genome (preC, core, HBsAg or HBx region) significantly reduced the levels of subgenomic HBV RNAs and secreted HBsAg, and upon removal of tet from culture media of the LgRNA transfected HepAD38 cells, significant reduction of HBV pgRNA was observed in cells transfected with all LgRNAs. Moreover, a single transfection of LgRNA into HBV-infected HepG2-NTCP cells expressing Cas9 achieved on-target editing of 10 to 40% of cccDNA as determined by NGS. Similar to that observed in HepAD38 cells, all tested LgRNAs targeting different regions of HBV genome

significantly reduced subgenomic HBV RNA and secreted HBsAg. In addition, LgRNAs targeting HBx, PreC, or core regions reduced both secreted HBeAg and the amount of cccDNA in the infected cells. Exceptionally, LgRNA-33 showed anti-HBV activity by multiple mechanisms of action (MOA). By a single treatment (10 pmol) of HBV-infected HepG2-NTCP cells-expressing Cas9, LgRNA-33 reduced HBV cccDNA level by >60%, while inactivated the remaining cccDNA by 30% (as indicated by NGS data), decreased sub-genomic RNAs by >70% and pgRNA by ~65%, and removed >90% of HBsAg and ~80% of HBeAg viral proteins in the infected cells. LgRNA-33 also showed dose-dependent activity in HepAD38 cells containing a full copy of integrated HBV DNA and nearly cleared both HBsAg (Fig. 1 (B)) and subgenomic RNA at a ten pmol dose (Fig. 1 (C)).

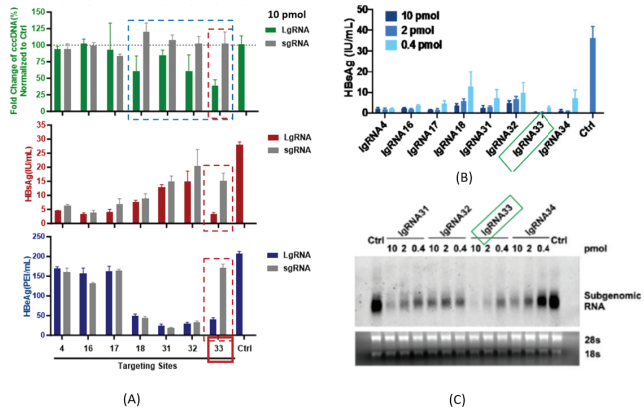

Figure 1. Anti-HBV activities of sgRNAs and LgRNAs in hepatocytes.

(A) Comparison study between sgRNAs and LgRNAs in HBV-infected hepatocytes. LgRNA-33 showed dramatically better efficiencies than sgRNA-33.
(B) Dose-dependent decreases of cellular HBsAg levels by LgRNAs in HepAD38 cells containing a full copy of integrated HBV DNA.
(C) Dose-dependent decreases of viral subgenomic RNA by LgRNAs in HepAD38 cells containing a full copy of integrated HBV DNA.

155. Engineering CasX to Create a Gene Editor with Potent Activity in Non-Human Primates

Addison Wright, Maroof M. Adil, Shyam Sundhar Bale, Katherine Baney, Isabel Colin, Fred Deiter, Benjamin Demaree, Sarah K. Denny, Michelle Eggers, Sean Higgins, Santhosh Karanth, Steven Keller, Kirsten A. Reimer, Han Spinner, Brett T. Staahl, Keith E. Szulwach, Kian Taylor, Ross White, Benjamin L. Oakes

Scribe Therapeutics Inc, Alameda, CA

The application of RNA-guided endonucleases from CRISPR-Cas systems has revolutionized the gene editing field. The need for Cas enzymes with reduced size, increased specificity, or distinct editing profiles or PAM preferences has driven the identification and characterization of diverse novel Cas effectors. However, many of these naturally occurring effectors have poor translatability into mammalian systems. Here, we present our work engineering the CasX (Cas12e) holoenzyme for improved activity and demonstrate its efficacy in human cells and animal models, including non-human primates. CasX is a Class 2 Cas effector enzyme that binds and cuts dsDNA substrates when loaded with a matching guide RNA. Unlike Cas9 and Cas12a variants, however, CasX is small enough (<1000 amino acids) to fit efficiently in an AAV vector with multiple guides or complex regulatory elements, generates distinct deletion patterns, and has less tolerance for mismatches between the guide RNA and dsDNA substrate. By building and screening hundreds of thousands of distinct CasX nucleases and guide RNAs, we have created novel and dramatically improved variants. The resulting "X-Editor" (XE) ribonucleoprotein (RNP) exhibits editing activity orders of magnitude higher than wild-type CasX molecules. We characterized XE editing efficiency compared to other engineered small Cas systems across dozens of loci in human cells, and we further show that XE can achieve knock-out rates of immuno-oncology targets equal to or better than SpyCas9 when delivered as RNP to primary human immune cells. We also show that XE achieves near-saturating levels of gene editing across the CNS, muscle, eye, and liver in mice when delivered via AAVs or LNPs. Finally, we show that XE is well-tolerated and saturates editing in the liver of non-human primates when delivered via LNPs. We demonstrate that XE is a potent and flexible platform for gene editing, with robust activity and specificity across a range of delivery modalities and targets.

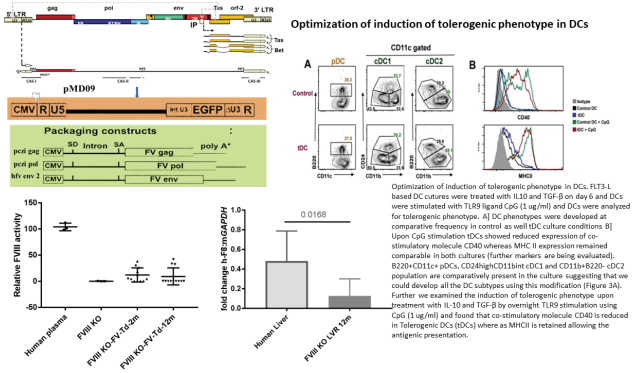
New Avenues for Viral Vectors

156. HDAd6/3+-cxcr4 Vectors: A Safe and Efficient Vector Platform for *In Vivo* HSC Transduction in Rhesus Macaques

Chang Li[1], Hongjie Wang[1], Anna K. Anderson[1], Lishan Huang[1], Aphrodite Georgakopoulou[1], Theo Koob[1], Sucheol Gil[1], Donna J. Palmer[2], Philip Ng[2], Hans-Peter Kiem[3], Andre Lieber[1]

[1]University of Washington, Seattle, WA,[2]Baylor College of Medicine, Houston, TX,[3]Fred Hutch, Seattle, WA

We generated helper-dependent adenovirus vectors (HDAds) targeting receptors present at high levels on hematopoietic stem cells (HSCs), namely CD46 and desmoglein 2 (DSG2). We used these vectors for an *in vivo* HSC gene therapy approach that we recently developed. This approach involves subcutaneous injections of G-CSF/plerixafor (AMD3100) to mobilize HSCs from the bone marrow into the peripheral blood stream, followed by intravenous injection of HDAd vectors. A large fraction of transduced HSCs returned to the bone marrow and can be expanded using $mgmt^{P140K}$ expression and O^6BG/BCNU treatment. Here we compared two HDAd vector platforms: *i)* HDAd5/35++, an Ad5 derived vector with affinity-enhanced fibers from Ad35 that targets CD46 and has been used in most of our previous studies; *ii)* HDAd6/3+-cxcr4, our latest HDAd vector platform derived from the relative rare serotype 6 and containing fibers from Ad serotype 3 with enhanced affinity to DSG2. The vector also transiently expresses cxcr4, which facilitates the return of mobilized HSCs to the bone marrow. In *in vitro* studies with human and rhesus $CD34^+$ cells, GFP-expressing HDAd6/3+-cxcr4 transduced $CD34^+$/$CD45RA^-$/$CD90^+$, a subfraction that is enriched for primitive HSCs, at least twice as efficiently as HDAd5/35++. For *in vivo* studies, rhesus macaques were mobilized with G-CSF/AMD3100 and intravenously injected with HDAd6/3+-cxcr4 vectors at a dose of 3.2×10^{12} vp/kg after cytokine prophylaxis with IL-6 and IL-1 blockers (N=6). At the peak of mobilization, the time point when HDAd vectors were injected, 40



- 150 x 10^3 $CD34^+/CD45RA^-/CD90^+$ cells per ml (~100-fold increase compared to non-mobilized animals) were detected in peripheral blood, indicating efficient mobilization. HDAd6/3+-cxcr4 vector clearance in peripheral blood was slower than that of HDAd5/35++, most likely because HDAd6/3+-cxcr4 was less sequestered by blood cells, specifically erythrocytes. While HDAd5/35++ injected animals showed low serum levels of IL-6 and TNFα at 6 hours after HDAd injection, no cytokines were detectable by cytometric bead array after HDAd6/3+-cxcr4 injection, again pointing toward less interaction of HDAd6/3+-cxcr4 particles with granulocytes and tissue macrophages. Furthermore, the HDAd6/3+-cxcr4 vector design, specifically the use of the Ad6 fiber shaft, minimized liver transduction as reflected by normal levels of liver enzymes. These data indicate that HDAd6/3+-cxcr4 vectors are safe. The efficacy of *in vivo* HSC transduction was measured based on vector copy number (VCN) in bone marrow aspirates. The VCN in HDAd6/3+-cxcr4-injected animals increased during the first weeks, most likely due to cxcr4-mediated translocation from the spleen to the bone marrow, reaching ~0.3 copies per $CD34^+$ cell; a transduction level that was 20-fold higher than that in HDAd5/35++ injected animals. In NHP studies with HDAd6/3+-cxcr4 vectors containing an integrating transgene expression cassette, stable VCN levels in bone marrow $CD34^+$ cells and PBMCs were demonstrated after two rounds of O^6BG/BCNU *in vivo* selection at 16 weeks after *in vivo* transduction (study is ongoing). The bone marrow and PBMC lineage composition (CD3, CD20, CD14) returned two pre-mobilization levels by week 6 after *in vivo* transduction. In summary, the DSG2-targeting HDAd6/3+-cxcr4 vector platform allows for safe and efficient HSC *in vivo* transduction in rhesus macaques. Our current efforts are focused on developing a strategy for HSC *in vivo* expansion that does not require chemotherapy drugs, including epitope editing in combination with non-genotoxic antibodies/antibody-drug conjugates or the expression of truncated versions of the erythropoietin receptor of HMGA2.

157. Foamy Viral Gene Therapy Using a Foamy Viral Vector and Strategies to Induce Transgene Tolerance

Sanal MG[1], Sarita Gupta[1], Rahul Saha[1], Prafullakumar B. Tailor[2], Nagarajan Perumal[2]

[1]Cellular and Molecular Medicine, Institute of Liver and Biliary Sciences, New Delhi, India,[2]National Institute of Immunology, New Delhi, India

Background: Haemophilias are genetic diseases where the patient tends to bleed excessively as a result of a defect in blood clotting. Currently, there is no cure but the condition is managed by the supplementation of the deficient factor such as recombinant factor 8/ 9. Here we attempted to cure Hemophilia A using a gene therapy approach [with a foamy viral vector (FVV) to transduce factor 8] in liver cells in a haemophilia-A (factor 8 Knock Out) mouse model. FVV can deliver larger cargos such as the factor 8 gene. Foamy virus as it is not endemic and is non-pathogenic in humans. Host immunity against transgene is a problem in gene therapy. Here we also explored tolerogenic DCs induced by treatment with immunosuppressive cytokines such as IL-10 in mitigating host immunity. Methods: We cloned the Factor 8 gene in a modified FVV pMD09 under a liver-specific promoter (TTR). The virus was generated in HEK293 cells. We injected retro-orbitally 2-6 × 10^6 infectious units of FVV in 12 mice and 6 animals (untreated) served as controls. At 2-12 months we estimated factor 8 activity in citrated plasma using the Electrachrome™ FVIII kit (Cat. #49730503 HemosIL® Wefen, MA, USA) following the manufacturer's instruction. We also isolated total RNA and gDNA from mouse liver. RNA was used to prepare cDNA to estimate human factor 8 transcripts by Real-Time PCR (normalized to mouse GAPDH). The gDNA was used to estimate integrated viral genetic elements by PCR. Results: We observed expression of factor 8 in 7 animals after two months and 3 animals at 1 year. The expression levels ranged from 2% of the positive controls to 38% at two months. All three animals that retained the expression had factor 8 levels of 30% or above compared to the control (human plasma). All animals that were positive for plasma factor 8, also had detectable factor 8 transcripts in liver tissue although the transcript levels did not correlate well with factor 8 plasma levels estimated (functional assay). We found FVV integrated into the genome of all 3 mice which expressed factor 8 at 1 year. Conclusion: FVV can transduce mice liver and express factor 8 up to 1 year. We are yet to see if tolerogenic DCs can improve the levels and duration of factor 8 expression in mice.

158. A Novel Method for Generating Unprecedented Unbiased, Ultra-High-Sequence Diversity Libraries of Plasmids and Recombinant Viruses (With Validation) for High-Throughput Screening, Data for Machine Learning (AI) and Targeted Therapy

Praveensingh B. Hajeri[1], Masato Yamamoto[2]

[1]Department of Surgery, University of Minnesota, Minneapolis, MN,[2]University of Minnesota, Minneapolis, MN

Background: A typical drug discovery pipeline needs good libraries of potential therapeutic candidates with high-sequence diversity. The probability of finding a good hit primarily depends on the quantity (diversity) and quality (distribution) of candidates in libraries used for screening. They include libraries of peptides, single-chain antibodies, nanobodies, CRISPRs, shRNAs, phage display, yeast display, Ribosome display, DARPins, BiKEs, TriKEs, CAR-T cells, and recombinant viruses (including adenoviruses, lentiviruses, AAVs, and other oncolytic viruses, etc.). Screening them for specific interaction with the target of interest to narrow down to fewer candidates, which can be further validated, are the basic steps in the generic discovery pipeline. Lately, artificial intelligence (AI) based designing has also been used to design candidates for targeted interaction. However, the quality of

such prediction depends on the data used in machine training. Since the current libraries are known to be biased, such libraries may not be as good as unbiased libraries. ***Current limitations:*** Generating high-sequence diversity libraries is very challenging. Several published studies and industries claim to have very high diversity libraries ranging over 10^9 sequence diversity. However, most of those libraries lack validation by stringent experimental standards, and the diversity claimed is mainly based on sequencing a small number of candidates in the library and statistical extrapolations. Most of the time, we found that those who claim very high diversity (over 10^8) did not validate their libraries with stringent next-generation sequencing (NGS) based methods, and those who used stringent NGS methods for validation usually do not claim such big diversity. Therefore, there is an imminent need for a method to generate genuine high-sequence-diversity libraries of high quality. ***Methods and results:*** We have developed a novel method to generate such libraries with very high sequence diversity and validated them with stringent NGS-based methods. Compared to other established methods, our libraries are at least 100 to 1000 times better in diversity (quantity) and have a more uniform and unbiased distribution (quality). Through benchmarking studies, we validated total diversity, duplication rate, sequence bias, and the ability to scale up. As a proof of concept, we generated libraries of plasmids (shuttle vectors to make recombinant adenoviruses) and recombinant adenoviruses with high sequence diversity in a structural protein (Fiber). We also used them for screening against a cancer-specific cell-surface protein. ***Applications:*** Our methods can generate quantitatively and qualitatively better (100-1000 times) libraries. They can be used in high-throughput screening against targets of interest to narrow down to fewer candidates. Smaller libraries resulting after serial and multiple rounds of screening can serve as a dataset for machine training to aid AI-based design. Our unbiased, high-diversity libraries provide a high-quality dataset to improve Ai-based design criteria. We expect our libraries may help in avoiding AI-based design altogether in some cases.

159. SV40 Vector-Based Gene Therapy: A Groundbreaking Platform for Genetic Disorders and Autoimmune Diseases

Petrus De Haan, Petrus De Haan

Amarna Therapeutics, Leiden, Netherlands

To date, adeno-associated virus (AAV) vectors are the most popular for use in *in vivo* gene therapy. However, clinical studies using AAV vectors revealed that administration of vector particles elicits innate and adaptive immune responses against the viral and transgene proteins in the vast majority of treated patients. For these reasons, an alternative non-immunogenic gene delivery vector is highly desired. Vectors derived from Simian Virus 40 (SV40) could be an attractive alternative to AAV vectors for clinical gene therapy. SV40 is a polyomavirus with icosahedral capsids containing a 5.25 kb long circular double-stranded DNA covered with histones to form euchromatic mini chromosomes. The virus strictly replicates in macaques, where it causes chronic asymptomatic infections. Unlike other viruses, polyomaviruses are able to evade the host's immune system after cell entry and since humans can be considered naive to SV40, it is expected that replication defective SV40 vectors are non-immunogenic and tolerogenic when applied in clinical settings. We at Amarna have developed a replication-defective SV40-based gene delivery platform named SVec. SVec particles are produced at high titers using a proprietary engineered Vero producer cell line named SuperVero. Because of its non-immunogenicity and tolerogenicity in humans SVec particles can be repeatedly administered to the same patient without the induction of any immune response. We tested SVec for its feasibility in developing gene replacement therapies for two genetic disorders, hemophilia B (HemB) and primary hyperoxaluria type 1 (PH1). For both diseases the genetic defect was successfully corrected by hepatic expression of SVec vectors encoding functional blood clotting factor IX in the F9 knockout HemB mouse model and alanine-glyoxylate aminotransferase in the AGxT knockout PH1 mouse model respectively. We next explored the potential of SVec to develop effective tolerization therapies for autoimmune diseases. There is an accumulating body of evidence that most of todays' major degenerative and inflammatory diseases are autoimmune diseases and it is generally accepted that the ultimate curative intervention for this cluster of diseases would be the induction/restoration of immune tolerance to the primary self-antigen of the disease. For two established autoimmune diseases, diabetes mellitus type 1 (T1DM) and multiple sclerosis (MS) we recently obtained prophylactic and therapeutic proof-of-principle in the relevant mouse models of both diseases. Using the inducible experimental autoimmune encephalitis (EAE) mouse model of human MS, hepatic expression of an SVec vector encoding myelin oligodendrocyte glycoprotein (MOG), the primary self-antigen of MS, both protects the tolerized animals from developing the autoimmune disease symptoms or ameliorates disease symptoms in symptomatic mice. Expression of an SVec vector encoding proinsulin, the primary self-antigen of T1DM in the liver stops the autoimmune destruction of pancreatic β-cells and hence disease progression in non-obese diabetes (NOD) mice that were on their way to develop T1DM. These remarkable therapeutic effects have been obtained using relatively low vector doses ($2x10^7$ infectious units per kilogram of body weight). Overall, we have shown in relevant animal disease models that SVec vectors are ideally suited for developing safe and effective gene replacement and tolerization therapies to treat genetic disorders and autoimmune diseases. On the basis of these encouraging results we are building a pipeline of SVec-based gene therapy products for treating todays major diseases including genetic disorders (PH1, HemB and hemophilia A), metabolic diseases (T1DM, diabetes mellitus type 2 (T2DM)/obesity) and neurodegenerative diseases (MS, Alzheimer's dementia, Parkinson disease and amyotrophic lateral sclerosis).

160. Delivery of Large Gene Circuits *In Vivo* Using an Engineered Baculovirus Vector for Multifactorial Control of Therapeutic Gene Expression

Lucas B. C. Brown, Linlin Zhang, Gang Bao, Caleb J. Bashor

Bioengineering, Rice University, Houston, TX

Many of the viral vectors used for gene therapy are limited by the cargo size they can deliver into cells in tissue. As a result, most therapies being actively considered today tend to consist of monomodal expression of one or two genes. While this modality is undoubtedly effective for many applications, there remains advantages to being able to deliver more genetic cargo. A viral vector with an increased cargo capacity could allow room not only for more and larger therapeutic genes,

but also regulatory elements that permit complex, multifactorial regulation of therapeutic gene expression. Here we use the insect-derived baculovirus capable of packaging and delivering >100kb of transgene DNA as a vector for complex gene circuits that regulate and enhance in vivo gene therapy. Baculovirus has many advantages over other vectors: the ability to transduce a broad spectrum of mammalian cells, a large packaging capacity, no replication in mammalian cells, and a low toxicity *in vivo.* However, while baculovirus has been used as a gene therapy vector previously, its potential has been limited by its transient expression, as well as its susceptibility to inactivation by the complement system. We first address several shortcomings of the baculovirus by pseudo-typing the AcMNPV baculovirus with two proteins, the Vesticular stromatitis virus protein G and a fusion protein consisting of several complement regulatory domains. This engineered vector has increased transduction and persistence in mouse liver, muscle, and brain tissue. To our knowledge, this is the first time systemic delivery of baculovirus has been shown to be an effective delivery route. We further increased the length of baculovirus transgene expression to more than a month *in vitro* and *in vivo* through the screening of promoters and other genetic elements such as the Ebna1-OriP system. We then implemented a hierarchical cloning scheme for the rapid generation and prototyping of baculovirus vectors containing up to 10 different expression units. Using this system, we screened a library of 24 variations of a tamoxifen inducible circuit in order to select the architecture with the highest dynamic range, up to a 67-fold increase over uninduced. Finally, we demonstrate two orthogonal small molecule inducible systems (grazoprevir and tamoxifen) delivered by baculovirus *in vivo*. Our findings will demonstrate the usefulness of complex regulation for the gene therapy field, as well as the utility of the baculovirus as a therapeutic vector.

161. Defining the Role of Viral and Cellular Insulators in Promoting Durable HSV-1 Vector Mediated Transgene Expression in Muscle and Brain

Selene Ingusci, Justus B. Cohen, Joseph C. Glorioso
Department of Microbiology and Molecular Genetics, University of Pittsburgh, Pittsburgh, PA

Herpes simplex virus 1 (HSV-1) replication defective vectors are promising new gene therapy vectors for expression of large or multiple genes. We have developed safe HSV-1 gene transfer vectors by functional deletion of all immediate-early (IE) genes and the reiterated JOINT region flanking the unique long (U_L) and unique short (U_S) genomic components, together providing a payload capacity of ~30kb. Deletion of the gene encoding the highly cytotoxic infected cell protein 0 (ICP0) completely abrogated viral gene expression and eliminated vector cytotoxicity and recruitment of inflammatory cells *in vivo.* While this enhanced vector safety, the transgene payload was also rapidly silenced. Transgene expression was rescued by replacing either the latency associated transcript (LAT) or the ICP4 lytic gene with the transgene cassette in close proximity to naturally occurring viral insulator/boundary elements that help maintain euchromatin. The viral insulators are enriched in binding sites for the CTCF protein, a master regulator of chromatin structure. Surprisingly, the LAT locus was more permissive for transgene expression in myotubes *in vitro* whereas the same cassette in the ICP4 locus was more active in differentiated SH-SY5Y neuroblastoma cells. *In vivo* delivery to skeletal muscle demonstrated stable transgene expression from the LAT locus for at least 1 year, whereas persistent transgene expression from the ICP4 locus was documented over a 5-month period in mouse hippocampus. However, the level of expression in brain neurons tended to decline over time. To remedy this decline and further enhance transgene expression, we designed a novel insulator construct by combining cellular and viral endogenous insulator elements. The new design included mouse tRNA genes and scaffold/matrix attachment regions (S/MARs) known to function as chromatin barrier elements shielding the transgene from the spread of repressive heterochromatin. This novel combination of insulator elements provided significantly higher levels of transgene expression in the brain and also eliminated the difference in transgene activity observed between the two loci in both muscle and neurons. This new cassette design will ensure high and durable transgene activity in multiple tissue types and should prove beneficial for treating a wide range of muscle and brain disorders.

162. Adenoviral DNA Replication of HC-AdV Genomes

Jonas Kolibius, Patrick Freitag, Fabian Weiss, Andreas Plückthun
Department of Biochemistry, University of Zurich, Zurich, Switzerland

Introduction: High-capacity adenoviral vectors (HC-AdVs) have shown to be a promising vector type for the nuclear delivery of large DNA cargoes. This includes the coding sequence of therapeutic antibodies, cytokines, genome editors, and combinations of immunotherapeutics. As the HC-AdV is devoid of all viral genes, the viral genome does not undergo viral DNA replication after nuclear translocation. This often results in weak payload expression, loss of transgene expression due to cell division, genome degradation, or cellular silencing effects. To circumvent these limitations, we are developing a new adenoviral vector type featuring intrinsic amplification of its delivered vector genome without viral particle formation and lysis of the host cell while preserving a large transgene capacity of more than 20 kb. Methods: We established a transfection-based complementation assay to identify the individual adenoviral proteins that are required for efficient viral genome replication in HEK293 and A549 cells. After transfection of plasmids encoding the viral replication machinery and followed by transduction of a HC-AdV, the expressed viral replication machinery triggers amplification of the delivered HC-AdV genome. Total DNA can then be extracted, and adenoviral genome replication can be precisely quantified by qPCR. When encoding a reporter on the HC-AdV genome, transcription and payload expression can be monitored via RT-qPCR and flow cytometry. Results: By applying the established *trans*-complementation assays, we were able to identify the minimal set of viral components necessary for adenoviral DNA replication. Expression of these proteins results in potent amplification of incoming HC-AdV genomes upon translocation to the nucleus. Replication of the delivered vector genome leads to a greatly increased expression of the encoded payload. There was no induction of a cytopathic effect observed, suggesting that killing of the host cell is successfully prevented by careful selection of the delivered viral genes. Conclusion: We have screened various adenoviral genes for the involvement of their respective gene products in the adenoviral DNA replication. As expected, the presence of a minimal set of adenoviral gene products

is crucial for the replication machinery to successfully amplify the genomes of HC-AdVs, while other genes mostly modulate the cellular environment to further increase the efficiency of the replication machinery so that more viral genome copies can be generated. Replication of the payload-encoding HC-AdV genome results in an elevated payload expression which potentially allows a dose reduction of HC-AdVs in a future therapeutic application to alleviate vector-mediated immunogenicity. Importantly, genome replication and increased payload expression does not induce a cytopathic effect, resulting in persistent payload expression due to the prevention of host cell death, which is usually a limitation when working with other replicating adenoviral vector classes, such as replicating single-cycle or fully replication competent adenoviral vectors.

Gene Transfer and Genome Editing for Inherited Metabolic Disorders

163. Long-Term Efficacy, Safety, and Extrahepatic Benefit of Liver-Directed Lentiviral Gene Therapy in a Methylmalonic Acidemia Mouse Model

Elena Barbon[1], Camilla Negri[1], Andrea Raimondi[1], Chiara Simoni[1], Elisabetta Manta[1], Francesca Sanvito[1], Giancarlo la Marca[2], Amy Argabright[3], Angelo D'Alessandro[3], Alessio Cantore[1,4]

[1]San Raffaele Telethon Institute for Gene Therapy, IRCCS San Raffaele Scientific Institute, Milan, Italy,[2]Department of Experimental and Clinical Biomedical Sciences, University of Florence, Italy, Florence, Italy,[3]University of Colorado Anschutz Medical Campus, Aurora, CO,[4]Vita-Salute San Raffaele University, Milan, Italy

Methylmalonic acidemia is an inherited metabolic disease due to deficiency of the mitochondrial enzyme methylmalonyl-coA mutase (MUT), resulting in the build-up of toxic circulating methylmalonic acid (cMMA). The disease-related morbidity and mortality in infancy led to liver transplantation as elective treatment. Integrative lentiviral vector (LV)-based gene therapy may represent an alternative to liver transplantation, allowing for stable gene transfer even in young children at initial disease stage. We assessed the long-term efficacy and safety of a liver-directed LV gene therapy in a mouse model of the disease (MCK-Mut-/-). MCK-Mut-/- mice present hepatic and renal cMMA accumulation early in life which further increase with aging, thus indicating a progressive worsening of the disease. The treatment of juvenile MCK-Mut-/- mice with a LV encoding a human MUT transgene under the control of a hepatocyte-specific expression cassette (LV.MUT, 5E10 TU/kg) showed rapid, substantial, and long-lasting (> 1 year) decrease in cMMA (mean of 146 μM and 979 μM in treated vs. untreated animals 12 months post LV) with normalization of FGF-21, a biomarker of mitochondrial function. Overexpression of MUT enzyme resulted in almost complete normalization of intrahepatic MMA concentrations (0.3 μM, 5.3 μM and 300 μM in wild-type, treated and untreated animals respectively). In line with this finding, liver histology and mitochondria ultrastructure of treated mice was fully normal while age-matched MCK-Mut-/- untreated mice displayed major disease-related alterations. Importantly, we observed significant MMA reduction in the brain (28 μM and 93 μM in treated vs. untreated animals) and in the kidney (81 μM and 552 μM in treated vs. untreated animals), indicating an extrahepatic benefit achieved by liver-mediated detoxification. Multiomic analysis on liver and serum samples of MCK-Mut-/- mice showed a major dysregulation of metabolic intermediates, lipids and proteins specifically related to the mitochondrial energy metabolism (i.e., carnitine and fatty acid metabolism and tricarboxylic acid cycle), which were partially to completely rescued upon gene therapy in both compartments. We treated additional MCK-Mut-/- mice at different LV doses (2.5, 5 or 10E10 TU/kg) and observed a dose-dependent correction of disease biomarkers. Mice treated at the lower LV dose displayed a progressive rescue, with full weight normalization and a decrease in cMMA comparable to those of mice injected at higher LV doses, only around 3 months post-LV. This kinetics suggest a selective advantage of the corrected cells, especially when starting from an initial lower LV dose/liver transduction. To further improve our approach, we tested a LV encoding a codon optimized MUT transgene (LV.MUTco) which was administered to juvenile MCK-Mut-/- mice at a dose of 2E10 TU/kg, lower than previously tested doses. LV.MUTco treatment resulted in a liver MUT transgene overexpression 6-8 fold higher compared to that obtained with LV.MUT at a similar vector dose, paralleled by a greater reduction in cMMA (199μM and 369μM in LV.MUTco and LV.MUT treated mice, respectively, vs 1120 μM in untreated mice, 6 months post LV), thus potentially allowing to reduce LV dose to achieve the same therapeutic efficacy. Overall, these data provide evidence for the efficacy, safety, and extrahepatic benefit of liver mediated LV gene therapy for methylmalonic acidemia.

164. Efficient Gene Therapy via Retrograde Injection into the Ductal Systems of Liver and Pancreas

Amita Tiyaboonchai[1], Leslie Wakefield[1], Anne G. Vonada[1], Sunghee Chai[1], Yulia Eygeris[2], Gaurav Sahay[2], Markus Grompe[1]

[1]Pediatrics, Oregon Health and Science University, Portland, OR,[2]Pharmaceutical Sciences, Oregon State University, Portland, OR

Gene therapy vectors targeted to the liver and pancreas are typically delivered intravenously via the systemic circulation. The biliary system connects to the liver via the common hepatic duct and to the pancreas via the pancreatic duct providing a direct localized route for targeted delivery of vectors to the liver and pancreas. In humans, retrograde injection is routinely performed using Endoscopic Retrograde Cholangiopancreatography (ERCP), enabling access to both liver and pancreas through the ampulla of Vater. Retrograde injection via the duct system has several potential advantages over systemic gene therapy including minimization of off-target transduction, increasing the local concentration of the gene therapy vector, and bypassing any liver fibrosis to potentially allow efficient transduction of hepatocytes even in the presence of sinusoidal capillarization. To test the feasibility of this strategy, we performed proof of principle experiments for ductal delivery of gene therapy vectors in mice. Here, we successfully delivered recombinant adeno-associated virus vectors (rAAVs) and lipid nanoparticles (LNPs) to both liver and pancreas through retrograde ductal injection.To target the liver, rAAV (serotype DJ) expressing

human Factor 9 (hF9) was injected into the common bile duct. Control animals received the same vector intravenously. Circulating hF9 was comparable in both the mice that received hF9 via the common bile duct or intravenously. Similarly, ductal injection with an rAAV of a different serotype (KP1) expressing a RFP reporter resulted in ~ 40% hepatocyte transduction. To test whether LNPs could also be delivered to the liver in this fashion, LNPs containing Cre-mRNA were administered via the bile duct to mTmG mice. mTmG mice express a tdTomato reporter flanked by LoxP sites upstream of a GFP reporter. Following Cre recombination, transgene expression in these mice switches from tdTomato to GFP. Retrograde ductal injection of the Cre-mRNA LNPs resulted in near 100% conversion of hepatocytes from red to green fluorescence, confirming successful ductal delivery of LNPs to the liver.The pancreas also has a ductal system that connects to the biliary network at the ampulla of Vater. Unlike the liver, it is very difficult to target gene therapy to the pancreas by systemic injection. An RFP-expressing rAAV (serotype KP1) was delivered by injection into the ampulla of Vater, resulting in a ~45% transduction of acinar cells. Next, Cre-mRNA containing LNPs were delivered to mTmG mice by injection into the ampulla of Vater. Approximately 20-30% of acinar cells were found to be GFP-positive indicating the successful delivery of the mRNA to the pancreas. Islet transduction was very rare. Together these data show that retrograde ductal injection into the liver or pancreas can provide an efficient route for gene therapy by rAAV or LNP-mediated mRNA. Experiments to compare vector dose responses, off-target transduction and immunogenicity of ductal vs. systemic administration are ongoing.

165. Development of ABO-101, a Novel Gene Editing Therapy for Primary Hyperoxaluria Type 1

Tia DiTommaso, Michael S. Kuefner, Sneha Halwasia, Anthony J. Garrity, Sejuti Sengupta, Rachel Wollacott, Raisa Lowe, Lijun Liu, Daniel S. Ory, Pamela Stetkiewicz, John E. Murphy

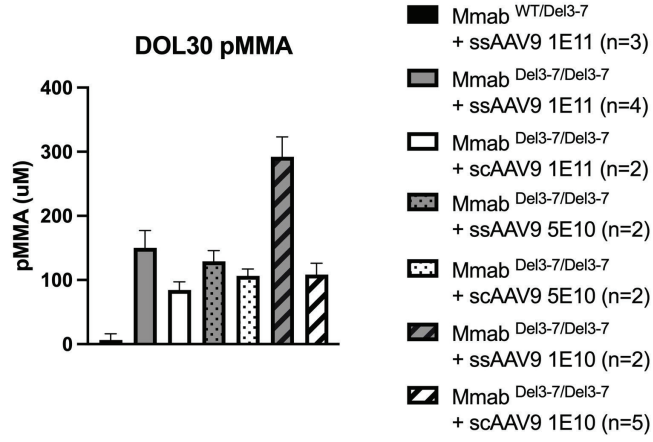
Arbor Biotechnologies, Cambridge, MA

Primary Hyperoxaluria, or PH, is a group of rare genetic metabolic disorders characterized by the overproduction of oxalate by the liver. Oxalate builds up and accumulates in the kidneys and other organ systems, causing kidney damage and progression towards renal failure. PH1, the most common and clinically severe subtype of PH, results from a mutation of the *AGXT* gene which is expressed primarily in the liver. Here we present pre-clinical *in vivo* evidence supporting ABO-101 as a novel CRISPR-Cas-mediated gene editing therapy for the treatment of PH1. The current standard of care siRNA therapy for PH1 requires lifelong treatment and targets *HAO1*, which encodes the glycolate oxidase enzyme (GO) and is upstream of the mutant *AGXT*. Inhibition of *HAO1* lowers the availability of oxalate precursors and thus results in a therapeutically meaningful reduction of oxalate levels and a corresponding increase in serum glycolate, a metabolic byproduct of *HAO1* inhibition which provides a measure of gene disruption efficacy. ABO-101 was designed to specifically inactivate the *HAO1* gene in liver hepatocytes and provide a durable reduction of oxalate levels through a single course of treatment. ABO-101 is comprised of a lipid nanoparticle (LNP) which encapsulates our proprietary engineered variant of Cas12i2 (ABR-001) and a guide RNA (gRNA), selected to share 100% sequence complementarity to the cynomolgus macaque NHP *HAO1* gene. In NHPs treated with ABO-101, we achieved *HAO1* indels of approximately 60% in whole liver tissue, which correlates to a greater than 2x increase in serum glycolate, all with a well-tolerated safety profile. We also observed a dose-dependent increase in indel levels with a concomitant increase in serum glycolate levels and further reduction of GO protein and enzyme activity levels. In addition to both rodent and primate pharmacology data, we also describe our approach optimizing our lead gRNA, ratios of components inside the LNP, and the mRNA encoding the gene editing machinery; these optimizations resulted in our lead therapeutic candidate ABO-101. Taken together, these results provide *in vivo* proof of pharmacology for a gene editing approach and support further advancement of ABO-101 as a potential treatment for PH1.

166. Ubiquitous Promoter in AAV9 GAMT Gene Therapy Yields Lower Levels of Guanidinoacetic Acid in the Brain

Puja Patel[1], Ilona Tkachyova[2], Andreas Schulze[2], Gerald S. Lipshutz[1]

[1]Pharmacology & Surgery, UCLA School of Medicine, Los Angeles, CA,[2]Biochemistry & Metabolism, The Hospital for Sick Children, Toronto, ON, Canada



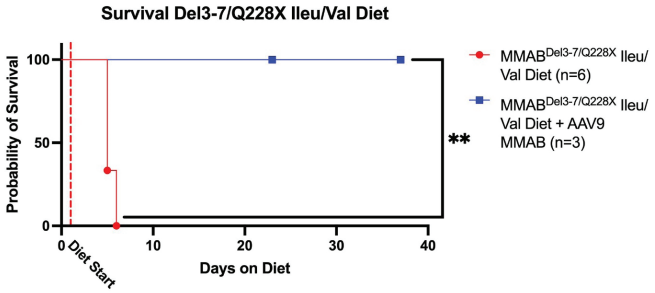
Introduction: Guanidinoacetate methyltransferase (GAMT) deficiency is a disorder of creatine biosynthesis that utilizes guanidinoacetate & S-adenosylmethionine to synthesize creatine, a vital high energy molecule for highly active tissues (i.e., brain, muscle). In people, this disorder is marked by developmental delays, intellectual disability, prominent speech delay, seizures, involuntary movements & decreased muscle tone. Present day therapy with high-dose creatine & ornithine is poor-tasting and commonly incomplete, leaving children at risk for intellectual disability & epilepsy that can be refractory to therapy. A mouse model of the disorder has been described that demonstrated marked guanidinoacetic acid (GAA), a neurotoxin, in the brain along with low levels of guanidinobutyric acid (GBA) which is normally not found in the brain. Previously our group demonstrated that an adeno-associated viral (AAV) GAMT gene therapy could restore the creatine biosynthesis pathway by targeting the liver exclusively; however, the mice had reduced but persistent levels of GAA in the brain. This poses as a problem as its presence may continue to affect brain function. In this study, we aimed to create an array of novel AAV based GAMT vectors & assess their efficacy in not only restoring function of the GAMT enzyme but also reducing the amount of GAA & GBA present in the brain. We hypothesized that by utilizing a ubiquitous promoter there would be increased expression of GAMT in the brain to lower the amount of GAA present & increase the amount of creatine available for brain function. Methods: Four AAVs were developed for this study: 1) a single stranded AAV rh10 serotype containing a TBG promoter; 2) a single stranded AAV8 serotype containing a TBG promoter; 3) a single stranded AAV9 containing a CAG promoter/enhancer; & 4) a self-complementary AAV9 containing a CAG/enhancer promoter. These 4 viruses were injected into two groups of Gamt-deficient mice at one of two doses, $1x10^{13}$ genome copies (GC)/kg or $5x10^{13}$ GC/kg. Both groups were euthanized 60 days post injection followed by transcardiac perfusion with PBS. GAA & creatine levels were analyzed in the plasma, brain, and liver; GBA levels were also analyzed in the

brain. Results: In comparison to the untreated Gamt-deficient mice, all AAV groups presented with restoration of GAMT function in varying amounts as detected by reduction of GAA & increase of creatine in the liver, brain, & plasma. Within the $5x10^{13}$ GC/kg group, the AAV9 with CAG promoter/enhancer proved to be the most effective in lowering GAA levels in the brain & the rh10 with TBG treatment proving to be the most effective in lowering the amount of GAA in the liver. The rh10 with TBG promoter, AAV8 with CAG promoter/enhancer, and AAV9 with CAG promoter/enhancer all were equally effective in lowering the total amount of GAA and increasing the total creatine levels in plasma. In addition, GBA was reduced in the brain in all groups but was completely resolved only with AAV9 with the CAG enhancer/promoter. Conclusion: The clinical signs & symptoms of GAMT deficiency, caused by both buildup of the neurotoxin GAA reduced creatine in the brain, can be effectively treated in a murine model by AAV-based gene therapy. While the liver is the main site for GAA synthesis, it is important that the brain also be transduced to reduce levels further. AAV-based approaches that utilize a serotype that can transduce the brain & a promoter that is ubiquitous can effectively restore function of the GAMT protein in both sites as demonstrated by lower levels of GAA in both the liver &, importantly the brain, along with restoration of creatine levels. The ability of AAV9 with a ubiquitous promoter to correct the biochemical abnormalities in Gamt deficiency may pave the way for a new treatment to replace the current and incomplete dietary standard of care.

167. *In Vitro* and *In Vivo* Efficacy of Single-Strand and Self-Complementary AAV9 Vectors to Treat Isolated Cobalamin B Type Methylmalonic Acidemia

Karenna Choi, Eun-Young Choi, Charles P. Venditti
NHGRI/NIH, Bethesda, MD

Background: Cobalamin B type (*cblB*) methylmalonic acidemia (MMAB) is a rare and severe inborn error of metabolism caused by mutations in the *MMAB* gene. *MMAB* encodes ATP cob(I) alamin adenosyltransferase and catalyzes the synthesis of 5'-deoxyadenosylcobalamin (AdoCbl), the cofactor for methylmalonyl-CoA mutase (MMUT). Patients with MMAB deficiency exhibit elevated levels of plasma methylmalonic acid (pMMA) and fibroblast growth factor 21 (FGF21), and deficiency of MMUT. Clinically, patients present with metabolic instability, and some require elective liver and/or liver-kidney transplantation. Currently, there are no therapies for MMAB deficiency, an indication for the Platform Vector Gene Therapy Program (PaVe-GT). **Methods:** A series of AAV gene therapy vectors designed to widely express MMAB in vivo were designed, tested in human MMAB knock out cells and then in *Mmab* mouse models. Optimized human *MMAB* genes were cloned into AAV backbones under the control of EF1L or EF1S promoters. The plasmids, packaged as either single-stranded or self-complementary vectors, were then pseudoserotyped with an AAV9 capsid (AAV9 EF1L MMAB "SS" or scAAV9 EF1S MMAB "SC", respectively) and tested in an infection study using a HEK293T MMAB knock-out (KO) cell line. Both vectors were assayed for in vivo efficacy using a recently developed MMAB mouse model whereby a severe mutation removing exons 3-7 was engineered into the Mmab locus, generating the $Mmab^{Del3-7}$ allele. **Results:** Both classes of AAV9 vectors produced robust MMAB expression in KO cells, demonstrating AAV9 vector-directed expression of properly processed MMAB. The SC vector showed higher MMAB expression compared to SS in all tested doses ranging from 5E4 GC/cell to 1E6 GC/cell. $Mmab^{Del3-7/Del3-7}$ mice, which display lethality around weaning age and manifest massively increased pMMA (~1500uM, 360x WT), much like patients MMAB deficiency, were treated on DOL1 with either class of vector, systemically delivered at a dose of 1E10, 5E10 or 1E11GC/pup. One month after a single neonatal injection of either 1E11, 5E10 or 1E10 of either vector, there was a drastic reduction of pMMA, approximately 17.7-fold for SC 1E11 compared to untreated mice. 1E10 SC treatment displayed similar level of metabolic correction as 1E11 SS treatment at both one month and two-months post-treatment (Figure 1). Further, a 2-fold reduction in plasma FGF21, as well as robust transgene expression in the liver and kidney, were observed in both SS and SC-treated mice that received 1E10 at DOL1 and sacrificed at DOL120 (Liver: SS 598%, SC 390% of WT; Kidney SS 105%, SC 98% of WT). The DOL30 weight of mutants treated with SC at all tested doses were closer to that of untreated heterozygotes compared to the weight of mutant mice treated with SS. **Conclusions:** We have developed single strand and self-complementary AAV9 vectors that can be used for neonatal gene therapy for MMAB deficiency. Both classes of AAV9 vectors produce high titer AAV and are potent in vitro. After systemic delivery over a wide dose range, correction of survival, reduction of pMMA and FGF21, and robust hepatorenal transgene expression were observed with both classes of vectors, with the metabolic phenotypes improved more in the SC-treated mice than those treated with SS vector at the same dose. Our study enables a new class of vectors and AAV9 gene therapeutics to treat patients with MMAB deficiency that are suitable for immediate human translation.



168. Hypomorphic Model of MMAB Deficiency: Resistance to Lethality from Dietary Challenge Conferred by Systemic AAV Gene Therapy

John M. Selser, Eun-Young Choi, Charles P. Venditti
National Human Genome Research Institute, Bethesda, MD

Background: Cobalamin B-type (cblB) methylmalonic acidemia (MMA) or MMAB is a severe ultra-rare autosomal recessive inborn error of metabolism. It is caused by pathogenic variants in the *MMAB* gene that encodes the ATP:cob(I)alamin adenosyltransferase (ATR) enzyme. ATR generates 5'-deoxyadenosyl-cobalamin (AdoCbl),

the obligate cofactor for the methylmalonyl-CoA mutase (MMUT) reaction. Current treatment relies on supportive care including dietary management, carnitine supplementation, and intermittent antibiotics. Elective liver (LT) or combined liver kidney (LKT) transplantation has been offered to severely affected patients as an experimental surgical therapy for the treatment of MMAB. **Methods**: Informed by successful strategies to develop mouse models and AAV gene therapy for the related form of MMA caused by deficiency, we first identified relevant patient mutations in a large cohort of subjects with MMAB deficiency evaluated in a natural history study (NCT00078078). One mutation was selected for further modeling in mice: the orthologue of a nonsense mutation frequently found in patients (Q234X, Q228X in mouse), bred to homozygosity ($Mmab^{Q228X/Q228X}$), and with mice carrying a null allele ($Mmab^{Del3\text{-}7/Q228X}$). These knock-in and compound mutants were characterized and challenged with a diet consisting of a 10-fold increase in isoleucine and valine amino acids while maintaining total caloric intake. In a proof-of-concept study, MMAB mice were then treated with a systemic retro-orbital injection of 1e+13 genome copies per kilogram of ssAAV9 EF1L MMAB and examined for response to challenge. **Results**: The hypomorphic model, $Mmab^{Del3\text{-}7/Q228X}$, displayed similar survival and weight gain compared to wild type controls, while homozygote mutant $Mmab^{Del3\text{-}7/Del3\text{-}7}$ showed neonatal lethality. $Mmab^{Del3\text{-}7/Q228X}$ mice displayed mild methylmalonic acidemia [MMA] (80 +/- 77 uM, ~100x WT) very much like patients with attenuated forms of *cblB* MMA. When treated with isoleucine and valine enriched diet, $Mmab^{Del3\text{-}7/Q228X}$ demonstrated significant weight loss (-6.2 +/- .8g n=6 over 4 days) and 100% lethality within 5 days, while controls fed the same diet thrived and gained weight. Plasma [MMA] levels were drastically increased with Isoleucine/Valine diet (1223 +/- 738 uM, ~1500x WT) and reflective of severe clinical disease. $Mmab^{Q228X/Q228X}$ mice, in contrast, survived an Isoleucine/Valine diet challenge and manifested mild MMAemia (142 +/- 74 uM) when challenged on the Isoleucine/Valine enriched diet compared to compound $Mmab^{Del3\text{-}7/Q228X}$ mice. In a proof-of-concept study, treatment of $Mmab^{Del3\text{-}7/Q228X}$ mice with an AAV9 MMAB vector, systemically delivered at a dose of 1e13 GC/kg on DOL26, approximately two weeks prior of Isoleucine/Valine diet resulted in complete rescue from lethality (p=.0081), and reduced weight loss. **Conclusions**: We have developed a new clinically relevant murine MMAB mutation and a suite of new murine models to enable preclinical gene therapy studies in adult mice. The $Mmab^{Del3\text{-}7/Q228X}$ mice models can be used in conjunction with an Isoleucine/Valine challenge diet to induce a lethal metabolic crisis, and fully rescued from lethality by systemic AAV9 gene therapy. This model shows that AAV9 gene therapy can be used to protect against acute lethal metabolic instability and will allow the facile assessment of vector efficacy and dose finding in the development of new gene therapeutics for patients with MMAB deficiency.

169. *In Vivo* Correction of Metabolic Pathogenic Variants via Base Editing and Prime Editing: Toward the Equitable Treatment of Hepatic Inborn Errors of Metabolism

Dominique Brooks[1], Madelynn Whittaker[1], Ping Qu[1], William Peranteau[2], Mohamad-Gabriel Alameh[2], Rebecca Ahrens-Nicklas[2], Kiran Musunuru[1], Xiao Wang[1]

[1]University of Pennsylvania, Philadelphia, PA,[2]Children's Hospital of Philadelphia, Philadelphia, PA

Phenylketonuria (PKU), an autosomal recessive disorder caused by pathogenic variants in the phenylalanine hydroxylase (*PAH*) gene, is the most common inborn error of metabolism. PKU results in the buildup of blood phenylalanine (Phe) to neurotoxic levels. Current dietary and medical treatments are chronic and reduce, rather than normalize, blood Phe levels. The most frequently occurring *PAH* variant in PKU patients is the c.1222C>T (R408W) variant. Using real-world data from a PKU cohort at an academic medical center, we found that most patients with at least one R408W allele (n = 36) experience chronic, severe Phe elevations and do not meet Phe monitoring guidelines—highlighting the high unmet medical need arising from the challenges of lifelong adherence to dietary and medical therapy. Motivated by these findings, we are developing "one-and-done" CRISPR editing therapeutics for PKU. We have established a pipeline to rapidly screen and optimize base editing or prime editing strategies *in vitro* and deploy them *in vivo* with either lipid nanoparticles (LNPs) or adeno-associated viral (AAV) vectors on a timescale of months. In initial work, we created six humanized PKU mouse models for the six most frequent *PAH* variants and, in parallel, prime-edited variant-bearing hepatocyte cell lines. In homozygous or compound heterozygous PKU mice, we observe complete and long-term durable normalization of blood Phe levels (>90% reduction) as soon as 48 hours after treatment, with whole-liver corrective *PAH* editing as high as >50% with either base editing or prime editing. We have developed therapeutic leads for multiple *PAH* variants to permanently normalize blood Phe levels and definitively treat PKU in these patients and are on track for early-phase clinical trials within a few years. Despite these encouraging results, we are cognizant of the risk of "mutational discrimination" in unduly focusing on more common diseases and on high-prevalence variants skewed towards specific ancestry groups. Accordingly, we have extended our pipeline to develop and validate a corrective therapeutic for *any* variant in *any* patient with a hepatic inborn error of metabolism. We have begun to apply this workflow in real time to patients with devastating, ultra-rare inborn errors of

metabolism, namely the urea cycle disorders and organic acidemias, tackling any variant—even n-of-1 variants—identified via universal newborn screening. The first four patients have (1) citrullinemia type 1, with homozygosity for an *ASS1* transition variant (G>A), (2) argininosuccinic aciduria, with homozygosity for an *ASL* transition variant (A>G), (3) propionic acidemia, with homozygosity for a *PCCA* 1-bp deletion, and (4) CPS deficiency, with compound heterozygosity for a *CPS1* partial gene deletion and a transversion variant (A>C). To address these specific variants in parallel, we have developed (1) a high-throughput lentivirus-based multiple-variant prime editing screening platform in human hepatocytes and (2) a multi-humanized mouse with a string of genomic sequences harboring each of the four variants inserted into the *Rosa26* safe harbor locus, allowing for *in vivo* testing of lead editing solutions for all four variants in a single mouse model, which is now underway. This augmented, scalable pipeline represents a critical step towards our goal of rapidly devising and deploying a personalized editing treatment for any patient in need.

Correction of Genetic Disorders of the Blood and Immune System

170. Highly Specific Non-Viral Gene Editing with P-KLKB1-101 for Hereditary Angioedema

Oscar Alvarez, Lucas Homa, Khalid Hajj, Zhibo Ma, Cindy Negron, Matthew Nitzahn, Mauricio Barajas-Mora, Arturo Barcenas, Alicia Davis, Mona Connerney, Pavan Battiprolu, Michael Bennett, Bonnie Jacques, Joshua Rychak, Brent Warner

Poseida Therapeutics, San Diego, CA

Recent advancements with our gene editing technology hold great promise for addressing debilitating genetic diseases like hereditary angioedema (HAE). HAE is a rare genetic condition characterized by excess plasma kallikrein activity leading to subcutaneous and submucosal edema with the risk of life-threatening swelling of the upper respiratory tract. Current treatments focused on C1 inhibitor restoration or plasma kallikrein antagonism, however, are inadequate due to lack of consistency (emergent attacks even with treatment) or can be refractory to standard-of-care and require continuous lifelong treatment. Here, we present an effective strategy for targeted inactivation of the gene encoding pre-kallikrein, *KLKB1*, using our Cas-CLOVER™ Gene Editing System and our non-viral lipid nanoparticle (LNP) delivery system. Our primary aim is to establish a high-fidelity gene therapy by inactivating the *KLKB1* gene for sustained relief across both Type I and II HAE patients. The Cas-CLOVER gene editing system is comprised of a next generation nuclease with a dual guide RNA (gRNA) targeting system that achieves high on-target editing. A comprehensive screening process identified lead human-specific gRNA pairs for optimal *KLKB1* editing in human hepatoma cell lines. Subsequent evaluations in primary human hepatocytes (PHH) revealed robust KLKB1 editing (>90%) and 85% reduction in KLKB1 protein secretion.Critical to the safety of any gene editing therapeutic, Cas-CLOVER off-target sites were nominated by iGUIDE, with amplicon-seq confirmatory studies revealing minimal off-target editing, at levels near background (<0.2%) in PHHs. Remarkably, at concentrations 10-fold higher than our EC90 LNP concentration, the low level off-target editing remained constant, demonstrating best in-class fidelity compared to other RNA-guided nucleases like Cas9.Activity of our P-KLKB1-101 LNP-encapsulated Cas-CLOVER mRNA with *KLKB1*-targeting gRNAs was then assessed in a TK-NOG mouse model in which livers are humanized by engraftment of PHHs. Liver-humanized mice received a single intravenous injection of P-KLKB1-101, achieving 60% successful editing at the *KLKB1* locus with no off-target edits detected.To further confirm the ability of P-KLKB1-101 to impact biomarkers of HAE *in vivo*, C57BL/6 male mice received increasing doses of a mouse-specific surrogate gRNA pair targeting *Klkb1* (dose range 0.1 to 3 mg/Kg). A single intravenous LNP injection achieved dose-responsive editing and more than 90% reduction in serum pre-kallikrein levels, within a wide therapeutic window, and well within the range predicted to achieve therapeutic benefit in humans. All doses were well-tolerated, with no serious adverse effects; importantly, no editing was detected in testes (no higher than PBS vehicle controls). In summary, P-KLKB1-101, utilizing our Cas-CLOVER gene editing system, demonstrates efficacy and specificity, laying a foundation for a targeted gene therapy for HAE. Our preliminary data offer insights into potential clinical applications, advancing targeted gene therapies for genetic disorders.

171. Base Editing of BCL11A Cis-Regulatory Regions to Treat Beta-Hemoglobinopathies

Letizia Fontana, Panagiotis Antoniou, Pierre Martinucci, Simone Amistadi, Annarita Miccio

Imagine Institute, Paris, France

Beta-hemoglobinopathies (e.g., sickle cell disease, SCD) result from mutations affecting β-globin chain production. The clinical severity is reduced by mutations causing elevated fetal hemoglobin (HbF) production, a condition termed hereditary persistence of HbF (HPFH). Transplantation of autologous, genetically corrected hematopoietic stem/progenitor cells (HSPC) is a promising therapy. Notably, a CRISPR/Cas9 approach to down-regulate BCL11A, a major HbF repressor (by targeting the erythroid-specific *BCL11A* enhancer) has been recently approved for the treatment of β-hemoglobinopathies. However, genotoxicity concerns arise from CRISPR/Cas9-induced double-strand breaks (DSBs). Therefore, novel therapeutic strategies need to be developed. Here, to down-regulate BCL11A, we targeted transcriptional activator binding sites (BS) within *BCL11A* erythroid-specific enhancers with base editors (BE) to precisely introduce point mutations (i.e., A>G or C>T) without generating DSBs. In particular, we targeted the GATA1 and ATF4 BSs in the +58-kb and +55-kb *BCL11A* enhancer regions, respectively. Single guide RNAs (sgRNA) were tested in HSPCs from SCD patients in combination with adenine or cytosine BEs (ABE or CBE), generating different nucleotide changes within the BS motifs with an overall editing efficiency up to 90%, with no or little DSB-induced Indels. HbF reactivation was observed in all edited samples as measured by cation-exchange HPLC. However, the HbF levels were not sufficient to achieve the full rescue of the sickling phenotype in erythroid cells derived from edited SCD HSPCs. Hence, we decided to simultaneously target the GATA1 and ATF4 BS with the aim to further increase HbF levels in edited cells. Furthermore, we obtained new editing profiles by combining selected sgRNAs

with newly developed dual base editor (TadDE) to simultaneously induce A>G and C>T conversions in the activator BSs. Erythroid cells differentiated from SCD HSPCs edited at both +58 and +55 enhancers showed an increased HbF expression compared to cells receiving individual sgRNAs. In particular, in cells edited at both enhancers, HbF represented up to around 34% of total hemoglobin, exceeding the levels achieved using the recently approved CRISPR/Cas9 nuclease-based strategy. Simultaneous targeting of *BCL11A* enhancers did not impact erythroid differentiation, as measured by flow cytometry analysis of erythroid markers and enucleation rates. Finally, HbF reactivation was sufficient to allow a substantial rescue of the sickling phenotype, as measured by microscopy under hypoxic conditions decreasing the proportion of sickling cells up to 16.4%. To assess DNA and RNA off-target activity, we used GUIDE-seq coupled with targeted sequencing, whole exome sequencing and RNA-seq, while on-target unwanted events were evaluated by long-read sequencing. Finally, to evaluate the BE efficacy in repopulating bona fide hematopoietic stem cells (HSCs), we transplanted edited HSPCs in immunodeficient mice. In conclusion, we have provided ample evidence of the effectiveness of simultaneous base editing of γ-globin *trans*-regulatory elements for reactivating HbF. This proof-of-concept work will enable the pre-clinical and clinical development of base-edited HSCs for the therapy of β-hemoglobinopathies.

172. A Novel Model of X-Linked Sideroblastic Anemia (*Alas2-KO*, XLSA) with Ring Sideroblasts, Severe Anemia, and Iron Overload is Rescued by Lentiviral Gene Transfer

Carlo Castruccio Castracani[1], Amaliris Guerra[1], Laura Breda[1], Tyler Papp[2], Enrico Radaelli[2], Charles-Antoine Assenmacher[2], Giovanni Finesso[2], Yink Tam[3], Barbara Mui[3], Simona Fontana[4], Chiara Riganti[4], Veronica Fiorito[4], Sara Petrillo[4], Emanuela Tolosano[4], Hamideh Parhiz[5], Stefano Rivella[1,2]

[1]Children's Hospital of Philadelphia, Philadelphia, PA,[2]University of Pennsylvania, Philadelphia, Philadelphia, PA,[3]Acuitas Therapeutics, Vancouver, BC, Canada,[4]University of Turin, Turin, Italy,[5]University of Pennsylvania, Philadelphia, PA

X-linked sideroblastic anemia (XLSA) is the most common form of congenital sideroblastic anemia caused by mutations in *Alas2*, a gene responsible for heme synthesis in erythroid cells. Most patients carry hypomorphic mutations, with variable phenotypic manifestations. Treatment options include pyridoxine supplements, transfusions, and allogeneic bone marrow (BM) transplantation. To study an inducible severe manifestation of XLSA, we engineered a conditional *Alas2*-KO mouse model using two approaches: tamoxifen administration and treatment with lipid nanoparticles (LNP) carrying Cre-mRNA and conjugated to the anti-CD117 antibody. *Alas2*-KO-BM animals displayed fetal anemia characterized by ineffective erythropoiesis (IE) and ring sideroblasts, the first model showing this phenotype. Erythropoiesis in these animals showed expansion of polychromatic erythroid cells, decreased activity in the electron transport chain and mitochondria's function, and reduced activity of crucial Tricarboxylic Acid (TCA) cycle enzymes. The IE was associated with marked splenomegaly and increased ERFE, the erythroid suppressor of hepcidin. Since hepcidin is responsible for limiting dietary iron absorption, decreased hepcidin levels were associated with increased serum iron, transferrin saturation levels, and iron overload. To investigate a gene therapy approach for XLSA, we developed a lentiviral vector (X-ALAS2-LV) that exploits a globin promoter and enhancers to direct human *ALAS2* expression in erythroid cells. We also included an insulator in the 3' self-inactivating long terminal repeat (SIN-LTR) to enhance safety. Infusion of BM cells with 0.6-1.4 copies of the X-ALAS2-LV in *Alas2*-KO-BM mice rescued these mice by improving erythropoiesis and tissue iron accumulation. While the hemoglobin and RBC levels were improved or corrected in the LV-treated group, the non-treated group showed fatal anemia, with low RBC levels. Accordingly, the untreated group showed increased erythropoietin levels and reticulocyte counts because of IE and severe anemia. The ineffective erythropoiesis was characterized by extra-medullary erythropoiesis and severe splenomegaly, while these parameters were improved or normalized in the X-ALAS2-LV-treated group. These data show that the fatal anemia in *Alas2*-KO animals can be improved or corrected by X-ALAS2-LV. Notably, animals rescued by X-ALAS2-LV showed vector copy numbers (VCN) in the range of 0.6-1.4, indicating that a small number of integrations were sufficient to rescue *Alas2*-KO animals. As XLSA patients still exhibit hypomorphic or residual expression of the ALAS2 gene (as the complete absence is incompatible with survival), we hypothesize minimal gene transfer or mini-transplants with HSCs treated with XALAS2-LV could be curative in this disease. Moreover, since X-ALAS2-LV rescues *Alas2*-KO-BM mice, we are now modifying X-ALAS2-LV with *ALAS2* human mutations to study milder forms of XLAS and develop alternative therapeutic interventions, such as pharmacological treatments and *in vivo* gene editing.

173. Development of Best-in-Class Gene Editing Therapy for β-Hemoglobinopathies Using Innovative Transformer Base Editor (tBE)

Lijie Wang[1], Peixue Li[1], Yichuan Wang[1], Rongrong Liu[2], Yaliang Li[1], Kewei Lan[1], Huiming Zheng[1], Di Zhu[1], Yan Zhang[1], Runni Guo[1], Hongxia Ma[1], Jing He[1], Qing Su[1], Lang Zhang[1], Gaohui Yang[2], Lingling Shi[2], Zhenbin Wei[2], Xuemei Zhou[2], Bei Luo[1], Yeqian Chen[1], Jia Wei[3], Yongrong Lai[2], Li Yang[3], Jia Chen[4], Xiaodun Mou[1], Bingbing Wu[1]

[1]CorrectSequence Therapeutics Co., Ltd, Shanghai, China,[2]The First Affiliated Hospital of Guangxi Medical University, Guangxi, China,[3]Fudan University, Shanghai, China,[4]ShanghaiTech University, Shanghai, China

Background: β-thalassemia and sickle cell disease (SCD) are among the most prevalent monogenic disorders worldwide and both these β-hemoglobinopathies are caused by mutations in the β-globin gene *HBB*. Reactivating the expression of the γ-globin genes (*HBG1/2*) mimicking the naturally occurring hereditary persistence of HbF (HPFH) is expected to be a universal strategy to treat β-thalassemia and SCD by the induction of fetal hemoglobin (HbF). **Methods**: CorrectSequence Therapeutics' first pipeline, CS-101, uses transformer Base Editor (tBE) to precisely edit the binding motif of transcription repressor BCL11A in *HBG1/2* promoter region in the CD34+

hematopoietic stem cells to trigger the reactivation of fetal hemoglobin (HbF) for treatment of β-Hemoglobinopathies. **Results**: Compared with the commonly used gene editing methods such as CRISPR/Cas nucleases or other base editors, tBE is a base editing system that avoids causing DNA double strand breaks or off-target mutations and exhibits more potent globin reactivation. A commercial scale manufacturing process to *ex vivo* edit HSC has been developed and validated with more than 10 batches of commercial scale production, all of which exhibited consistent process performance and product quality. Pre-clinical *in vivo* studies showed that while tBE-mediated editing of HSC induces robust γ-globin expression, tBE did not cause adverse effect on the engraftment or differentiation of the HSC in mice after transplantation. In the investigator-initiated trial study, one patient who suffered from transfusion-dependent β-thalassemia (β^0/β^+ type) had been receiving 4 units of red blood cells (RBC) every two weeks before beginning CS-101 treatment. After receiving CS-101 treatment, the patient successfully achieved hematopoietic reconstruction, with neutrophil engraftment occurring within 20 days, and stopped receiving blood transfusions within 20 days post-transplantation. Up to now, the patient's hemoglobin level has been maintained at or above 130 g/L, and no adverse effects related to CS-101 have been observed. In addition, another patient has been free from transfusion for more than one month after receiving CS-101 treatment. **Conclusions**: CS-101 holds great promise to become the best-in-class gene editing therapy and first-in-class base editing therapy for β-hemoglobinopathies.

174. A Non-Genotoxic Conditioning Regimen Based on a Combination of Monoclonal Antibodies and Hematopoietic Stem and Progenitors Cell Mobilizers Enhances Engraftment Levels and Theraputic Efficacy

Isabel Ojeda Pérez[1,2,3], Omaira Alberquilla-Fernandéz[1,2,3], Aida García-Torralba[1,2,3], Rebeca Sánchez-Domínguez[1,2,3], Jose-Carlos Segovia[1,2,3]

[1]CIEMAT, Madrid, Spain,[2]Centro de Investigación Biomédica en Red de Enfermedades Raras, Madrid, Spain,[3]Unidad Mixta de Terapias Avanzadas. Instituto de Investigación Sanitaria Fundación Jiménez Díaz (IIS-FJD, UAM), Madrid, Spain

Hematopoietic gene therapy holds significant promise as a therapeutic alternative for various hematological disorders including Piruvate Kinase Deficiency (PKD), a rare genetic condition causing chronic hemolytic anemia by affecting red blood cell function. However, current genotoxic conditioning treatments, necessary for the successful engraftment of corrected hematopoietic stem cells (HSC) are associated with high toxicity, leading to substantial adverse effects in patients. To establish gene therapy as a primary treatment for hematopoietic inherited disorders, such as PKD, it is necessary to develop less toxic conditioning regimens that specifically target HSCs without adversely affecting other tissues. Here, we have explored a synergistic approach that combines monoclonal antibody (mAb) treatment to eliminate diseased HSCs, with HSC mobilizers to enhance the accessibility of mAbs to these cells. Our novel combination approach, which consists of a combination of 6 monoclonal antibodies (anti-CD117, anti-CD47, anti-CD40/CD40L, anti-CD122, anti-CD4 and anti-CD8) and Plerixafor, a CXCR4 antogonist, has demonstrated specific depletion of endogenous HSCs in both wild-type (WT) and PKD mice. The results revealed a remarkable three-fold increase in exogenous engraftment in WT mice. Moreover, the combination reduced the mortality of PKD mice by 60% in comparison with PKD mice treated with the combination of MoAbs alone. This new non-genotoxic conditioning regime has demonstrated therapeutic efficacy when PKD mice were transplanted with congenic wild type cells. Our non-genotoxic approach showed that the percentage of healthy cells required to reverse the disease phenotype was half of that needed with conventional total body irradiation genotoxic conditioning. This finding suggests a significantly reduced toxicity associated with our approach. These results constitute preclinical proof of concept for a non-genotoxic conditioning regimen that enables the establishment of a therapeutic hematopoietic graft. This represents a crucial step toward establishing gene therapy in the forefront for the treatment of genetic hematological disorders.

175. Hematopoietic Stem Cell Gene Therapy for the Treatment of X-Linked Agammaglobulinemia

Christopher Luthers[1], Aurelien Colomartino[2], Annika Mittlehauser[2], Zulema Romero[2], Donald B. Kohn[2]

[1]Molecular Biology, University of California, Los Angeles, Los Angeles, CA,[2]MIMG, University of California, Los Angeles, Los Angeles, CA

Introduction Bruton's Tyrosine kinase (BTK) is expressed primarily in B cells and is critical to their development and function. Absence of *BTK* gene function is the genetic cause of the primary immune deficiency X-linked agammaglobulinemia (XLA). Males with XLA lack mature B cells and have negligible antibody levels, leaving them susceptible to recurrent infections and various infectious complications. Autologous hematopoietic stem cell gene therapy (HSC-GT) with gene-corrected HSC serves as a promising therapeutic strategy for the treatment of XLA; this therapy would improve their quality of life, provide a one-time cure, and could reduce life-long costs versus chronic immunoglobulin replacement therapy. HSC-GT of XLA will require precisely regulated expression of the *BTK* gene to support optimal B cell development and humoral immune function. To achieve this, we have developed methods for site-specific insertion of a normal *BTK* gene into the 5' end of the endogenous *BTK* gene locus, using CRIPSR-Cas9 dsDNA break followed by adeno-associated virus (AAV) mediated delivery of a wild type *BTK* gene. **Methods** To study the effectiveness of this therapy, we edited murine hematopoietic stem and progenitor cells using the CRISPR-Cas9/rAAV6 method and transplanted them in a murine gene knock-out model of human XLA. Following transplant, tissue editing efficiency and engraftment of donor cells was measured via droplet digital PCR. Immunophenotypic analysis of B, T, NK, and myeloid cell frequencies in the spleen, bone marrow, and blood and analysis of mature B cell frequencies from the spleen as well as frequencies of B-progenitors from the bone marrow were performed via FACS analysis. ELISA analysis was performed on serum isolated from peripheral blood to characterize levels of total immunoglobulins as well as responses to immunization via NP-CGG foreign antigen. **Results** Upon transplantation of edited cells into myeloablated XLA mice, high levels of engraftment as well as mature cells from the spleen, blood, and bone marrow with detectable levels of Btk gene integration were detected, being highest in the spleen. Upon

immunophenotypic analysis, there were no significant increases in the frequencies of non-B immune cells (T, NK, Myeloid), confirming that our site-specific editing approach did not result in proliferation of non-target cell types. Edited mice showed significant increases in their B cell levels above that of the XLA mouse model that received no transplant, and not different than XLA mice that received a transplant of WT cells. ELISA analysis showed increased total antibody production of IgG, IgD, IgA, and IgE in edited mice relative to the unedited XLA mouse. The B cell deficiency in XLA is caused by a loss of the progenitor development of early Pre-Pro B cells to immature and mature B cells. Using FACS on bone marrow cells of edited mice, we were able to detect a significant increase in the proportion of immature/mature B cells relative to early pre/pro B cells, elucidating a mechanism for the increases in mature B cells detected in secondary lymphoid tissues. Edited mice displayed antigen-specific primary and secondary humoral responses as evidenced by increases in NP-specific antibodies. **Conclusions** Collectively, we have modeled a gene therapy strategy in a disease model of XLA and thoroughly validated our site-specific genome editing approach. Through extensive peripheral blood, spleen, and bone marrow analysis of edited XLA mouse cells, we have characterized the promising potential of our therapeutic approach. The findings from this study will guide further FDA interactions as we work towards a phase I clinical trial, and serve as further validation for similar monogenic diseases in which site-specific genome editing could be a feasible approach, advancing the field as a whole.

176. Lipid Nanoparticle Delivery of Circular mRNA Improves Hematopoietic Function in Fanconi Anemia HSPCs

Sarah Adams[1], Omar Banda[2], Linah Omer[1], Seul Jung[1], Stefano Rivella[3], Mohamad-Gabriel Alameh[2], Peter Kurre[4]

[1]Comprehensive Bone Marrow Failure, Children's Hospital of Philadelphia, Philadelphia, PA,[2]Department of Medicine, University of Pennsylvania, Philadelphia, PA,[3]Department of Pediatrics, Children's Hospital of Philadelphia; Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA,[4]Comprehensive Bone Marrow Failure, Children's Hospital of Philadelphia; Perelman School of Medicine; University of Pennsylvania, Philadelphia, PA

Fanconi Anemia (FA) is a recessive multisystem disorder, characterized by defect in DNA repair and symptomatic failure of hematopoiesis early in life. Lentiviral gene therapy has shown promise based on the curative outcomes of allogeneic stem cell transplantation. Still, depleted stem cell pools, poor mobilization, conditioning toxicity, and oligoclonal repopulation continue to limit this approach. Lipid nanoparticle (LNP) delivery of mRNA for protein replacement has successfully been applied to monogenic metabolic disorders. Therefore, we set out to adapt this approach using modified Fancc mRNA lipid nanoparticle (LNP^{Fancc}) delivery to improve function in Fancc -/- hematopoietic stem and progenitor cells (HSPC). Using 5' Clean Cap, 101 poly-A tail methyl-pseudouridine modified linear mRNA constructs, we first performed intravenous and intrafemoral injections in C57B/6 animals and showed mCherry mRNA expression in both hematopoietic and non-hematopoietic cells, that peaked between 6 and 24 hours, remaining detectable for at least 72 hours. To improve durability of expression, we next investigated a circularized mRNA (luciferase, for enhanced sensitivity). Luminescence was detectable for up to 4 days after HSPCs were treated in vitro with linear luciferase mRNA, compared with 7 days after circularized luciferase mRNA. For functional testing we tested circularized Fancc mRNA constructs as LNP cargo, LNP^{Fancc}. To directly investigate FA HSPC function we tested LNP performance in an ex vivo long-term expansion system with LNP dosing on days 7-, 10- and 14. At baseline, we first noted an 18.7% deficit in cell doubling (HSC+MPP1-4) between days 7 and 10 in Fancc-/- HSPC, compared to wild-type (WT). By contrast, when Fancc-/- HSPCs were treated with LNP^{Fancc} we observed an 11.5% increase in doublings between days 7 and 10 from baseline. Importantly, flow-cytometric immunophenotyping of ex vivo expanded cells on day 15 revealed 8.5% fewer Fancc-/- long-term-hematopoietic stem cells (LT-HSC) than WT, a gap that narrowed to 1% after LNP^{Fancc}. Moreover, LNP treatment of FA HSPC in vivo conferred improved progenitor colony formation. FA hematopoietic cells are sensitive to inflammatory cytokines (IFNg, TNFa) and toll like rector (TLR)-8 engagement. Alongside understanding the innate immunogenicity of LNPs as some studies have reported, we wanted to explore if LNP^{Fancc} ameliorated the FA innate immune response upon treatment. Using a commercial PCR array to screen for common immune response targets, we exposed ex vivo expanded cells WT and Fancc-/- HSPC (HSC+MPP1-4) to LNP^{Fancc}. At 6- and 24 hours, we harvested cells, extracted RNA and performed RT-PCR. There was modest upregulation of innate immune targets due to LNP administration in general. More selectively, candidate targets relevant to FA, IL-6, IL-1β, GM-CSF and TLR-8, were substantially downregulated after administration of LNP^{Fancc}. These results were further confirmed by target specific RT-PCR. In conclusion, the data indicate that LNP^{Fancc} delivery is a promising protein replacement approach for temporary functional restoration of FA HSPC function. mRNA delivery provides a potential bridging approach for BM HSPC mobilization (defective in FA patients and mice), and for minimizing losses during ex vivo manipulation in the context of conventional gene therapy.

Ophthalmic and Auditory: Disease Focus

177. Gene Therapy for Clarin-2, a New Deafness Gene in Humans and Mice

Clara Mendia[1], Thibault Peineau[2], Chloé Felgerolle[1], Nawal Yahiaoui[1], Carlos Aguilar[3], Michael R Bowl[3], Didier Dulon[2], Aziz El-Amraoui[1], Sandrine Vitry[4]

[1]Institut de l'Audition / Institut Pasteur, Paris, France,[2]Université de Bordeaux, Bordeaux, France,[3]UCL Ear Institute, London, United Kingdom,[4]Institut Pasteur, Paris, France

Hearing impairment is one of the most prevalent sensory disorders worldwide, affecting social interaction, cognition, education and employment, and increasing the risk of dementia. Current treatments are limited to cochlear implants, unable to restore quality hearing function. Adeno-associated virus (AAV)-mediated gene therapy has emerged as a promising alternative, though some key hurdles remain. We used Clarin-2 deficient mice, a transgenic model of progressive hearing loss, to address some of these challenges, namely

the effective window for intervention and the long-term efficacy of AAV-mediated gene supplementation. We delivered AAV9-PHP.eB coding for human or murine *Clarin-2* locally into the inner ear of *Clrn2*$^{-/-}$ mice. Injections were done at postnatal day 1, 5, 10 or 14 and beneficial outcomes assessed up to 6 months after treatment. Gene transduction efficiency was evaluated by qRTPCR, RNAscope and confocal microscopy. Scanning electron microscopy was used to monitor the architecture of hearing sensory hair cells. Auditory brainstem responses (ABR), distortion product otoacoustic emissions (DPOAE), along with mechano-electrical transduction (MET) and capacitance measurements were used to assess hearing sensitivity, hair cell MET and synaptic activity. Our AAV injections lead to robust transgene expression in inner and outer hair cells, and prevent all the defects described in the *Clrn2*$^{-/-}$ inner ear. The structure of sensory hair bundles is preserved, as is the function of their MET channels and synapses. The ABR and DPOAE thresholds of treated mice remain normal over time. We found that early neonatal injections allowed for the best therapeutic outcomes, with effectiveness decreasing with intervention age. To confirm the pathogenicity of the c.494C>A *CLRN2* mutation detected in deaf patients, we demonstrated that, unlike the wild-type human allele, its variants T165K and 146fs*26 were unable to rescue hearing in *Clrn2*$^{-/-}$ mice. Our work shows that AAV-mediated gene supplementation substantially and durably preserves normal hearing when applied before symptom onset, underscoring the promising potential of gene therapy for auditory restoration. *This study was recently accepted for publication in Molecular Therapy (DOI: 10.1016/j.ymthe.2024.01.021).*

178. *In-Vitro* and *In-Vivo* Studies of HG202 as a CRISPR/Cas13 RNA Targeting Therapy for Macular Degeneration

Weiwei Wu, Qi Yang, Sheng He, Mengke Zhu, Chenhua Yang, Shaoran Wang, Xing Wang, Xuan Yao, Hui Yang, Alvin Luk, Linyu Shi

HuidaGene Therapeutics Co., Ltd., Shanghai, China

Background: The current gold-standard treatment for neovascular age-related macular degeneration (nAMD) is frequent intravitreal injections of anti-VEGF agents, leading to suboptimal patient adherence and elevated risk of complications. Moreover, a considerable proportion of nAMD patients have a poor response to standard anti-VEGF therapy. To address these issues, we have developed a novel RNA-targeting therapy, HG202, which is a single adeno-associated virus (AAV) vector incorporating high-fidelity CRISPR/Cas13 RNA targeting technology to specifically and effectively suppress the expression of VEGFA in the retina for nAMD treatment. **Methods:** Choroidal neovascularization (CNV) was induced in mouse eyes through laser photocoagulation. Seven days after injury, fundus fluorescein angiography (FFA) and optical coherence tomography (OCT) were performed, followed by immune-stained choroidal flatmounts. We evaluated the *in vitro* and *in vivo* editing efficiency of HG202, quantified the suppression of *Vegfa* mRNA expression in the retina, and measured the reduction in laser-induced CNV area. We compared the efficacy of HG202 with AAV-anti-VEGF and Aflibercept and conducted a toxicity study in non-human primates (NHPs) to evaluate the safety of HG202. **Results:** After injecting HG202, over 40% of *Vegfa* mRNA expression in the retina of mice (n=8) was suppressed. Mice treated with HG202 showed an 87% reduction ($P < 0.0001$, $n = 14$) in the area of laser-induced CNV. In comparison, AAV-anti-VEGF achieved a 70% reduction ($P < 0.01$, $n = 14$) when compared to the vehicle control, while Aflibercept showed a 47% reduction ($P < 0.01$, $n = 18$) when compared to HG202. In the mouse model, a single injection of HG202 resulted in a durable therapeutic effect for at least 13 weeks. No systemic toxicity and immunotoxicity were observed in NHPs. Only the high-dose group (Figure 1) showed moderate fluorescence leakage and retinal structure changes. There were no obvious abnormalities in retinal function observed in any of the tested animals. **Conclusion:** By successfully blocking VEGFA signaling, HG202 demonstrates long-term transgene expression and RNA editing after a single injection, thus eliminating the need for monthly injections and providing enduring therapeutic benefits. Therefore, HG202 has the potential to provide an effective and long-lasting treatment option for patients with nAMD who do not respond well or are resistant to anti-VEGF therapy. HG202 as a CRISPR RNA-targeting strategy is currently being investigated in humans.

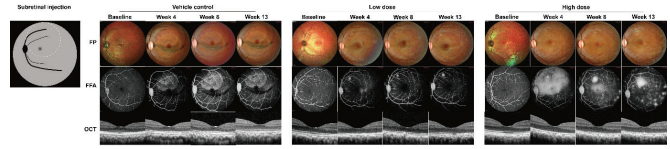


Figure1 Ophthalmological examinations after subretinal delivery of HG202 at different doses in NHPs.

179. AAV-Mediated RhoA Knockdown as a Potential Gene Therapy for Glaucoma

Tapan Sharma[1,2], Meng Gao[1,3], Bo Tian[1,3], Haijiang Lin[1,3], Jun Xie[1,2,4], Guangping Gao[1,2], Phillip Wl Tai[1,2]

[1]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[2]Department of Microbiology and Physiological Systems, UMass Chan Medical School, Worcester, MA,[3]Department of Neurobiology, UMass Chan Medical School, Worcester, MA,[4]Viral Vector Core, UMass Chan Medical School, Worcester, MA

Glaucoma is one of the leading causes of adult blindness and affects about 80 million individuals globally. In primary open angle glaucoma (POAG), one of the high-risk factors that aggravates blindness is the accumulation of aqueous humor (AH), which results in increased intraocular pressure (IOP) and causes damage to the optic nerve. The cells of the ciliary body synthesize AH, while natural drainage happens through Schlemm's canal and layers of the trabecular meshwork (TM). All current glaucoma treatments aim to decrease the secretion and increase the outflow of AH to reduce IOP. Rho kinase (ROCK) inhibitors are a new class of glaucoma drugs, which act on the trabecular tissue to increase AH outflow. RhoA is a ubiquitously expressed GTPase that is known to regulate actin polymerization/depolymerization. Activated GTP-bound RhoA can associate with serine/threonine kinases of the ROCK1/2 family and can assist with phosphorylation of a variety of substates, such as myosin light chain (MLC) and myosin phosphatase target subunit (MYPT-1), which contribute to increased actin polymerization, contraction of the TM, and resistance to AH outflow. Using artificial microRNAs (amiRs), we aimed to target RhoA expression. We screened eleven seed sequences targeting the coding sequence (CDS) of RhoA and its 3'-UTR in human trabecular meshwork (hTM1) cells. Three amiR candidate designs displayed reduced expression of the target gene at the protein level (60-80% reduction). Evaluation of off-target effects

using small-RNA sequencing showed that endogenous microRNAs were largely unaffected. We also found that transduction of TM cells via intracameral injection by AAV2 outperformed those of AAV3b, AAV6, and AAV8; thus, the delivery of *amiR-RhoA-10* by AAV2 was chosen as the final vector strategy. We demonstrate that when scAAV2-*amiR-RhoA-10* is administered intracamerally to wildtype mice (7.33E8 vg/eye), mean IOP was dramatically reduced within three weeks of dosing (from 16.5 mmHg to 14.5-15.0 mmHg) and remained so for over a period of twelve weeks. Furthermore, the observed reduction was also dose dependent.In summary, our proof-of-concept study demonstrates that AAV-mediated knockdown of RhoA using amiRs can reduce intraocular pressure in mice, showing significant promise as a gene therapy for treating primary open angle glaucoma. J.X., G.G. and P.W.L.T. are corresponding authors

180. AAV-Mediated Delivery of a Novel CasX-Editor Molecule Achieves Allele-Specific and Potent Editing of P23H Rhodopsin in a Mouse Model of Retinitis Pigmentosa

Cécile Fortuny[1], Lewis E. Fry[2], Michelle E. McClements[2], Sean Higgins[1], Isabel Colin[1], Angelica Castaneda[1], Ross White[1], Maroof M. Adil[1], Imran H. Yusuf[2], Sarah K. Denny[1], Brett T. Staahl[1], Robert E. MacLaren[2], Benjamin Oakes[1]

[1]Scribe Therapeutics Inc, Alameda, CA,[2]Oxford University, Oxford, United Kingdom

Inherited retinal dystrophies are a heterogeneous group of progressive blinding genetic diseases caused by mutations in over 200 genes, resulting in a strong phenotypic convergence towards the gradual loss of photoreceptors. Autosomal dominant retinitis pigmentosa (adRP) is a genetic disorder that results in progressive vision loss and blindness and is commonly induced by mutations in the RHO gene, with the P23H gain-of-function mutation being a highly prevalent causative mutation. To date, effective therapy for RHO-based adRP remains a significant unmet need. One strategy to address P23H. RHO-related adRP is the selective removal of the mutant Rho protein while preserving its wild-type (WT) counterpart, rescuing affected rod photoreceptors, and ultimately preventing vision loss. Here, we demonstrated for the first time a novel gene editing strategy using a highly engineered CasX and gRNA molecule called the X-Editor (XE) to allele-specifically edit the mutant RHO locus in rod photoreceptors, converting the P23H missense into a null variant without affecting the WT RHO allele both in vitro and in vivo. We first showed that XE, delivered by all-in-one AAV vectors, was able to edit efficiently a reporter locus in rod photoreceptors selectively when administered subretinally at a therapeutically relevant dose. We next examined the effects of XE-mediated allele-specific editing of the mutant P23H. RHO allele on retinal structure and function in RHOP23H/+ mice. These results demonstrated the first AAV-mediated delivery of an engineered XE in vivo to achieve allele-specific editing of the P23H. RHO locus resulting in therapeutic benefit. Further engineering of XE subsequently enhanced therapeutic potency. Our study illustrates the potential for XE to treat P23H.RHO-related adRP, and more broadly, other forms of autosomal dominant disorders in an allele-specific manner.

181. LX103 a Novel Recombinant AAV Gene Therapy for Intravitreal Treatment of X Linked Juvenile Retinoschisis

Zhuoyu Ni[1], Fei Wu[1], Junran Sun[2], Ping Gan[1], Ying Zhu[1], Yang Zhou[1], Linhao Lu[1], Yang Liu[1], Xiaodong Sun[2], Fenghua Wang[1]

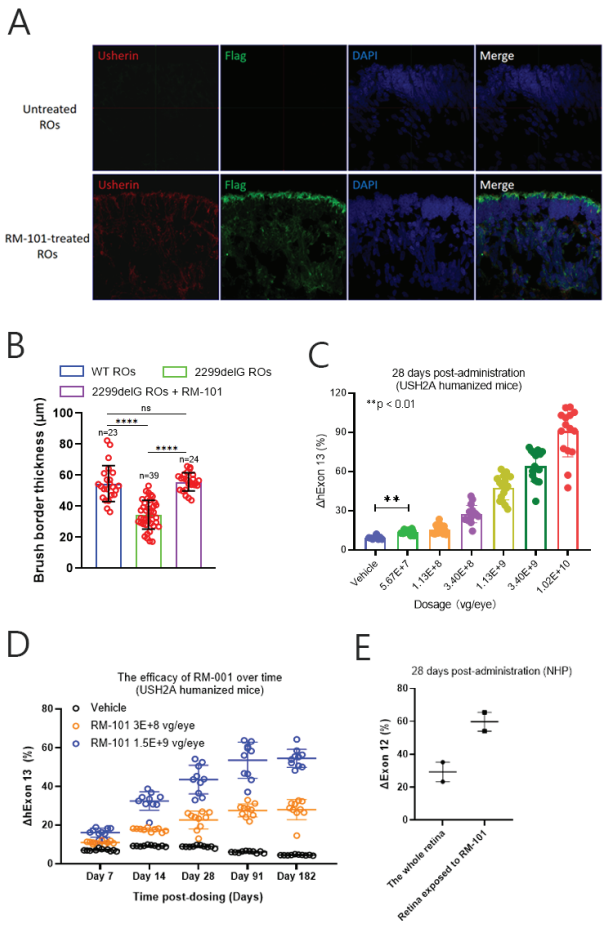
[1]Innostellar Biotherapeutics, Shanghai, China,[2]Shanghai General Hospital, Shanghai, China

X-linked juvenile retinoschisis (XLRS) is an early onset retinal degenerative disease involving abnormal schisis through the retinal neurosensory layers that leads to vision impairment. It is a rare X-linked monogenic disease caused by mutations in the RS1 gene which is normally expressed in photoreceptors and bipolar cells and secreted to intercellular space as a mediator for cell-cell adhesion. LX103 is a novel recombinant adeno-associated virus (rAAV) vector carrying normal human retinoschisin RS1 gene. Its vector is a novel Capstellar capsid RC-C08 engineered from wild type AAV2. RC-C08 capsid possesses much better ILM (inner limiting membrane) penetration and retinal cell transduction capability and lower immunogenicity. Via intravitreal (IVT) administration, LX103 can effectively deliver and express RS1 gene in expected retinal cells in both rodent and large animal models. When rs1-/- knockout mice were treated with LX103, correct RS1 protein expression and retina structural improvement were observed in a dose-dependent manner. To evaluate the safety and efficacy of LX103 as a potential therapeutic clinical intervention, a cohort of XLRS patients (n=6) was enrolled in a single-arm, open-label investigator-initiated trial (IIT). Fundus examinations, visual acuity, visual fields, electroretinography (ERG), and optical coherence tomography (OCT) were employed to monitor both safety and efficacy outcomes. Following intravitreal injection of LX103 (1 month to a year), no serious ocular or systemic AEs were encountered, and no patient experienced vision decrease. 3-month follow-up analysis (n=5) demonstrated a substantial enlargement in dynamic visual field and an increase in ETDRS BCVA in all subjects, and different levels CST decrease and structural ameliorations in the macular EZ intensity. Overall, LX103 was developed with a novel engineered AAV capsid that can efficiently deliver RS1 gene via intravitreal injection. Both the animal studies and the IIT clinical study highlight the promising potential of LX103 as a novel therapeutic approach for XLRS. Further research and clinical studies are warranted to verify these initial results.

182. AAV Vectorized Antibody Fragment-Mediated Dual Complement Pathway Inhibition for the Treatment of AMD

Suzanne B. R. Jacobs[1], Jennifer Sullivan[1], Amy Frederick[1], Ronald Gorham[2], Michael Charewycz[2], Matthew A. Adamowicz[1], Soumya Nair[2], Ken Simmons[2], Anna Park[3], Hendrik Wesseling[4], Ingeborg Langohr[5], James E. Morris[1], Michael Storek[2], Vaishnavi Rajagopal[2], Christian Mueller[1], Catherine O'Riordan[1]

[1]Genomic Medicine Unit, Sanofi, Waltham, MA,[2]Immunology and Inflammation Research, Sanofi, Cambridge, MA,[3]Large Molecules Research, Sanofi, Cambridge, MA,[4]Precision Medicine and Computational Biology, Sanofi, Cambridge, MA,[5]Translational Models Research Platform, Sanofi, Cambridge, MA



Age-related macular degeneration (AMD) is a common, complex disease that is the leading cause of central vision loss in individuals 60 years of age and older. In geographic atrophy (GA), an advanced form of AMD, metabolic and inflammatory stresses in the retina lead to the death of photoreceptors and retinal pigment epithelial cells, the appearance of atrophic lesions, and eventual blindness. Human genetic variants in complement pathway genes are among the most common and strongest genetic risk factors associated with AMD and implicate roles for both the classical and alternative pathways in disease pathogenesis. Here, we describe an AAV-mediated gene therapy approach to inhibit proximal steps in both the classical and alternative complement pathways through sustained expression of vectorized antibody fragments targeting active C1s (aC1s) and Factor Bb in the eye. In addition to its benefit as a potential one-time treatment for GA, this bifunctional strategy has potential to show improved efficacy compared to approaches that target downstream components in the complement pathway because it will broadly inhibit both proximal and terminal mediators of inflammation, phagocytosis, and membrane attack complex-mediated cell lysis. To inhibit both the classical and alternative pathways, we designed a novel AAV vector AAV-aC1s$_{scFab}$-Bb$_{scFab}$ that co-expresses anti-aC1s and anti-Bb single-chain antibody fragments (scFabs). The vector derived scFabs demonstrate target engagement and inhibitory activity for their respective targets and pathways *in vitro*. AAV-aC1s$_{scFab}$-Bb$_{scFab}$ was evaluated *in vivo* following intravitreal (IVT) administration in wild-type C57BL/6 mice and cynomolgus monkeys. At multiple dose levels and timepoints following IVT delivery, the AAV-aC1s$_{scFab}$-Bb$_{scFab}$ vector transduces the retina and expresses transcripts encoding both scFabs. Vector-derived scFabs secreted from transduced cells are detectable in the aqueous and vitreous humors, maintain target engagement capacity, and improve clinical indicators in an NHP model of ocular inflammation. Overall, these data demonstrate that dual complement pathway inhibition through IVT delivery of vectorized antibody fragments has potential as a one-time treatment for GA secondary to AMD.

183. Pre-Clinical Study of RM-101, a Novel AAV-Based Gene Therapy for *USH2A*-Related Retinitis Pigmentosa

Jiayu Ou[1], Jiaqi Tu[1], Hong Zhang[1], Fazhou Zhang[1], Kun Wu[1], Yan Li[1], Hui Xu[1], Zhendong Xiao[2], Junjiu Huang[3], Junbin Liang[1]

[1]Reforgene Medicine, Guangzhou, China,[2]Biotherapy Center, The Third Affiliated Hospital, Sun Yat-Sen University, Guangzhou, China,[3]School of Life Sciences, Sun Yat-sen University, Guangzhou, China

Introduction: Mutations in the *USH2A* gene are the leading cause of autosomal recessive retinitis pigmentosa and Usher syndrome, with exon 13 mutations being the most common. Previous studies have demonstrated that the removal of exon 13 from the *USH2A* gene can lead to the production of a functional protein, suggesting that exon skipping could be a potential treatment for retinal degeneration associated with *USH2A* mutations. Here, we reported RM-101, a novel strategy based on adeno-associated virus (AAV) for exon skipping, aimed at treating retinal degeneration caused by *USH2A* exon 13 mutations. **Methods:** We developed a U7 SmOPT snRNA that specifically targets *USH2A* exon 13 and encapsulated it into an AAV delivery system (RM-101). The safety and efficacy of RM-101 were evaluated in retinal organoids (ROs), *USH2A* humanized mice, and non-human primates. The ROs used in our study contained a biallelic c.2299delG mutation in the *USH2A* gene, along with a flag tag inserted before the stop codon. The *USH2A* humanized mouse model was created by replacing the mouse *Ush2a* exon 12 and its flanking sequences with a human *USH2A* exon 13 carrying the c.2802T>G mutation and the flanking sequences. **Results:** In ROs treated with RM-101, the skipping of exon 13 in *USH2A* transcripts was 52.8% ± 12.5%, while no exon 13 skipping was observed in control samples. Immunohistochemistry demonstrated that the expression of Usherin protein was restored in RM-101-treated ROs with correct subcellular localization (Fig. 1A), and the deficiency of brush border was rescued (Fig. 1B). In *USH2A* humanized mice treated with RM-101, *USH2A* exon 13 skipping was significantly increased in a dose-dependent manner (Fig. 1C) and efficacy was sustained over time (Fig. 1D). A single subretinal administration of RM-101 (5E+10 vg/eye) in cynomolgus monkeys resulted in 24.3% exon 12 skipping detected in *USH2A* transcripts from cells throughout the retina, and that was 59.8% in cells of the retinal region directly exposed to RM-101 (Fig. 1E). In a GLP toxicity study in 30 rhesus monkeys, no RM-101-related abnormalities were observed during the 13-week observation period. RNA-Seq analysis of retinal organoids and monkey retina and choroid samples confirmed that RM-101 specifically induced skipping of the target exon and no significant off-target splicing was found. **Conclusions:** Our results demonstrated that RM-101 can effectively induce *USH2A* exon 13 skipping both *in vitro* and *in vivo*, and it has an acceptable safety profile. These preclinical studies provide support for RM-101 as a potential gene therapy for the treatment of *USH2A*-related retinal degeneration.

CAR T-cell Therapies

184. Innovative Applications of CAR T-Cell Therapy in Organ Transplant Patients

Yan Luo[1,2], Tanya Hundal[1], Rose Mary Attieh[3], Shuhua Li[1], Yaqing Qie[1], Martha Gadd[1], Mao Shennen[3], Burcin C. Taner[3], Mohamed A. Kharfan-Dabaja[4,5], Tambi Jarmi[3], Hong Qin[1,2,4,6]

[1]Regenerative Immunotherapy and CAR-T Translational Research Program, Mayo Clinic Jacksonville, Jacksonville, FL,[2]Department of Cancer Biology, Mayo Clinic, Jacksonville, FL,[3]Department of Transplantation, Mayo Clinic Jacksonville, Jacksonville, FL,[4]Department of Internal Medicine, Mayo Clinic Jacksonville, Jacksonville, FL,[5]Blood and Marrow Transplantation and Cellular Therapy Program, Mayo Clinic, Jacksonville, FL,[6]Department of Immunology, Mayo Clinic, Jacksonville, FL

Anti-HLA donor specific antibodies have been extensively documented for their critical role in organ transplant rejection and resulting adverse outcomes. Several approaches have been employed to desensitize these patients; however, none of these explored therapeutic approaches has exhibited enduring clinical benefits. In this proof-of-principle study, we explore a novel strategy of utilizing chimeric antigen receptor T cells (CAR T-cells) to target B cells in sensitized organ transplant recipients. Specially, we assessed our innovative MC10029 CAR T-cells, which are designed to target the B cell activating factor receptor (BAFF-R), for their cytotoxicity against patient autologous B cells. Ten sensitized patients were enrolled in the study, with their B cells confirmed for BAFF-R expression. Employing our optimized protocol for CAR T-cell generation from minimal blood samples, we successfully produced patient-specific MC10029 CAR T-cells for all participants. Among the seven patients with adequate autologous B cells, consistent antigen-specific cytotoxicity of their CAR T-cells against autologous B cells was observed, accompanied by cytotoxic granule release. For the remaining three patients with insufficient autologous B cell availability, we demonstrated the antigen-specific cytotoxicity of their CAR T-cells using a set of BAFF-R-positive and BAFF-R-negative target cells. The proof-of-principle data from this study pave the way for the pioneering the first-ever application of CAR T-cell therapy in sensitized patients waiting for life-saving organ transplants.

185. Discovering Novel Transcriptional Regulators of T Cell Exhaustion for Epigenetic Reversal of T Cell Dysfunction

Christian McRoberts Amador[1], Aretha Gao[2], Sean McCutcheon[3], Charles A. Gersbach[3]

[1]Pharmacology and Cancer Biology, Duke University, Durham, NC,[2]Biology, Duke University, Durham, NC,[3]Biomedical Engineering, Duke University, Durham, NC

T cells are part of the immune system's adaptive defense; they specifically target and kill both virally infected and cancerous cells through antigen recognition. Unfortunately, cancer can exploit intrinsic T cell mechanisms to survive attack by the immune system. T cell exhaustion arises from chronic antigen stimulation, which shifts a portion of the T cell population to the exhausted state (T_{EX}), resulting in diminished T cell proliferation and tumor/viral clearance. Modern genome engineering technologies have the potential to dramatically advance T cell therapy by programming T_{EX} cells into desirable phenotypic states. The transcription factor (TF) TOX drives and maintains the T_{EX} state through epigenetic regulation of exhaustion-associated programs. To recapitulate T cell exhaustion *in vitro*, we repeatedly stimulated primary human T cells with anti-CD3/CD28 beads to mimic chronic stimulation and confirmed induction of the exhaustion program via RNA- and ATAC-seq. Specifically, multiple genomic regions within the TOX locus became differentially accessible with *in vitro* chronic stimulation. Through a CRISPR interference (CRISPRi) screen tiling the TOX locus, we confirmed modulation of TOX expression by targeting these accessible non-coding regions, emphasizing the highly regulated epigenetic control of TOX downstream of chronic stimulation. To understand what other TF regulators might be driving or preventing T cell exhaustion upstream of TOX, we designed two screens using a CRISPR activation (CRISPRa) approach targeting all genes encoding TFs in the human genome or an Open Reading Frame (ORF) library encoding all the TFs in the human genome with TOX protein expression as a readout. CD8+ T cells from three distinct donors were used in an acute stimulation setting (one TCR stimulation with anti-CD3/CD28 beads) and a chronic stimulation setting (two additional stimulations). Comparing screen results in the

context of acute versus chronic stimulation facilitated identification of factors specific to the TEX state. The ORF screen yielded more TF hits that were modulating TOX expression than the CRISPRa screen (3 gRNA hits versus >100 ORF hits). Over 100 TF ORFs were enriched in TOX-high and TOX-low bins, including both known and novel regulators of TOX. Individual validations of top enriched TFs unique to chronic stimulation confirmed modulation of TOX expression in the expected direction at the protein and transcript level. FACS staining of exhaustion (LAG3, PD-1, and TIGIT) and memory (IL7R) surface markers revealed significant differences in expression levels, suggesting potential phenotypic changes in T cell function. Ongoing work is focused on validating the effects of these TFs on T cell function (T cell killing of cancer cells and cytokine expression assays), transcriptome (RNA-seq), and epigenome (ATAC-seq). In addition, we are testing these candidate TFs to reprogram tumor-infiltrating lymphocytes from primary lung tumor resections. Through epigenetic reprogramming, we hope to achieve clinically relevant T cell phenotypes to improve current immunotherapies in both viral infection and cancer contexts.

186. T-Cell Epigenetic Reprogramming with TGIF2LX-Overexpression Enhances Adoptive Cell Therapy

Tomer Rotstein[1], Mike Brown[2], Sean McCutcheon[3], Charles A. Gersbach[4]

[1]Biomedical Engineering, Duke University, Durham, NC,[2]Neurosurgery, Duke University, Durham, NC,[3]Duke University, Apex, NC,[4]Duke University, Durham, NC

Memory T-cells exhibit distinct functional characteristics depending on their location within the body. Recent advancements have unveiled a significant population of memory T-cells residing in non-lymphoid tissues. These resident memory T-cells are critical for combating infections and their abundance has a positive correlation with improved survival rates across many solid tumor types. Motivated by this observation, we aimed to harness the potential of resident memory T-cells for adoptive cell therapy. However, isolating these cells from donor-derived tissues is impractical. Therefore, we focused on epigenetic reprogramming of blood-derived T-cells towards a tissue resident state. We conducted two cDNA overexpression screens, using open reading frames (ORFs) encoding all known transcription factors, in human primary CD8 T-cells to identify genetic regulators of *CD103* (a residency marker) and *IL7R* (a memory marker). The intersection of these screens identified the transcription factor *TGIF2LX*, capable of upregulating both markers. Interestingly, this transcription factor is only expressed in male reproductive tissues, although other TGIF family members have been implicated in T-cell function. Bulk RNA-sequencing revealed that *TGIF2LX* overexpression in T-cells leads to widespread transcriptional reprogramming, including activation of genes associated with increased tissue residency programs (e.g. *ITGAE*, *CD69*, *CXCR6*) and decreases in genes associated with circulation programs (e.g. *KLF2*, *S1PR1*). We further characterized *TGIF2LX*-overexpressing T-cells using a multimodal single cell readout, pairing scRNA-seq with a CITE-seq library of 134 unique cell surface markers. This demonstrated a distinct cell state with *TGIFL2X*-overexpressing T-cells existing in clusters unique from those containing unenhanced cells. Of note, these cells also clustered separately from T-cells overexpressing RUNX3, a transcription factor previously identified to enhance tissue residency and improve tumor control, suggesting a novel axis for controlling tissue residency. We tested the effect of TGIF2LX overexpression in modulating CAR-T efficacy in a human breast cancer xenograft model. HCC1954 breast cancer cells were implanted orthotopically into the mammary fat of NSG mice. After 10 days, HER2-targeting CAR-T cells were administered intravenously at a subcurative dose (5x10^5 cells). TGIF2LX-overexpression dramatically improved tumor control by CAR-T cells relative to unmodified control and RUNX3-overexpressing CAR-Ts. These data provide proof-of-concept of a novel strategy for enhancing adoptive cell therapies for solid tumors.

187. Identification of Exhaustion-Associated Genes by Non Viral Editing of Human CD8+ T Cells

Brandon W. Simone[1], Leonel Torres[1], Junwei Shi[2], E. John Wherry[3], Saar Gill[1]

[1]Center for Cellular Immunotherapies, University of Pennsylvania, Philadelphia, PA,[2]Epigenetics Institute, University of Pennsylvania, Philadelphia, PA,[3]Institute for Immunology and Immune Health, University of Pennsylvania, Philadelphia, PA

T cell exhaustion is a hypofunctional state caused by chronic antigen exposure, characterized by decreases in cytotoxicity, proliferation, and cytokine production. Immunotherapies such as Chimeric Antigen Receptor (CAR-T) cells and bispecific T-cell engagers (BiTEs) have been transformative in the treatment of B-cell malignancies, resulting in durable remission in approximately 50% of patients. A prevailing hypothesis explaining CAR-T and other immunotherapy failures implicates T cell exhaustion. Current approaches thought to mitigate T cell exhaustion include monoclonal antibody-based blockade of inhibitory receptor (IR) signaling, such as cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) or the programmed death-1 (PD-1)/PD-L1 axis. It was recently estimated that approximately 40% of US cancer patients may be eligible for immune checkpoint inhibitors (ICI), but that the overall response rate is approximately 10%. Thus, while ICI therapy has been transformational and possibly curative for some patients, ultimately only a minority of patients benefit. It is now thought that ICI largely act to prevent the transition from T_{pex} to T_{ex}, and even genetic interventions such as transcription factor deletion (e.g. *TOX*) do not appear to reverse truly exhausted cells. Thus, genes with a role in reversing established exhaustion are yet to be described. To overcome the mechanistic and therapeutic gaps in T cell exhaustion, we developed an *in vitro* T cell exhaustion assay coupled with non-viral cell-penetrating peptides to deliver CRISPR reagents to already-exhausted cells. Our system enables the screening and identification of the underlying genetic effectors and mechanisms of T cell exhaustion and facilitates the identification of targets capable of reversing T cell exhaustion. In this work we demonstrate that a blinatumomab-based *in vitro* exhaustion assay results in phenotypic (increased PD1, CTLA-4, TOX expression) and functional (decreased cytokine secretion and proliferation in response to antigen) alterations consistent with T cell exhaustion. We show that *in vitro* exhausted cells are amenable to non-viral gene editing using cell penetrating peptides combined with CRISPR nucleases, enabling the identification of genes associated with reversal (rather than prevention) of T cell exhaustion. We used the amphiphilic peptide A5K coupled with Cas9 protein to

efficiently knockout exhaustion-associated genes such as *PRDM1* in phenotypically exhausted T cells. In addition to targeted gene disruption, we show that our system is compatible with off-the-shelf CRISPR/Cas9 sgRNA libraries and enables forward genetic screening for identifying exhaustion-associated genes. Finally, we demonstrate an orthogonal approach using cell-penetrating Cas12a to demonstrate efficient gene editing in exhausted T cells. Taken together, this work enables editing of already-exhausted T cells by leveraging non-viral CRISPR effectors to identify genes associated with reversal, rather than prevention, of T cell exhaustion by targeted or pooled gene editing.

188. CRISPR Engineering of Armoured CAR T Cells Enables Tumour-Restricted Payload Delivery with Enhanced Safety and Efficacy

Amanda X. Y. Chen, Kah Min Yap, Phillip K. Darcy, Imran G. House, Paul A. Beavis

Cancer Immunology Program, The Peter MacCallum Cancer Centre, Melbourne, Australia

INTRODUCTION: Chimeric antigen receptor (CAR) T cell therapy, while highly efficacious for the treatment of certain haematological malignancies, remains ineffective in solid cancers. This can be attributed to various factors, including immunosuppression in the tumour microenvironment, tumour antigen heterogeneity and limited trafficking of CAR T cells into the tumour. "Armouring" CAR T cells to express anti-tumour factors such as proinflammatory cytokines is a promising strategy to address their limitations in the solid tumour setting and engage endogenous anti-tumour immunity, which we have demonstrated to be critical for the treatment of heterogeneous solid cancers[1]. However, conventional armoured CAR T cells utilise a synthetic promoter to drive cytokine expression, which leads to unrestricted cytokine production and can cause severe clinical toxicities[2]. We aimed to use CRISPR/Cas9-mediated homology directed repair (CRISPR-HDR) to achieve expression of proinflammatory cytokines under the control of endogenous tumour-restricted promoters, and hypothesised that this would enhance the safety and efficacy of armoured CAR T cells. **METHODS:** Genome-wide RNA sequencing was performed in both a syngeneic murine CAR T cell model and a xenogeneic human CAR T cell model to identify genes that are specifically upregulated in CAR T cells within the tumour. Tumour specificity of candidate target genes was assessed *in vivo* through HDR-mediated insertion of GFP into each locus followed by comparison of GFP expression between CAR T cells within the tumour and peripheral sites. Following identification of ideal target genes, a panel of proinflammatory cytokines was inserted into these loci, and the safety, therapeutic efficacy and mechanism of the engineered T cells was evaluated in 2 immunocompetent murine tumour models and 1 xenograft human tumour model. **RESULTS:** Through assessment of 27 potential target genes, *NR4A2* was identified as the top candidate for enabling stringent tumour-restricted payload expression. Strikingly, expression of IL-12 via the endogenous *NR4A2* promoter mediated robust therapeutic responses in the absence of toxicities, in contrast to promoters with higher peripheral expression such as that of *PD-1*. Additionally, NR4A2/IL-12-engineered CAR T cells exhibited enhanced cytotoxic and proliferative capacity as well as the ability to stimulate endogenous anti-tumour immunity. We further demonstrate that our approach enables superior tumor-restricted expression of payloads compared to currently utilised synthetic systems such as the NFAT-inducible promoter system. **CONCLUSION:** Tumour-localised delivery of potent payloads is a significant challenge in developing safe and effective cancer therapies. By leveraging endogenous tumour-restricted promoters to drive transgene expression, we have engineered armoured CAR T cells to deliver proinflammatory payloads directly to the tumour site, enabling robust anti-tumour effects while minimising systemic toxicities. **REFERENCES:** 1. [1]Verismo Therapeutics, Philadelphia, PA,[2]Department of Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA,[3]Center for Cellular Immunotherapies, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA

Single-chain CD3-based chimeric antigen receptors (CARs) targeting CD19 with FMC63-derived single-chain variable fragment (scFv) show remarkable clinical responses in patients (pts) with B-cell malignancies. Despite high response rates in diffuse large B cell lymphoma, about a third of pts do not respond, and of those who do, around a third relapse. Therapies that improve CAR T cell function are thus critical. Previously we developed a multi-chain mesothelin-specific killer immunoglobulin-like receptor (KIR)-CAR T cell therapy, SynKIR-110, with enhanced anti-tumor function and durability in a murine xenograft model of human mesothelioma [1, 2]. SynKIR-110 is currently being investigated in a Phase I trial, STAR-101 (NCT05568680) for pts with mesothelin-positive solid tumors. Using our KIR-CAR platform we next developed a novel CD19-specific KIR-based CAR T cell therapy for CD19-positive hematologic malignancies. To identify an optimal anti-huCD19 scFv for KIR-CAR we screened a highly diverse 40-billion member canine scFv phage display library. 19 human CD19-specific scFvs were identified that competed with the clinically validated FMC63 scFv. KIR-CARs were constructed with candidate scFvs, and used to transduce primary T cells. We compared in vitro and in vivo potency of these unique KIR-CAR T cells with FMC63-KIR-CAR T cells. In traditional in vitro potency assays such as antigen (ag)-specific tumor lysis and cytokine secretion, we saw no differences across KIR-CAR T cells. However while other binders demonstrated less effective or durable tumor control in a NSG xenograft mouse relapse model of B-cell leukemia NALM6, the selected DS191 had comparable in vivo anti-tumor efficacy to FMC63. Thus SynKIR-310 was generated in human T cells with a lentiviral vector to express DS191 in the KIR-CAR platform for further characterization. Ag sensitivity of SynKIR-310 was compared to FMC63-KIR-CAR T in vitro using target cells with a 5 log-fold range of CD19 expression. SynKIR-310 and FMC63-KIR-CAR T cells showed comparable dose-dependent, ag-specific activation, as well as specificity and sensitivity. Anti-tumor efficacy was next assessed in vivo. Using increasing doses of cells, both SynKIR-310 and FMC63-

KIR-CAR T cells showed similar dose-dependent anti-tumor efficacy. In a membrane proteome array of 5,220 unique human proteins and 243 heterocomplexes, DS191 showed no off-target binding, supporting CD19 specificity. Co-culture of SynKIR-310 with a panel of CD19-negative primary cell types from normal tissues showed no evidence of off-target cytotoxicity, supporting minimal cross-reactivity. Together, these data demonstrate high CD19 ag sensitivity, specificity, and potency of DS191 scFv, that combined with the prolonged functionality of KIR-CAR, supports SynKIR-310 as a promising T cell therapy against CD19-positive malignancies. Finally, these results suggest that current in vitro assays do not sufficiently correlate to in vivo potency, highlighting the need for improved in vitro potency assays for CAR T preclinical development. 1.Wang, E., et al., Generation of Potent T-cell Immunotherapy for Cancer Using DAP12-Based, Multichain, Chimeric Immunoreceptors. Cancer Immunol Res, 2015. 3(7): p. 815-26.2.Xu, J., et al., 321 Preclinical potency assessment of SynKIR-110, a mesothelin-specific KIR-CAR T cell therapy for mesothelioma. Journal for ImmunoTherapy of Cancer, 2023. 11(Suppl 1): p. A365-A365.

190. *In Vivo* Generation of αCD19-CAR T Cells Using a Novel LV-based Platform Successfully Clears Advanced NALM-6 Tumor without Noticeable Toxicity

Karina Krotova[1], Gopal Naik Nenavath[1], Nandakumar Packiriswamy[1], Yumeng McDaniel[1], Rianna Vandergaast[1], Chia-Hsuan Chin[1], Kyle Gromer[1], Luke Schnebec[1], Zachary Larson[1], Kah-Whye Peng[2], Stephen J. Russell[2]

[1]Imanis Life Sciences, Rochester, MN,[2]Vyriad, Rochester, MN

In the past few years, there has been a surge of interest in generating CAR-T cells directly in patients through a straightforward injection of vector containing the CAR transgene. This "in vivo" approach has the potential to streamline the treatment procedure and decrease its overall cost. Imanis Life Sciences and Vyriad recently developed a new platform for efficient in vivo T cell-specific delivery. It is based on lentiviral vectors pseudotyped with LDLR detargeted VSV-G glycoproteins incorporating a CD3-specific single-chain antibody fused at the N-terminus (G-CD3). Targeting T cells by G-CD3-LV was first confirmed in ex vivo experiments with human peripheral blood mononuclear cell cultures and then with fresh human whole blood. T cells were efficiently and exclusively infected in these heterogeneous cell populations without the need for prior activation or the presence of any cytokines. For in vivo evaluation, G-CD3 LV encoding αCD19-CAR/GFP (G-CD3/LV-CAR) was used to treat advanced NALM6 -Luc tumors in NSG mice engrafted with human PBMC. Intraperitoneal administration of G-CD3/LV-CAR led to complete tumor eradication without recurrence by the 60 days post-injection study end point. The peak level of circulating CAR-T cells in these animals was 57.5±10.7% of human T cells on day 15 post injection, at which point integration analysis revealed a copy number of 1.2±0.6 integration sites per transduced human T cell. At later time points, after tumor clearance, the number of circulating CAR-T cells was greatly reduced and their phenotype shifted from mostly effector/effector memory toward central memory/stem-like cells. In general, mice tolerated the treatment well, and analysis of cytokines associated with CAR-T cell cytotoxicity confirmed the absence of severe cytokine storm. Interestingly IL-6 was undetectable at all time points analyzed and IFN-gamma was the only cytokine which significantly increased during the expansion period of CAR-T cells, while IL-2, IL-10, and TNF-alpha exhibited only a minor increase. Aside from the possibility of a CAR-T driven cytokine storm, we also investigated whether the infused CD3-targeted vector particles might activate T cells sufficiently to provoke an immediate "infusional" cytokine storm. Exposing human PBMC to G-CD3-LV led to the rapid induction of T cell activation markers CD69 and CD25 and to the release of IFN gamma and TNF alpha measured 6 hours after infection in the culture medium. To evaluate CD3 scFv -induced toxicity in vivo, fully immunocompetent mice transgenic for the γ, δ, and ε subunits of human CD3 ("GDE mice") were used. After infusing high doses of the G-CD3 LV into GDE mice, CD69 was rapidly upregulated on the T cells after 2-6 hours. However, despite this evidence for vector-mediated activation of the T cells (presumably by delivering signal 1), there was no detectable increase in serum IL-2, IL-4, IFNγ, TNFα or IL-6, neither at early (2-6 hours) nor later (1-4 days) time points. Also, the animals did not lose weight and did not appear unwell after vector infusion. These data suggest that though G-CD3 LV activates T cells, it does not induce an infusion-related cytokine storm in vivo. In summary we demonstrate novel CD3-targeted lentiviral vectors that efficiently and accurately deliver their CAR-T genetic payload to human T cells in fresh whole blood and humanized tumor-bearing mice, leading to in vivo CAR-T cell generation and potent antitumor activity without severe cytotoxicity.

Targeted Gene Insertion

191. Efficient and Versatile Programmable Large-Gene Integration by Evolved Recombinases and Prime Editing

Xin D. Gao[1,2,3], Smriti Pandey[1,2,3], Nicholas A. Krasnow[1,2,3], Amber McElroy[4], Jordyn E. Duby[1,2,3], Sarah Pierce[1,2,3], Jakub Tolar[4], Mark J. Osborn[4], David R. Liu[1,2,3]

Current methods to achieve targeted integration of multi-kilobase DNA sequences into mammalian genomes suffer from low efficiencies, specificities, or programmability, limiting their usage in synthetic biology, biotechnology, and cell and gene therapies. To overcome these challenges, we developed a phage-assisted continuous evolution (PACE) selection system for recombinases, then applied the system to substantially improve the activity of large serine recombinase (LSR) for prime editing-assisted site-specific integrase gene editing (PASSIGE), an approach that couples the programmability of prime editing with the specificity of recombinases to precisely integrate large DNA cargoes into the mammalian genome. PACE-evolved LSR variants mediate up to 60% donor integration in human cell lines with pre-installed recombinase landing sites. When used in tandem with prime editing,

the evolved recombinase variants can consistently achieve single-transfection targeted gene integration efficiencies of ≥30% (up to 50% without any selection) at therapeutically relevant sites in human cells. PASSIGE with the evolved and engineered Bxb1 variant substantially outperforms previously reported methods for programmable large gene integration—for example, outperforming PASTE and original PASSIGE system by an average of 16-fold and 4.2-fold, respectively across three human and mouse cell types and 12 genomic loci. To our knowledge, the evolved and engineered Bxb1 variants generated in this study enable the most effective targeted gene integration in mammalian cells reported to date. We anticipate that these recombinase variants may also be applied to modify DNA for various applications that will advance both biological research and therapeutic development. Finally, the rapid continuous evolution system developed in this study can also be used to improve the activity of other recently discovered integrase systems to enhance their activity. X.D.G. and S.P. contributed equally to this work.

192. Directed Evolution of Bxb1 for the Development of Modular Integrases (MInts)

Serine integrases have recently emerged as promising reagents for the site-specific integration of large DNA cargo into genomes. Their ability to insert large DNA payloads with high precision at pre-defined sites without causing double-strand breaks or nicks and without reliance on a host's DNA repair machinery makes them attractive tools for genome engineering for therapeutic applications and synthetic biology more generally. The recent discovery of thousands of serine integrases and their putative attB and attP sites has significantly expanded the toolbox of integrases available for synthetic biology. Nevertheless, such novel integrases are constrained by their natural DNA sequence preference, and their use has been limited to integration at sites pre-inserted into host genomes using complex prime editing reagents. A much more desirable alternative may be a set of bespoke engineered integrases able to target genomes in the absence of other gene editing tools with high precision and efficiency. We sought to provide such an alternative by the directed evolution of the serine integrase from the Bxb1 phage. While structures of a distantly related serine recombinase from the *Listeria inoccua* prophage have shed light on the mechanism of recombination, the low homology to other well-characterized serine integrases and extensive DNA contact surface have posed a significant challenge to the engineering of the large serine integrases. Based on the published integrase structures as well as structural predictions made by RoseTTAfold, we hypothesized that serine integrases may recognize their DNA targets through distinct and structurally independent submotifs (Modules), and as such, allow the systematic reprogramming of integrases towards divergent attachment sites. Using site-directed mutagenesis and plasmid recombination assays, we mapped protein submotifs crucial for the protein-DNA contacts between Bxb1 and its attB site. We then developed an ultra-high throughput bacterial selection system capable of assaying billions of Bxb1 variants, and carried out hundreds of selections against artificial attB and attP sites, with nearly 70% of selections yielding clear consensus sequences at the selected peptide submotif. We characterized the molecular specificity of hundreds of selected submotifs and found that their sequence preference has been profoundly changed from that of their natural counterpart. Importantly, we discovered that such novel Bxb1 variants can be assembled and give rise to fully synthetic, Modular Integrases (MInts), with attB sequences diverging significantly from the natural Bxb1 attB site. Moreover, such MInts can be used for the targeted integration of large DNA cargo in human cells (See Poster by Fauser et al) . We estimate that our current bank of pre-characterized MInts may allow us to target the human genome every 10kb, with the potential to target the first intron of most disease-related human alleles in cases where other gene editing approaches are insufficient as a means of correcting multiple mutations and to address multiple patient populations at once.

While numerous technologies for the characterization of potential off-target editing by CRISPR/Cas9 have been described, the development of new technologies and analytical methods for off-target recombination by Large Serine Integrases (LSIs) are required to advance the application of LSIs for therapeutic gene integration. Here we present the development of two complementary off-target recombination discovery technologies and a hybrid capture validation technology as a comprehensive framework for off-target characterization of LSIs. HIDE-Seq (High-throughput Integrase-mediated DNA Event Sequencing) is a PCR-free unbiased genome-wide biochemical assay capable of discovering sites with LSI-mediated DNA double-strand breaks and off-target recombination events. Cryptic-Seq is a PCR-based unbiased genome-wide biochemical or cellular-based assay that is more sensitive than HIDE-Seq but is limited to the discovery of sites with off-target recombination. Potential off-target loci discovered by HIDE-Seq and Cryptic-Seq can then be validated with our hybrid capture NGS sequencing of genomic DNA from cells after LSI-mediated gene insertion that has been qualified to 0.1% sensitivity. Hybrid capture sequencing of >450 discovered off-target sites led to the validation of 90 detectable off-target recombination sites with less than 1% frequency in cells. Furthermore, the lack of indels at these sites suggests that Bxb1 integrase does not generate significant double strand breaks, consistent with our HIDE-seq data. To demonstrate the sensitivity of our framework to discover bona fide sites of off-target recombination, we performed unbiased whole genome sequencing

(WGS) on LSI-edited samples and found WGS detected only 2 of the 90 off-target sites discovered by our discovery and validation framework, yielding a 45-fold increase in sensitivity. We expect the dissemination of these sensitive technologies will advance the application of LSIs in therapeutic genome editing by establishing benchmarks for sensitivity of off-target detection.

194. *In Vivo* Expansion of Gene-Targeted Hepatocytes through Transient Inhibition of an Essential Gene

Marco De Giorgi[1], So Hyun Park[2], Adam Castoreno[3], Mingming Cao[2], Ayrea Hurley[1], Lavanya Saxena[2], Marcel A. Chuecos[1], Christopher J. Walkey[1], Alexandria M. Doerfler[1], Mia N. Homology Directed Repair (HDR)-based genome editing is an approach that could permanently correct a broad range of genetic diseases. However, its utility is limited by inefficient and imprecise DNA repair mechanisms in terminally differentiated tissues. For example, HDR requires cell division, generally limiting targeting of adult liver to ~1% of hepatocytes. The goal of this work is to develop a system for selective expansion of gene-targeted hepatocytes using essential genes, which we call "Repair Drive". Repair Drive consists of: (1) transient conditioning of the liver by knocking down an essential gene - Fumarylacetoacetate hydrolase (Fah), which is important for tyrosine catabolism, and (2) delivery of an untargetable version of the essential gene in *cis* with the therapeutic transgene. To test this approach, we used AAV vectors to insert *FAH* in tandem with a fluorescent marker (TdTomato) into a highly expressed locus in the liver (*Apoa1*). Mice were injected with AAV8 vectors encoding CRISPR/Cas9 (AAV-CRISPR) and a Donor template (AAV-Donor) with *FAH* and a TdTomato transgene. Monthly injections of N-acetylgalactosamine (GalNac)-modified siRNA targeting murine *Fah* were used as a conditioning agent to deplete untargeted hepatocytes and drive expansion of correctly repaired cells. Three months later, mice receiving the conditioning siRNA - Repair Drive mice - showed a dramatic increase in the number of TdTomato positive hepatocytes, versus those receiving the viral vectors alone - Unselected mice (~10% vs 0.5%). Selective expansion could be further improved to >25% of hepatocytes by manipulation of tyrosine catabolism with a high protein diet. To evaluate the translatability and long-term safety of this approach, we inserted a human Factor IX (*FIX*) transgene into the *Apoa1* locus. Following genome editing, the mice were injected monthly with the conditioning siRNA for three months, and then followed for 1 year. Repair Drive mice showed sustained FIX expression over 1 year with a ~5-fold increase as compared to Unselected mice. Liver conditioning caused only a transient elevation of ALT at early time points (4 to 8 weeks), which fully resolved over time. Histology revealed no evidence of liver toxicity and full reconstitution of Fah expression. Importantly, the expansion protocol did not increase the risk of tumorigenesis. SMRT-seq analysis at the *Apoa1* locus revealed 20- to 50-fold increase of correct HDR-, 5'-HDR/3'-NHEJ- or partial integration of the Donor cassette in Repair Drive mice. NGS data showed a dramatic reduction in the relative frequency of off-target to on-target editing in Repair Drive mice. Overall, these data show a novel strategy for selectively expanding targeted hepatocytes for liver gene therapy.

195. Programmable Genomic Integration in Induced Pluripotent Stem Cells and Hematopoietic Stem and Progenitor Cells

Tome Biosciences, Watertown, MA

CRISPR/Cas9-based technologies have revolutionized basic and applied biomedical research in the past decade. Current targeted gene insertion approaches require DNA double-strand breaks (DSBs), risking translocations, and rely on DNA repair pathways (e.g., homology-directed repair, HDR) that are inactive in quiescent or terminally differentiated cells. Programmable and multiplexed genome integration of multi-kilobase (kb) DNA cargo independent of HDR is still challenging. Here, we present a proof-of-concept (PoC) evaluation of Tome Biosciences' proprietary technology, integrase-mediated programmable genomic integration (I-PGI), on induced pluripotent stem cells (iPSCs) and CD34+ hematopoietic stem cells (HSCs). I-PGI combines CRISPR-mediated genome editing and site-specific integrases, enabling efficient and targeted genomic integration without DSBs. Two unique features of iPSCs, unlimited expansion and the ability to differentiate into almost all cell types, provide an unprecedented opportunity for cell therapy. The current FDA-approved autologous cell therapies are costly, labor-intensive, time-consuming to manufacture, and carry a risk of oncogenic transformation due to random integration using lentivirus. Allogeneic iPSC-derived cell products, which can be manufactured on a large scale and used "off-the-shelf", hold promise to overcome these limitations. First, we leveraged attachment site-containing guide RNAs (atgRNAs), Cas9 nickase, and reverse transcriptase to place integrase-recognizing landing sites (beacons) at the B2M locus and achieved over 90% beacon placement (BP) efficiency. We followed by integrating a DNA cargo of 5.2kb into the placed beacon and achieved up to 46% efficiency. We then tested a template of 31kb and successfully reached 6% integration. To assess multiplex integration, we simultaneously placed orthogonal beacons at four different genetic loci and integrated 4 corresponding templates into these beacons. We observed integration of 1.4%, 6.8%, 8.1% and 10.2% respectively with DNA templates ranging in size from 4 to 6kb. HSC transplantation has been a curative therapy for many hematological disorders and malignancies in the last few decades, and the field is further energized by the recent approval of Casgevy. However, durable gene replacement requires editing of the quiescent long-term (LT)-HSC population, which is limited by HDR-mediated approaches. In donor-derived CD34+ HSCs, we achieved BP efficiencies of over 80% at the B2M locus and over 30% I-PGI efficiencies. To determine if I-PGI can

engineer LT-HSCs, we isolated the primitive HSC sub-population and demonstrated that PGI efficiencies correlated with the bulk engineered HSC population. We are currently evaluating if the I-PGI engineered HSC successfully engraft and persist *in vivo.* In summary, our PoC study demonstrated efficient, DSB-free engineering of iPSCs and HSPCs by I-PGI technology. This novel approach gives us the advantage of speed, precision, and specificity for next generation cell therapies.

196. Internal Base Modifications Enable Highly Efficient Gene Insertion in Primary Cells Using Single Stranded DNA

Sriram Vaidyanathan[1], Karen Kanke[1], Cormet-Boyaka Estelle[2], Mark Hester[3], Rachael E. Rayner[2], Ma Suu[2]

[1]Nationwide Children's Hospital, Columbus, OH,[2]The Ohio State University, Columbus, OH,[3]The Research Institute at Nationwide Childrens Hospital, Columbus, OH

In vivo genome editing using CRISPR/Cas9 has the potential to durably treat chronic disorders including monogenic diseases such as cystic fibrosis (CF). The development of lipid nanoparticles (LNP) has enabled the delivery of Cas9 mRNA and sgRNA without eliciting significant immune responses. Although this enables therapies that rely on knocking out genes, the ability to insert genes in vivo can further improve our ability to durably treat diseases. Gene insertion relies on homologous recombination (HR) which requires a template carrying the sequence of interest. Adeno-associated viruses result in efficient gene insertion but can trigger innate and adaptive immune responses. Single-stranded DNA (ssDNA) templates may enable high efficiency gene insertion using LNPs packaged with Cas9 mRNA/sgRNA and ssDNA templates. However, ssDNA templates suffer from low efficiency. Previous studies have used chemical modifications (e.g. phosphorothioate) at the ends of ssDNA templates to improve efficiency. We reasoned that the chemical modification of internal bases may further protect ssDNA templates and improve gene insertion further. However, it was unclear if the base modifications that prevent nuclease activity may also prevent efficient HR. We tested the use of ssDNA with 10% - 33% modified bases to improve gene insertion in airway basal stem cells (ABCs), hematopoietic stem cells, T-cells, and vascular endothelial cells *in vitro* by delivery using electroporation. We used 200 bp templates targeting the *CFTR*, *HBB* and *CCR5* loci involved in cystic fibrosis, hemoglobinopathies and HIV infections respectively. Our results show that ssDNA with chemical modifications in 10-17% of internal bases (eDNA) is compatible with the homologous recombination machinery. In the *CFTR* locus in airway basal stem cells (ABCs), eDNA templates showed gene insertion in 41 ± 15% of alleles compared to 24 ± 6% for end-modified and 15 ± 5% for unmodified ssDNA (Figure 1). Compared to end-modified templates, improved gene insertion by eDNA templates was also observed in the *HBB* (51 ± 9% vs 22 ± 4%) and *CCR5* (41 ± 5% vs 17 ± 1%) loci in ABCs. Similar improvements in gene insertion were also observed in hematopoietic stem and progenitor cells, T-cells and endothelial cells. We further tested the use of this approach to correct the F508del mutation in the *CFTR* gene using CF patient-derived airway cells. We achieved correction in 49 ± 15% alleles in CF ABCs. Upon differentiation, the corrected cells showed CFTR function that was 30-60% relative to non-CF controls. This level of correction is therapeutically relevant and is comparable to adeno-associated virus-based templates. Further studies are needed to determine if eDNA templates show similar improvements in gene insertion when delivered using LNP formulations *in vivo*.

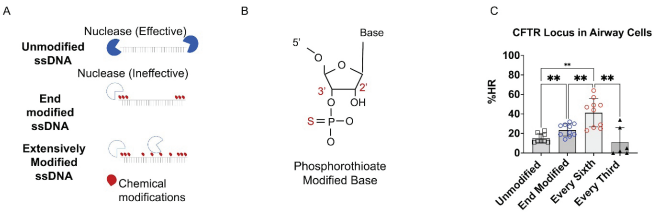

Figure 1: A) Graphic showing the chemical modifications of ssDNA and predicted nuclease degradation activity and inactivity. B) Graphic showing the chemical structure of modified bases. C) In airway cells at the CFTR locus, ssDNA templates with every sixth base modified show significantly higher HR than end-modified ssDNA and unmodified ssDNA (15 ± 5%). Modifying every third base results in the least gene insertion (11 ± 15%). Statistical comparison was made using one-way ANOVA and Tukey-test. ****, ***, ** and * represent p <0.0001, p < 0.001, p< 0.01 and p < 0.05 respectively for all panels.

197. Targeted Gene Insertion of Vectorized Monoclonal Antibodies in Non-Human Primates Overcomes AAV Genome Silencing in the Liver and Supports High, Sustained *In Vivo* Expression of Functional Antibodies

Rachel Sattler, Anthony LoMastro, Juanita Ezemba, Tara Sterlacci, Ellen-Marie Koehler-Stec, Asma Parveen, Elena Ivanova, Kristen Pascal, Leah Sabin, Christos Kyratsous

Regeneron Pharmaceuticals, Inc., Tarrytown, NY

As more liver-directed, adeno-associated virus (AAV)-based therapies move to human clinical trials, a strong disconnect in the efficiency of the strategy is observed when transitioning from mouse to monkey to human. These conventional AAV gene therapies rely on formation of extrachromosomal DNA episomes in the nucleus of host cells and a promoter to drive transgene expression. In our work, and work reported by others, we observe that conventional AAV episomes support robust liver expression in mouse models but achieve significantly lower levels of mRNA and protein expression in livers of both non-human primates (NHPs) and mice with human-engrafted hepatocytes. This phenomenon persists across multiple transgenes, promoters, and capsids. It poses a major limitation for clinical translatability of liver-directed, conventional AAV therapy. The exact mechanism underlying the species-specific differences in expression is under active investigation. Reported data suggests multiple causes, including epigenetic regulation of the episomal DNA and interactions between host immune factors and the AAV capsid. We have developed an alternative, CRISPR-based approach for gene therapy in the liver. Using a dual lipid nanoparticle (LNP) and AAV delivery system, this turnkey platform enables targeted insertion of a promoterless expression cassette into the *Albumin* locus of liver hepatocytes. In this study, we investigated if the targeted gene insertion of a monoclonal antibody (mAb) cassette would overcome the limitations of conventional AAV episomes in NHPs. Vectorized antibody treatment is an attractive

alternative to traditional antibody-based drugs for chronic conditions requiring continuous dosing, and for use as a vaccine alternative or prophylaxis treatment in special populations. We delivered the same transgene, encoding an anti-SARS-CoV2 antibody, to both mice and NHPs using either conventional AAV episomes or the CRISPR-based targeted insertion approach. As expected, when conventional AAV episomes were used, significantly lower levels of circulating mAb expression were measured in NHPs compared to mice. Conversely, when CRISPR-based targeted insertion was used, therapeutically relevant levels of circulating mAb were measured as early as day 7 post-dosing in both mice and NHPs. Further, peak mAb levels of greater than 100 ug/ml were measured in both species and levels were sustained through the study completion at week 19. Of note, vector DNA levels in the NHP livers were similar regardless of the platform used, but mRNA and protein levels measured more than a log higher in the livers of NHPs that received the targeted gene insertion. In summary, durable, therapeutic levels of mAb expression were achieved in NHPs using liver-directed, CRISPR-based, targeted gene insertion. This approach overcomes the increasingly reported disconnect between mouse and NHP studies that use conventional AAV gene delivery for liver expression of therapeutic proteins. Since the insertion platform is a "plug and play" approach, the demonstration here of high levels of mAb expression via insertion suggests that the platform will enable robust protein expression in other therapeutic contexts as well. Finally, the expression of therapeutic mAbs was long-lasting, providing a path forward for truly "one-and-done" liver-directed gene therapies.

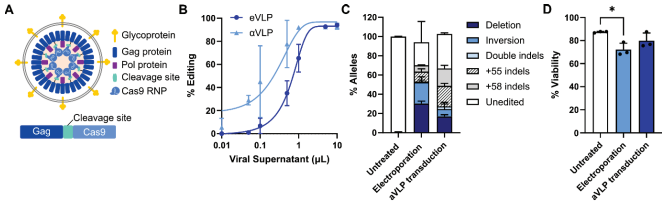
Emerging Viral Vectors

198. Lentiviral Gene Therapy to the Liver for Homozygous Familial Hypercholesterolemia (FH): Assessing the Best Vector Design

Cesare Canepari[1], Michela Milani[1], Francesco Starinieri[1], Anna Fabiano[1], Fabio Russo[1], Mauro Biffi[1], Rossana Norata[1], Martina Rocchi[2], Francesca Sanvito[2], Alessio Cantore[1,3]

[1]San Raffaele Telethon Institute for Gene Therapy, Milan, Italy,[2]IRCCS San Raffaele Scientific Institute, Milan, Italy,[3]Vita Salute San Raffaele University, Milan, Italy

Homozygous FH (HoFH) is a severe rare early-onset inherited disease, mostly due to mutations in low-density lipoprotein (LDL) receptor (LDLR)-encoding gene. The disease is characterized by high circulating LDL cholesterol (LDL-c), due to impairment in its clearance by LDLR. Patients rapidly develop atherosclerosis. Available treatments do not normalize LDL-c. *In vivo* gene transfer to hepatocytes may rescue LDLR expression upon a single intravenous (i.v.) administration. Lentiviral vectors (LV) may be used for this purpose since they integrate in the genome of target cells and thus are maintained upon cell proliferation in liver growth. For this reason, LV may be applied to pediatric patients. LV are typically pseudotyped with vesicular stomatitis virus glycoprotein (VSV.G). However, VSV.G-LV have been shown to interact with LDLR and LDLR family members to access target cells. Indeed, when producing VSV.G-LV expressing LDLR transgene, we obtained very low infectious titers (>10-fold lower than infectious titers of other LV), likely due to interaction between VSV.G and LDLR overexpressed by producer cells and subsequent re-infection during LV production. We overcame this issue by avoiding LDLR expression during production. Specifically, we placed the LDLR sequence and its hepatocyte specific promoter in reverse orientation with respect to LV genome transcription. Alternatively, we added a LDLR negative modulator during LV production. These improved LV designs showed complete rescue of infectious titer. We then tested if hepatic gene transfer was feasible in mice Ldlr-/-, mouse model of HoFH. We injected them with LV expressing a reporter coagulation factor IX (FIX) transgene and observed higher transgene output in mice Ldlr-/- compared to controls at two different LV doses, possibly due to efficient LV uptake by LDLR family members expressed by hepatocytes. We then moved on to evaluate therapeutic efficacy: we produced LV expressing LDLR under the control of a hepatocyte-specific cassette based on a strong enhanced transthyretin (ET) promoter. We injected ET.LDLR-LV into juvenile Ldlr-/- mice and observed normalization of blood LDL-c. We stressed the system by feeding the mice with Western Diet (21% fat, 0.2% cholesterol) for three months. No atherosclerosis was present in treated mice (N=6), while it was marked in Ldlr-/- untreated controls (N=5). Histopathology analysis showed abnormalities in the liver of LV-treated mice. Moreover, liver lipid vacuolation was higher in those showing lower corrected liver area, suggesting that few LDLR-overexpressing cells experienced excessive lipid intake. To improve this outcome, we tested a weaker alpha-1-antitrypsin (HAAT) promoter. At matched LV doses, HAAT was ~20-fold less potent than ET in the human Huh7 hepatoma cell line and around 7-fold lower *in vivo*. Interestingly, when tested in Ldlr-/- mice, we found similar therapeutic efficacy of LV equipped with the different promoters at similar doses (N=5). HAAT-LV treated mice are currently being challenged with Western diet. Histopathological analysis of the liver and comparisons between the LV with the two different promoters will be presented. Here, we show, for the first time, to our knowledge, full normalization of LDL-c and atherosclerosis prevention, by liver-directed LV gene therapy in a mouse model of HoFH. These data provide the basis for further development towards clinical translation.



199. Alpha-Retrovirus-Based Virus-Like Particles for Efficient Gene Editor Delivery into Hematopoietic Stem Cells

Denise Klatt[1], Josephine Mayer[1], Jing Zeng[1], Chi-Yuan Zhang[2], Nola Neri[1], Sébastien Levesque[1], Axel Schambach[1,3], Els Verhoeyen[4,5], Daniel E. Bauer[1], David A. Williams[1], Christian Brendel[1]

[1]Hematology/Oncology, Boston Children's Hospital, Harvard Medical School, Boston, MA,[2]Dana-Farber Cancer Institute, Boston, MA,[3]Hannover Medical School, Hannover, Germany,[4]INSERM/CIRI/EVIR, Lyon, France,[5]Université Côte d'Azur, Nice, France

Electroporation of ribonucleoprotein (RNP) complexes or mRNA is currently the method of choice for delivery of CRISPR-Cas9-based genome editors into hematopoietic stem cells (HSCs). While efficient, these methods affect cell viability and physiology, require specific equipment, and are limited to *ex vivo* applications. Cas9-delivery by virus-like particles (VLP) is a promising alternative, such as the γ-retrovirus-based Nanoblade or eVLP systems. These VLP systems consist of a designer nuclease fused as a RNP complex to structural

components of the virus shell, which is liberated into target cells by the viral protease. Here, we engineered α-retrovirus-based VLPs (αVLPs) for genome editor delivery (Figure A). This approach was motivated by the favorable genome organization of α-retroviruses, where the gag-Cas9 fusion resides entirely within the gag-gene reading frame, which is >10-fold more efficiently translated than the downstream pol-genes, where the Cas9 fusion is placed in the eVLP system. We showed that the αVLPs are 5-fold more efficient than the described eVLP system for Cas9 delivery using VSVg-pseudotyped particles as assessed by indel formation in various cell lines and human CD34+ HSCs (Figure B). We identified optimal configurations through sequential testing of four different gag-Cas9 fusions, multiple viral protease sites and tuning the component ratios during αVLP-production. Optimal editing was achieved by the fusion of Cas9 downstream of the nucleocapsid coding region separated by the naturally present protease cleavage site. Physical characterization revealed a larger size of αVLPs compared to eVLPs (118 nm vs 108 nm) but no significant difference in the amount of Cas9 molecules per editing particle. Over 90% indel rates were observed targeting multiple different loci, such as B2M, SBDS or BCL11A, with <1 µL viral supernatant in cell lines (1.1-9.8x10^8 editing VLPs/mL) and over 70% indel formation in HSCs using a MOI 100 while maintaining viability equivalent to untransduced cells. We additionally explored αVLP for multiplex editing, simultaneous delivery of an integrating payload, and flexible pseudotyping for editing quiescent HSCs. Using a hybrid envelope consisting of VSVg and BaEVRLess, we were able to edit over 50% of alleles in freshly thawed, quiescent CD34+ HSCs using a MOI 100 during a two-hour transduction period. As a therapeutic target to treat sickle cell disease, we deleted the erythroid enhancer of BCL11A in CD34+ HSCs and compared αVLPs to electroporation. Both methods achieved over 60% editing of the BCL11A locus and about 50% HbF induction upon erythroid differentiation (Figure C). In contrast to electroporation, αVLP mediated editing was less cytotoxic to HSC, indicated by a viability of 80% compared to 72%, which resulted in higher human chimerism in transplanted NBSGW mice (Figure D). Next, we explored the delivery of prime editors via αVLPs to avoid DNA double-strand breaks and improve safety. Initial results demonstrated over 60% prime editing in HEK293T cells targeting the B2M locus. In summary, αVLPs are an efficient and versatile tool for the delivery of CRISPR-Cas9-based genome editors and have potential use for *in vivo* gene editing.

200. Structure Derived Insights into the Similarities and Differences in Coagulation Factor Binding to Species C and Species D Adenoviruses

Michael A. Barry[1], Haley Mudrick[1], Shao-Chia Lu[1], Janarjan Bhandari[2], Mary E. Barry[1], Olivia Ma[2], Vijay Reddy[3]

[1]Mayo Clinic, Rochester, MN,[2]University of Minnesota, Austin, MN,[3]Hormel Institute, Austin, MN

Adenoviral (Ad) vectors are potent vectors for *in vivo* applications. However, Ads suffer from strong innate and adaptive immune responses that can start by the binding of host proteins to the surfaces of their virions in a serotype-specific fashion. For example, human species C human Ads bind vitamin K-dependent blood clotting factors FII and FX whereas most other serotypes do not. Conversely, all Ad serotypes can be bound by natural antibodies or neutralizing antibodies that can trigger complement activation, innate immune responses, and their destruction by macrophages and Kupffer cells. This problem of host protein binding to Ad virions was made more apparently by observations of vaccine-induced thrombotic thrombocytopenia (VITT) in Ad COVID-19 vaccines. It has been proposed that binding of another blood protein, platelet factor 4 (PF4), different adenoviruses surfaces can induce antibodies against PF4 to induce VITT. While VITT could theoretically occur with any Ad, the particular serotype of each Ad may influence the risk of this side effect because different proteins bind to different Ad serotype's hexon proteins. For example, blood clotting factors FII and FX bind human species C Ads, Ad5, Ad6 and Ad57 with affinities that are up to a 1000-fold higher than the affinity PF4 these viruses. In addition, the concentration of FX and FII in human blood is 1,000- and 10,000-fold higher than PF4, respectively. While FII and FX bind species C Ads, they do not bind other adenoviruses including species D Ad26 that has been used as HIV and COVID-19 vaccine. Given these variations in host protein binding to different Ad serotypes, we examined the interactions of PF4, FII, and FX to species D and species C Ads by cryo-EM. The Gla-domains of both FII and FX were observed binding to the exterior cavities of Ad5, Ad6, and Ad657 hexons primarily by interactions with hypervariable loops 5 and 7. Only the Gla-domain of FX could be observed at high (~3.7Å) resolution. In contrast, both the Gla and KR1 domains of FII was observed bound to all 3 viruses. Both the Gla its proximal EGF domain of FX was visible at lower resolution (10Å) and showed three equivalent binding modes that were consistent with the 3-fold symmetry of the hexon trimer. Docking of AlphaFold2 models of FX and FII into EM-densities suggests that both of their Gla-domains bind similarly in the hexon cavities. However, the different c-terminal regions of FII and FX modify the degree to which the two proteins shield the surface of hexon trimers. FII appeared to bind all three viruses equally well, while FX bound Ad5 and Ad657 viruses significantly better than Ad6. While FII and FX were readily observed by cryo-EM, PF4 binding was not observed on any adenovirus including Ad26 by this method. These data suggest that there are unique binding modes to how different highly abundant host blood proteins bind to the surfaces of different adenovirus serotypes. Understanding these natural interactions will allow these viruses to be engineered to increase the efficacy and decrease side effects of different Ad serotypes as vaccines, as gene therapies, or as oncolytic viruses.

201. Rational Design of a Detargeted Vesiculovirus Fusogen to Enable Targeted *In Vivo* Gene Delivery

Ronnie M. Russell, Debasish Boral, James I. Andorko, Bruce C. Schnepp, Timothy D. Culp, Philip R. Johnson
Interius BioTherapeutics, Philadelphia, PA

Current ex vivo autologous and allogenic CAR T cell approaches utilize wild type (WT) VSV-G pseudotyped lentiviral vectors to achieve high efficiency transduction of patient or donor cells. In vivo generation of CAR T cells is meant to circumvent complications with ex vivo approaches, such as limited accessibility and lengthy manipulation processes that can negatively affect the outcome of therapy; however, WT VSV-G cannot be used for in vivo approaches due to a broad tropism that is not limited to T cells. Our goal was to rationally design a fusogenic molecule to enable targeted in vivo delivery of a gene of interest. Previous work has shown that binding and fusion mediated by VSV-G are uncoupled processes[1]; thus, we reasoned the tropism of VSV-G pseudotyped vectors could be redefined by reducing the affinity of VSV-G for its native receptor (LDL-R) while simultaneously redirecting vector binding to a target molecule expressed by cells of interest. Using the available crystal structure of VSV-G bound to LDL-R[1], we visually scanned for residues in VSV-G whose side chains protrude toward the negatively charged contact residues in LDL-R. We then introduced negatively charged side chains at the identified sites in VSV-G to destabilize critical ionic interactions with its receptor. Substitution of isoleucine at position 182 with either glutamic acid or aspartic acid was sufficient to abolish the transduction by vector pseudotyped with the mutant glycoproteins. Providing a membrane-anchored scFv redirecting vector to target cells restored titers to within a log of WT VSV-G, indicating these mutations only impacted binding to LDL-R, but not fusogenic activity. Importantly, substitution of alanine at residue 182 did not have this effect, suggesting the mechanism is dependent on charge as designed. Cells transfected with the I182E mutant were not labeled by a soluble form of LDL-R (sLDL-R), confirming the reduced affinity to the native receptor. As a concern with using VSV-G based vectors is the reported sensitivity to complement, we also incorporated substitutions in VSV-G that have been shown to improve stability in human serum[2]. Reflecting the iterative nature of this fusogen's design, we dubbed this version Generation 2.1 or "Gen 2.1" for short. To further demonstrate specific retargeting, lentiviral vectors pseudotyped with the Gen 2.1 fusogen were produced and used to transduce CD7+ cells. As expected, vector pseudotyped with the Gen 2.1 fusogen alone did not effectively mediate transduction. When a plasmid encoding a binder specific to CD7 was included during vector production, infectivity titers were restored on CD7+ SupT1 cells, but not on the same cells in which CD7 was knocked out or a panel of CD7- B cell lines. Additionally, vectors pseudotyped with the Gen 2.1 fusogen were resistant to neutralization by sLDL-R, confirming the retargeting via the CD7 binder. These data suggest that the Gen 2.1 fusogen has potential to be used as a platform for targeted *in vivo* delivery. Leveraging industry standard manufacturing processes for WT VSV-G based lentivirus production, we have successfully manufactured Phase 1 clinical supplies of a CAR20 vector product (INT2104) made with Gen 2.1 fusogen and a CD7 binder to support a FIH study in oncology starting in 4Q2024. [1]Nikolic, J., et al. "Structural basis for the recognition of LDL-receptor family members by VSV glycoprotein." *Nature Communications* 9.1 (2018): 1029. [2]Hwang, B-Y., and D. V. Schaffer. "Engineering a serum-resistant and thermostable vesicular stomatitis virus G glycoprotein for pseudotyping retroviral and lentiviral vectors." *Gene Therapy* 20.8 (2013): 807-815.

202. Engineering Single-Cycle Measles Vector for CRISPR/Cas9 Gene Editing

Naga Sai Ramya Rallabandi[1], Brenna Sharp[2], Spencer Majerus[2], Sarriana (Ria) Hoffer[2], Ikeda Mia[2], Patricia Devaux[1,2]
[1]Mayo Graduate School, Rochester, MN,[2]Mayo Clinic, Rochester, MN

Clustered Regularly Interspaced Short Palindromic Repeats/CRISPR-associated 9 (CRISPR/Cas9) mediated gene editing has vast applications in basic and clinical research and is a promising therapeutic for several disorders. Our lab previously developed a non-integrating RNA virus, measles virus (MeV), as a single-cycle vector by replacing the viral attachment protein with the reprogramming factors, OCT4, SOX2, KLF4, and c-MYC for induced pluripotent stem cell generation (Rallabandi et al. 2022 and unpublished). Encouraged by the MeV reprogramming vector efficiency, in this study, we develop a single-cycle MeV vector to deliver gRNAs targeting specific human genes and Cas9 nuclease for efficient gene editing. We showed that the expression of both gRNA and Cas9 from a single MeV genome did not affect the propagation of the viral vector compared to a control MeV vector. We showed that the MeV editing vector achieved efficient on-target knock-out gene editing of a reporter (*mCherry*) and endogenous genes (*HBB* and *FANCD1*) in human cells via non-homology end-joining repair. Analysis of off-target sites for the gRNAs used to target *HBB* and *FANCD1* genes showed limited to no off-target in all samples tested. Finally, the MeV vector achieved up to 13% precise knock-in via homology-directed repair (HDR) using a single-stranded oligodeoxynucleotide (ssODN) donor. In conclusion, for the first time, we present a novel single-cycle MeV vector platform as a new and flexible platform for gene knock-out and knock-in modifications in human cells, capable of incorporating new editing technologies as they are developed.

203. Anellovectors, a Gene Delivery Platform Based on Commensal Human Anelloviruses, Have the Potential to Evade the Immune System and Deliver DNA Payloads to a Broad Range of Tissues in a Redosable Manner

George S. Bounoutas, Riana Pozsgai, Isabella Gold, Alexander Auld, Parmi Thakker, Hiral Gujar, Erin Ozturk, Maitri Trivedi, Tuyen Ong, Ashley Mackey, Chris Wright
Ring Therapeutics, Cambridge, MA

Anelloviruses are a highly diverse family of commensal ssDNA viruses that are a principal constituent of the human virome. These viruses have been found in many vertebrates and demonstrate broad tropism to multiple organs and tissues in humans. They are capable of evading induction of the humoral immune response, persist for many years, and do not appear to cause any pathology in humans. Though the mechanism of immune evasion is currently under investigation,

these properties make anellovectors (vectorized anelloviruses) an attractive candidate as a potentially redosable vector platform for gene therapy. An anellovirus originally discovered in a human subject was vectorized as a wild-type vector or to include the CMV.eGFP payload and has demonstrated broad tropism to multiple tissues in mice. Here, we compare the redosability of this anellovector (ANV.X) to AAV2, which has been shown to elicit an immune response in mice and patients. Mice were initially pre-dosed intravenously (IV) with either vehicle, ANV.X-WT, or AAV2-mCherry (dose-matched to ANV.X). After three weeks, mice were then re-dosed IV with ANV.X-eGFP or AAV2-eGFP (also dose-matched to ANV.X). Mice pre-dosed with AAV2-mCherry demonstrated fewer AAV2-eGFP DNA copies in liver, heart, lung, and kidney in comparison to mice pre-dosed with vehicle. This data suggests that the initial dose of AAV2 triggered an immune response which generated neutralizing antibodies against AAV2. In contrast, mice that were pre-dosed with ANV.X-WT demonstrated similar or greater ANV.X-eGFP DNA copies in all assayed organs as compared to mice pre-dosed with vehicle suggesting no neutralizing antibodies were raised against ANV.X. Current viral gene therapies cannot be re-administered if the initial dose was subtherapeutic due to immunogenicity. In addition, cell turnover dilutes therapeutic genes over time, causing waning clinical efficacy. A redosable gene therapy platform that evades the immune system, such as the Anellovector, has the potential to ensure sustained efficacy for patients suffering from a broad range of genetically-driven diseases.

204. Novel Self-Replicating RNA Vectors Broaden Therapeutic Window and Expand Use Outside of Vaccines

Darina Spasova, Shigeki Miyake-Stoner, Christian Maine, Melanie Olesiuk, Christine Domingo, Gaelle Picarda, Hunter Little, Emily Brand, Annie Chou, Jessica Sparks, Jacqueline Posy, Terrina Bayone, Thomas Goodman, Andrew Geall, Nathaniel Wang, Parinaz Aliahmad

Replicate Bioscience, Inc, San Diego, CA

Clinical applications using RNA technology have thus far been limited to vaccines for infectious disease and oncology. This constraint is due to the narrow therapeutic window for RNA technology as doses needed to achieve bioactivity are often nearing the maximum tolerated dose (MTD). Self-replicating RNA (srRNA) technology is a fully synthetic platform that allows for lower dosing due to the co-encoding of a viral replicase machinery that self-amplifies *in situ*. Using novel proprietary srRNA vectors, we have demonstrated enhanced bioactivity and safety, thus broadening the therapeutic window for applications outside of simple infectious disease vaccines.Higher bioactivity from these next generation vectors was exemplified by achieving protective antibody titers using picogram doses of vaccines in preclinical mouse studies using influenza as a model. Immunization with two doses as low as 1 picogram led to neutralizing antibody titers above the WHO protective threshold as tested by hemagglutination inhibition assay. In addition, a comprehensive cellular immune response, inclusive of polyfunctional CD8 and CD4 T cells, was also observed. Importantly, these ultra-low doses led to minimal reactogenicity *in vivo* demonstrating the broadening of the therapeutic window from optimized srRNA vectors. Implications of a broader therapeutic window is the ability to expand the utility of RNA technology outside of simple infectious disease vaccines. Specifically, bioactivity at lower doses allows us to express multiplex targets for complex vaccines in infectious disease or oncology. In addition, an increased therapeutic window, which translates into higher clinical doses and/or more frequent dosing without nearing a MTD, allows expanded use of RNA in protein replacement therapies currently inaccessible with traditional mRNA. Our current srRNA vectors have shown superior pharmacokinetic profiles to mRNA and circular RNA amenable to expression of proteins at biotherapeutic levels.

Liver Genetic Diseases

205. Correction of Ornithine Transcarbamylase Deficiency Using a Mutation-Independent CRISPR-Cas9-Mediated Targeted Integration Approach with Restoration of Liver-Wide Metabolic Zonation

Samantha L. Ginn[1], Fatemeh Doroudian[1], Caitlin W. Lucas[1], Erhua Zhu[1], Sile F. Yang[1], Beena Devanapalli[2], Anne H. Klein[3], Sharon C. Cunningham[1], Sophia H. Y. Liao[1], Joseph Vitale[1], Marti Cabanes-Creus[4], Leszek Lisowski[4], Ian E. Alexander[5]

[1]Gene Therapy Research Unit, Children's Medical Research Institute, Westmead, Australia,[2]NSW Biochemical Genetics Service, The Children's Hospital at Westmead, Westmead, Australia,[3]Australian e-Health Research Centre, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Sydney, Australia,[4]Translational Vectorology Research Unit, Children's Medical Research Institute, Westmead, Australia,[5]Gene Therapy Research Unit, Sydney Children's Hospitals Network, Westmead, Australia

Ornithine transcarbamlyase deficiency (OTC) is an X-linked urea cycle disorder that can lead to episodes hyperammonemia resulting in coma and death without therapeutic intervention. For urea cycle disorders, genome editing technologies represent a promising approach for permanent disease correction. This is of particular importance in the context of the growing pediatric liver where benefit may be lost in concert with liver growth when using vector systems such as recombinant adeno-associated virus (rAAV) vectors that are maintained predominantly as episomes. Major challenges associated with the use of genome editing technologies include achieving therapeutically effective levels of editing, particularly *in vivo*, avoidance of unwanted on- and off-target events and the inadvertent inactivation of hypomorphic target alleles. In addition, implementing universally configured, mutation agnostic, reagents circumvent the need to re-design new vectors for each individual patient mutation. As validation of our editing approach, we are targeting *OTC* as model locus with a high therapeutic threshold. Here we report efficient, deep-intronic, targeted integration into the *OTC* locus in both the murine liver and patient-derived primary human hepatocytes xenografted into the FRG mouse liver *in vivo*. This was achieved by using dual rAAV vectors to deliver both the CRISPR-SaCas9 editing machinery and a promoterless donor template for site-specific integration. Notably, in both wild-type and Otc-deficient mice, liver-wide metabolic zonation

was observed, consistent with on-target integration events that captured the native promoter to drive gene expression. Using optimally configured vector doses, we observed expression in greater than 80% of hepatocytes *in vivo*. Importantly, in treated Otc-deficient mice, the appearance of donor-derived transcripts, increased enzymatic activity and correction of their metabolic phenotype (elevated urinary orotic acid) was observed. In patient-derived OTC-deficient primary human hepatocytes engrafted into the FRG mouse, again we observed high levels of targeted integration, appearance of donor-derived transcripts and restoration of OTC expression. Collectively, these data demonstrate that targeted integration can be achieved in both the murine liver and primary human hepatocytes *in vivo* at levels that would provide benefit for even the most therapeutically challenging liver disorders.

206. Safe and Effective Liver Directed AAV-Mediated Homology Independent Targeted Integration in Mouse Models of Inherited Diseases

[1]TIGEM, Pozzuoli, Italy,[2]University Medical Center Freiburg, Freiburg, Germany,[3]University of Freiburg, Freiburg, Germany,[4]AAVantgarde Bio, Milan, Italy,[5]Tigem, Pozzuoli, Italy,[6]Fondazione Telethon, Pozzuoli, Italy,[7]Faculty of Medicine, University of Freiburg, Freiburg, Germany,[8]Medical Center – University of Freiburg, Freiburg, Germany,[9]Fondazione Telethon, Pozzuoli (Naples), Italy,[10]Medical Center - University of Freiburg, Freiburg, Germany,[11]Fondazione Telethon, Roma, Italy

Liver-directed gene transfer using adeno-associated viral (AAV) vectors holds promise for treating liver and systemic diseases. However, the non-integrative nature of AAV vectors limits their application to newborn livers which is necessary for treating conditions like early-onset inborn errors of metabolism.To overcome this shortcoming, we developed CRISPR/Cas9 AAV-mediated homology-independent targeted integration (HITI) of therapeutic transgenes at the 3' end of mouse Albumin locus which is highly expressed in hepatocytes.We show the effectiveness of AAV-HITI in two different mouse models of inherited diseases, Haemophilia A (HemA) and Mucopolysaccharidosis type VI (MPS VI) in which we achieve stable therapeutic levels of systemic proteins, even at low AAV doses. Moreover, we extensively characterised the landscape of HITI donor DNA integrations at the on-target, demonstrating partial AAV genome integrations as well as full length HITI donor DNA which is preferentially cleaved from the flanking ITRs as expected based on its design.In addition, within the 1-year follow-up no gross chromosomal rearrangements and negligible insertions/deletions events were found at off-target sites. In line with this, no evidence of hepatocellular carcinoma was observed. Finally, we show that AAV-HITI is effective also in adult MPS VI or HemA livers, at vector doses considered safe if translated to humans. Overall, our data support AAV-HITI as a potential therapeutic option for the treatment of those conditions which involve the liver as target tissue.

207. Correlation of Antigen Expression with Epigenetic Modifications After rAAV Delivery of a Hyperactive Human Factor IX Variant in Mice and Rhesus Macaques

Katja Pekrun[1], Calvin Stephens[1], Adriana Gonzalez-Sandoval[1], Aranyak Goswami[2], Feijie Zhang[1], Alice F. Tarantal[3], Grant Blouse[4], Mark A. Kay[1]

[1]Departments of Pediatrics and Genetics, Stanford School of Medicine, Stanford, CA,[2]Stanford School of Medicine, Stanford, CA,[3]University of California, Davis, Davis, CA,[4]Catalyst Biosciences, South San Francisco, CA

We sought to investigate long-term human coagulation Factor IX expression of a novel high-potency variant when delivered into mice and rhesus macaques and comparing transduction efficiencies using two AAV capsids. Different human FIX variant rAAV vectors packaged with the KP1 capsid were injected into hemophilic mice. As expected, the group of mice that had received vector expressing the hyperactive FIX variant showed ten- and two-fold enhanced specific FIX activity plasma levels when compared to wild-type and Padua huFIX injected mice, respectively. We next infused CpG-depleted human codon-optimized rAAV vectors packaged into the LK03 and the KP1 capsids into rhesus macaques and found that AAV-LK03 outperformed AAV-KP1 in terms of antigen expression and liver transduction. Two animals from each group showed sustained low-level huFIX expression at 3 months post-administration, while one animal from each group lost huFIX mRNA and protein expression. Nevertheless, the two macaques that had lost expression contained vector copy numbers in liver comparable to those from the other animals in the same group. We investigated if epigenetic differences of the vector episomes could explain the loss of transcription. We did not find any indications that CpG methylation within the rAAV promoter region had contributed to the repressed state of transcription. However, Cut&Tag experiments revealed that rAAV genome-associated histones in the two animals that had lost expression contained lower levels of activating histone marks in liver. When comparing rAAV genome-associated histone modifications in rhesus macaques to those in mice administered the same vector, the activating histone marks were starkly reduced for macaque-derived episomes. Differential epigenetic marking of AAV genomes may explain differential expression profiles in mice and rhesus macaques as well as the wide dose response variation observed in primates in both preclinical and human clinical trials.

208. Knock-Out, Tissue Specific Transgenic, and Knock-In Mouse Models of PCCB Deficiency Recapitulate of the Clinical Spectrum of Propionic Acidemia and Enable the First Successful Proof-of-Principial Gene Therapy Studies

Charles P. Venditti[1], Randy J. Chandler[2]

[1]NIH, Bethesda, MD,[2]National Institutes of Health, Bethesda, MD

Propionic acidemia (PA) is rare autosomal recessive metabolic disorder caused by defects in the mitochondrial localized enzyme propionyl-CoA carboxylase (PCC). The PCC enzyme is composed of six nuclear encoded α- and six β-subunits with causative variants in either of the *PCCA* or *PCCB* genes found at equal frequencies in the patients. Individuals with PA can suffer from poor growth, potentially lethal metabolic decompensations and cardiomyopathy despite current medical management, which has led to the pursuit of gene therapy as a new treatment option for patients. While murine models and genomic therapies have been published for PA caused by PCCA deficiency, there are currently no animal models of PCCB deficiency. To explore the pathophysiology of PA and generate a platform to test new therapies for PA, we have developed 5 new murine models of *PCCB* deficiency. CRISPR-Cas9 gene editing of the murine *Pccb* gene was used to create loss of function alleles: a 4 bp deletion in the 7th exon, and an 8 bp deletion in the 14th exon. Homozygous are designated $Pccb^{E14_4bpdel/E14_4bpdel}$ and $Pccb^{E7_8bpdel/E7_8bpdel}$. Both these alleles result in a frameshift and premature stop codon in *Pccb* gene and homozygotes manifest an immediate neonatal lethal phenotype accompanied by massive elevations of plasma 2-methycitrate and 3-hydroxypropionate (Table 1). Due to the severe lethality displayed by the homozygous Pccb knock-out mice, we designed a germline transgene to express the murine *Pccb* cDNA under the control of a muscle specific promoter ($Tg^{MCK\text{-}Pccb}$) to rescue the $Pccb^{E14_4bpdel/E14_4bpdel}$ mice. The resultant $Pccb^{E14_4bpdel/E14_4bpdel}$;$Tg^{MCK\text{-}Pccb}$ animals are rescued from neonatal lethality but perish by 2 months of age. $Pccb^{E14_4bpdel/E14_4bpdel}$;$Tg^{MCK\text{-}Pccb}$ mice have milder biochemical perturbations of plasma methylcitrate and 3-hydroxypropionate in comparison to the $Pccb^{E7_8bpdel/E7_8bpdel}$ mice but are severely growth retarded, very much like patients with PA, and only achieve ~ 50% of the weight of unaffected littermates at weaning. To generate mice with a late onset form of PA, we used CRISPR-Cas9 gene editing to knock-in a missense mutation noted in mildly affected patients, designated $Pccb^{MS}$, into the murine *Pccb* gene, and studied $Pccb^{MS/MS}$ homozygous and compound $Pccb^{MS/E7_8bpdel}$ mice. Both $Pccb^{MS/MS}$ and $Pccb^{MS/E7_8bpdel}$ mice display attenuated metabolic changes and less impaired growth than $Pccb^{E14_4bpdel/E14_4bpdel}$;$Tg^{MCK\text{-}Pccb}$ animals but experience lethal metabolic decompensation when fed an increased protein diet. To demonstrate the utility of these models to test new therapies, $Pccb^{E14_4bpdel/E14_4bpdel}$ were treated with AAV9.CAG.PCCB at a dose of 1e11 vg/pup at birth, which resulted in a significant increase in survival in comparison to untreated mutant controls ($p<0.01$). We also treated $Pccb^{E14_4bpdel/E14_4bpdel}$;$Tg^{MCK\text{-}Pccb}$ mice at weaning with a dose of 1e14 vg/kg with either AAV9.CAG.PCCB or AAV9.EF1a.PCCB vectors, which likewise resulted in a significant increase in survival and growth in comparison to untreated $Pccb^{E14_4bpdel/E14_4bpdel}$;$Tg^{MCK\text{-}Pccb}$ controls . These new murine models replicate the clinical and biochemical features of PA over wide clinical spectrum, spanning neonatal, juvenile, and late onset disease presentations, and can be used to test the effects of new genomic and small molecule therapies for PCCB deficiency.

209. *In Vivo* Lentiviral Gene Therapy for Arc Syndrome

Andrei Claudiu Cozmescu[1,2], Loukia Touramanidou[1], Sonam Gurung[1], Dany Perocheau[1], Yi-Ting Hu[1], John R. Counsell[3], Rajvinder Karda[4], Simon Waddington[4], Julien Baruteau[1,2,5], Giandomenico Turchiano[1], Paul Gissen[1,2,5]

[1]Great Ormond Street Institute of Child Health, University College London, London, United Kingdom,[2]NIHR Great Ormond Street Hospital Biomedical Research Centre, London, United Kingdom,[3]Research Department of Targeted Intervention, Division of Surgery and Interventional Science, University College London, London, United Kingdom,[4]EGA Institute for Women's Health, University College London, London, United Kingdom,[5]Metabolic Medicine, Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom

Arthrogryposis-renal dysfunction-cholestasis (ARC) syndrome is a severe autosomal recessive disorder caused by mutations in the *vacuolar protein sorting 33 homolog B* (*VPS33B*) gene. Patients with ARC syndrome exhibit characteristic symptoms such as congenital joint contractures, renal tubular acidosis, and neonatal cholestatic jaundice. The genetic anomaly in the hepatocytes impairs the secretion of various bile components, leading to liver fibrosis, cirrhosis, and terminal liver disease. While liver-directed AAV gene therapy is effective in treating adults with haemophilia, sustaining long-term AAV expression in young children's livers may be challenging due to the episomal nature of the vector. Recent studies on animal models suggest lentiviral vectors might be safe for *in vivo* use and can promote persistent transgene expression. Our group has previously presented the safety and efficacy of a liver-specific LV.*coVPS33B* lentiviral vector in treating ARC syndrome's liver phenotype when administered to neonate *Vps33b*(fl/fl)xAlfp-Cre mice. Here, we aimed to improve the therapeutic impact of the LV.*coVPS33B* lentiviral vector. The results have shown that the effects of the treatment have been enhanced by transient depletion of Kupffer cells with clodronate-encapsulated liposomes before LV.*coVPS33B* administration and prolonged selective pressure imposed on treated hepatocytes by administering a 0.25% cholic acid diet for 8 weeks to *Vps33b*(fl/fl)xAlfp-Cre mice. This regimen has normalised blood parameters of liver toxicity close to wild-type values. Given ARC syndrome is a systemic disorder, we have also developed an LV.Ubq.*coVPS33B* vector that can express the therapeutic gene in multiple tissues, by the use of a ubiquitous (Ubq) promoter. Assessing the safety of this vector in 9 months old *Vps33b*(fl/-)xAlfp-Cre mice treated as neonates with the LV.Ubq.*coVPS33B*, we have observed an increased incidence of hepatocellular carcinoma (3:10) compared to (0:10) observed in the safety analysis of the LV.*coVPS33B* vector. These malignancies are currently under investigation to better understand the causative mechanism. While the novel results build a stronger case for the efficacy of the liver-specific LV.*coVPS33B* therapeutic approach, they also emphasize the importance of safety screening for newly developed lentiviral vectors.

210. Sustained FVIII Expression with a Tolerable, Titratable, Fully Non-Viral Gene Therapy for Hemophilia A

Brian Truong, Khalid Hajj, Johannes Schwerk, Dongyang Zhang, Johnnatan Tamayo, Hua Wang, Alicia Davis, Lijun Huang, Gopi Vemuri, Kevin Johnson, Sang Jun Lee, Bernard Kok, Mu Li, Pranavanand Nyshadham, Fernando L. Espinoza, James Yen, Min Tong, Joseph Lucas, Bonnie Jacques, Joshua Rychak, Blair B. Madison

Poseida Therapeutics, San Diego, CA

Primary lines of treatment for Hemophilia A (HemA) involve clotting factor replacement or bi-specific antibodies, necessitating lifelong infusions with continued risk of breakthrough bleeds and chronic joint damage. Viral-based gene therapy faces multiple challenges with prevalent pre-existing immunity, liver toxicity, and waning expression over time. Thus, there remains a high unmet need for safe, effective, and durable therapies for HemA patients. Employing our piggyBac® DNA insertion system, we highlight our novel hepatocyte-targeted lipid nanoparticle (LNP) technology. With this technology we achieve robust durability and safety. For potential individualized correction in HemA patients we also demonstrate the ability to achieve near full correction (96%) in HemA mice through repeat dosing. Overcoming historical challenges in DNA delivery, our non-viral platform efficiently delivers DNA and mRNA, combining the super piggyBac (SPB) transposase mRNA with plasmid human FVIII (hFVIII) transposon DNA (P-FVIII-101). A single dose in adult HemA mice showed sustained hFVIII expression for over 12 months, unlike non-integrated controls that declined steadily, underscoring the need for integration for lasting expression. Additional delivery enhancements, through novel formulation excipients, provided additional benefits to DNA delivery. Such enhancements are critical for FVIII delivery, which has been hindered by large transgene size and DNA toxicity at high doses. This optimization led to a 10-fold increase in hFVIII expression, addressing both efficacy and safety concerns. Typical LNPs function through passive mechanisms that result in uptake by immune cells, resulting in an immune response and toxicity. To augment hepatocyte specificity, we added N-Acetylgalactosamine (GalNAc) targeting ligands to our co-encapsulated LNP formulation and demonstrated a 2 to 3-log reduction in pro-inflammatory serum cytokines (IL-6, IFNγ). We maintained high hFVIII expression and no elevation in transaminases (ALT, AST) after single and repeat dosing in immunocompetent animals. To further demonstrate the translatability of these stacked improvements to our non-viral gene integration platform for FVIII, we tested them in rat. Adult Sprague-Dawley rats and C57Bl6 mice were administered the same LNPs. Delivery to rats resulted in 50-75% hFVIII Ag expression, which translates to anticipated therapeutic correction. This validation of Poseida's non-viral platform components—including novel ionizable lipids, targeting ligands, and excipients—highlights the capabilities of the piggyBac DNA insertion system and our non-viral approach for stable FVIII transgene expression, with potential for re-dosing, providing proof-of-principle for an effective and durable therapy for Hemophilia A.

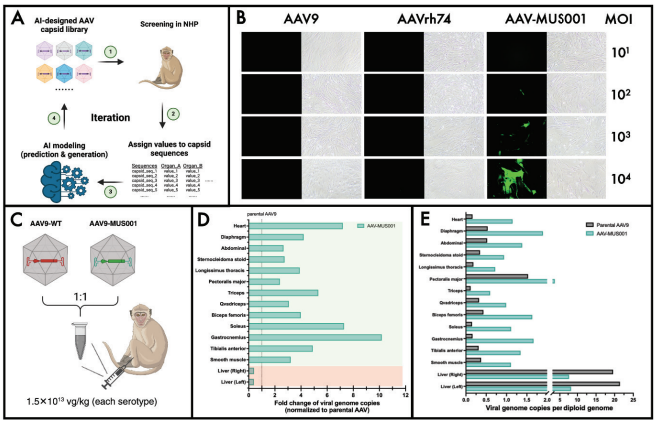
211. Pursuing Optimal Therapeutic Conditions through *In Vivo* Lentiviral Vector Gene Therapy for Primary Hyperoxaluria Type 1

Andrea Molinos Vicente[1,2], Aida García Torralba[1,2], Virginia Nieto Romero[1,2], Alessio Cantore[3,4], Michael Tadros[5], Eduardo Salido[6], Jose Carlos Segovia[1,2], María García Bravo[1,2]

[1]Biomedical Innovation Unit, Centro de Investigaciones Energéticas, Medioambientales y Tecnológicas (CIEMAT) and Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Madrid, Spain,[2]Unidad Mixta de Terapias Avanzadas. Instituto de Investigación Sanitaria Fundación Jiménez. (IIS-FJD, UAM), Madrid, Spain,[3]San Raffaele Telethon Institute for Gene Therapy (SR-Tiget), Milan, Italy,[4]"Vita-Salute San Raffaele" University, Milan, Italy,[5]DanausGT Biotech, Madrid, Spain,[6]Pathology Department, Hospital Universitario de Canarias, Universidad La Laguna. Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), La Laguna, Spain

Primary hyperoxaluria type 1 (PH1) is a rare autosomal recessive metabolic disorder caused by a deficiency in the liver enzyme alanine glyoxylate aminotransferase, encoded by the *AGXT* gene. PH1 patients suffer from oxalate overproduction, which can lead to end-stage renal disease and life-threatening oxalosis. Thirty percent patients show infantile onset. The only permanent curative treatment is double liver and kidney transplantation. *In vivo* lentiviral vector (LV) gene therapy has emerged as a promising strategy for liver monogenic diseases, especially for pediatric patients, taking advantage of its integrative capacity. We have previously reported that *in vivo* injection of a hepatocyte-specific LV encoding an enhanced AGT protein into *Agxt1* KO mice ($2x10^{10}$ TU/kg) showed a partial pathological phenotype reversion with an estimated transduction efficiency of 5% of hepatocytes. No further improvements were obtained with increasing doses. *In vivo* LV administration induces an IFN-alfa-mediated immune response that may interfere with LV hepatocyte transduction. The addition of a peri-injection immunosuppressive treatment to the *in vivo* LV protocol tripled the basal transduction efficiency to 15% in adult wild-type mice. Therefore, adult PH1 mice were intravenously injected with the LV expressing the enhanced AGT protein in combination with dexamethasone. These mice showed an increase in *AGXT* expression levels compared to mice treated with the LV alone, consistent with an improvement in transduction efficiency. Treated male *Agxt1* KO mice showed a 43% reduction in urinary oxalate production compared to untreated mice, reaching wild-type-like levels and a reduced number of animals developed renal damage in response to ethylene glycol treatment in both sexes. Due to the important infantile onset in PH1 together with the integrative capacity of LV, we tested whether this strategy could be efficiently implemented in juvenile mice toward application to pediatric context. *In vivo* LV injection in 3-week-old wild-type mice showed a significant improvement in hepatocyte transduction to 10%. Therefore, 3-week-old *Agxt1* KO mice were intravenously injected with the therapeutic LV and sacrificed six months later. We observed maintenance of LV integrations and detectable transgene expression, suggesting that transduced cells were maintained throughout the growth of the animals. In addition, we observed a partial pathological phenotype reversion with a 29% reduction in urinary oxalate levels in LV-treated animals compared to untreated animals together with a reduced

number of animals developing renal damage in response to ethylene glycol treatment. Immunosuppressive treatment in young animals is underway. In conclusion, we have demonstrated the therapeutic efficacy of an improved *in vivo* LV gene therapy protocol in the context of PH1, achieving a clinically relevant reversion of the pathological phenotype. Furthermore, the proposed *in vivo* LV treatment could potentially be implemented in pediatric patients. These results reinforce *in vivo* LV gene therapy as a viable option for PH1 patients.



Developing the Next Generation of Muscle-Targeted Gene Delivery Vehicles via AAV Capsid Engineering

212. An AI-Generated Novel AAV Variant Targeting Pan-Muscle and Sparing from the Liver in NHP

Heng Zhang[1], Qingkai Song[2], Hui Chen[1], Zhike Lu[1], Lijia Ma[2]

[1]Westlake Genetech, Hangzhou, China,[2]School of Life Sciences, Westlake University, Hangzhou, China

Background: As of the end of June 2023, the FDA has approved seven gene therapy drugs using adeno-associated virus (AAV) as a vector. While a single injection can cure severe genetic diseases, controversy arises due to the serious side effects caused by the high-dose and price. As a gene therapy vector, AAV typically requires a dose of more than 1×10^{14} vg/kg for intravenous administration to compensate for its insufficient tropism to the therapeutic targeting organs, significantly increasing the risks and production costs. Therefore, altering the in vivo tropism of AAV vectors is one of the most crucial bottlenecks in the current gene therapy development. **Results:** We developed an AI-assisted technology platform to evolve AAV variants from a wild-type parental serotype (AAV9) with altered tropism in non-human primates (NHP) **(Fig. A)**. Data from the original screening was used to train AI models to generate the input sequences for the next iteration of NHP screening. Capsids preferentially targeting various organs emerged from the AI-generated library, including muscle, heart, CNS, et al. We validated the superior transduction efficiency of the leading capsid with muscle tropism, AAV-MUS001, in human primary muscle in vitro with the comparison to the wild-type AAV9 and AAVrh74 **(Fig. B)**. The in vivo transduction efficiency and bio-distribution of AAV-MUS001 were further validated in NHP animals with 1.5×10^{13} vg/kg dose of intravenous injection with a head-to-head comparison to the wild-type AAV9 **(Fig. C)**. The data from this experiment showed an increase in pan-muscle transduction of AAV-MUS001 compared to the wildtype AAV9. This was coupled with decreased liver tropism **(Fig. D)**. Additionally, the overall bio-distribution of AAV-MUS001 shifted from the liver to the muscles, as indicated by the viral genome copies per diploid genome **(Fig. E)**. A set of cell surface receptors was identified from CRISPR screening, which was further validated to be responsible for the high transduction efficiency of AAV-MUS001 to muscles. **Conclusion:** In this study, we demonstrated the acceleration contribution of artificial intelligence in evolving capsids. The AI-generated leading capsid AAV-MUS001 exhibited promising clinical potential to develop gene therapy drugs, which must be effectively delivered to muscle and heart with a lowered livered transduction. This platform technology, together with the in vitro and in vivo validation data, shed light on the capsid evolution and effective, safe, and accessible gene therapies drug development.

213. An Integrin-Targeting AAV Developed by a Novel Computational Rational Design Methodology Presents an Improved Targeting to the Skeletal Muscle and Reduced Tropism to the Liver

Ai Vu Hong, Laurence Suel, Isabelle Richard

GENETHON, Evry, France

Adeno-associated virus (AAV) has shown potential as a gene therapy vector due to its efficiency in delivering transgenes and low toxicity. However, its effectiveness can be limited by non-optimal tissue targeting and accumulation in the liver. High doses are often required to achieve therapeutic efficacy, particularly in the treatment of muscular diseases where the target tissue represents half the body mass. Such doses can lead to severe adverse effects, including hepatotoxicity as seen in recent clinical trials. With the primary aim to lower treatment doses, we present here a novel methodology for AAV computational rational design targeting skeletal muscle, resulting in a new myotropic AAV variant. First, integrin alpha V beta 6 (AVB6) was selected from screening of potential receptors with high enrichment in skeletal muscle tissue compared to other organs. A liver-detargeting AAV capsid backbone, a hybrid between AAV-9 and -rh74 (AAV9rh74), was engineered to bind specifically to AVB6. Inspired by recent successes of various protein design studies, we modified the entire sequence and structure of variable region IV loop from its predicted 3D structure, in such a way that the designed capsids acquire the RGDLxxL/I motif structure with low estimated energy. It allows a high-affinity binding to AVB6 but remains stable, thus better AAV production. Five AAV variants from *in silico* design were experimentally tested. Compared to AAV9rh74, all designed AAVs showed better productivity, better binding to AVB6, and greater infectivity towards human differentiated myotubes and murine skeletal muscles in vivo while entering poorly in the liver. One notable variant, LICA1, greatly increases transgene expression at 16.6/25.0-fold greater in human myotubes, and murine skeletal muscle at 13.7/129.3-fold greater than AAV9 and AAV9rh74, respectively. We further examined its efficacy, in comparison with

AAV9, in delivering therapeutic transgenes in mouse models of Duchenne muscular dystrophy and limb-girdle muscular dystrophy R3 at a low dose of 5E12 vg/kg. At this dose, AAV9 is suboptimal where it can only infect 22.1-58.1% of total muscle fibers. In contrast, LICA1 effectively delivered and expressed transgenes in 74.8% myofibers in severely affected diaphragm, or at almost 100% in other tested muscles. Consequently, LICA1 corrected pathohistology by lowering centronucleation index and fibrosis, and restored global transcriptomic dysregulation. Compared to AAV9, the anti-capsid antibody in LICA1 one-month treatment in DMD mice halves and lower titers of neutralizing antibodies were observed in a small human serum cohort indicating a lower immunogenic profile. Furthermore, compared to other published state-of-the-art myotropic AAVs, LICA1 is better at production, and targets skeletal more specifically since accumulates significantly less in the liver. These results suggest the potential of our design method for AAV engineering and demonstrated the interest of the novel AAV variant for the gene therapy treatment of muscular diseases.

214. Directed Evolution of Novel MyoAAV Capsid Variants Enabling Effective Systemic Muscle Transduction While De-Targeting the Liver in Non-Human Primates

Saurav Seshadri, Simon Ye, Chelsey Tiger, Danielle Velez, Caroline Dang, Harvir Wetzel, Tamera Toland, Brian Ferguson, Mark Fielden, Nate Jones, Sharif Tabebordbar

Kate Therapeutics, San Diego, CA

Liver toxicity has been reported following systemic administration of multiple AAV gene therapies in clinical trials. Liver safety is particularly important for muscle-directed gene therapy, where high doses are required when using naturally occurring AAV capsids.We previously reported directed evolution of the MyoAAV class of capsids, which enables highly potent systemic gene delivery to skeletal muscles and heart across species. While the first generation of MyoAAV capsids were highly effective in transducing skeletal muscle and heart and thus lowering the efficacious dose, they resulted in similar number of vector genomes per diploid genome in the liver of non-human primates (NHPs) at equivalent doses of naturally occurring capsids (e.g., AAV8 and AAV9). To develop liver de-targeted capsid variants that also transduce muscles effectively, we used the DELIVER (Directed Evolution of AAV capsids Leveraging In Vivo Expression of transgene RNA) platform to simultaneously co-evolve liver de-targeting and muscle-targeting properties. Using this strategy, we successfully evolved capsid variants that functionally transduce skeletal muscles up to 20-fold and cardiac muscle up to 11-fold more effectively than AAV9, while also having 6-10-fold lower vector genomes in the liver when tested in a pooled experiment compared to AAV9 in NHPs. The top liver de-targeted muscle-tropic capsid variants from the pooled benchmarking experiment in NHPs outperformed external engineered capsid variants used in various muscle gene therapy candidates, as well as the first generation MyoAAV capsids. Manufacturability analysis also showed that these new capsids can be produced with similar yields and can be purified by affinity chromatography with similar efficiency as AAV9. We will also present a head-to-head comparison of one of our top liver de-targeted muscle tropic capsid from this directed evolution experiment compared to AAV9 in NHPs.

215. Identification of Natural Human-Derived AAV2 Variants with Muscle Tropic Properties in Non-Human Primate Screens

Fang Zhang[1], Mengtian Cui[1], Jackson McGowan[1], Dan Wang[1,2], Jialing Yang Liang[1], Guangping Gao[1,3], Phillip Tai[1,3]

[1]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[2]RNA Therapeutics Institute, UMass Chan Medical School, Worcester, MA,[3]Microbiology and Physiological Systems, UMass Chan Medical School, Worcester, MA

Muscle-targeting AAV gene therapy is hampered by high-dose-associated toxicity, immunogenicity, and nonspecific targeting to other organs. While methods like directed evolution and iterative rounds of selection from a complex library have recently produced several promising muscle-tropic capsids, the screening process has several inherent limitations, such as the potential for cross-packaging, capsid mosaicism, and collateral transduction. Furthermore, promising capsids discovered in this manner may have poor production yields. In this study, we sought to evaluate the ability of AAV capsid variants isolated from human tissues to robustly transduce skeletal muscles of non-human primates (NHPs) following direct muscle injections. The rationale for pursuing this route of delivery was to employ the muscle as a continuous and reversible therapeutic bio-factory, distributing secreted transgene products to diseased cells via the bloodstream or the affected muscle itself. One highlighted application is the use of rAAV to deliver genes encoding broadly neutralizing antibodies against deadly viruses causing pandemic infections. Despite being efficacious in rodent and non-human primate studies, anti-antibody responses in NHPs (and humans) present a significant hurdle, potentially hindering initial protection. To advance this strategy, we have screened our library of natural capsid for their potential to robustly transduce muscle tissues following direct intramuscular (IM) injection.Taking advantage of a relatively low complexity library, we have been employing a single variant to single barcoded non-coding RNA transgene production scheme to identify AAV capsids with favored tropism profiles. In the current study, we injected into cynomolgus macaques (n =3) a pool of ~100 AAV2 variants via intramuscular administration (vastus lateralis). After one month, tissues at the site of injection and livers were collected, and subjected to targeted amplicon-sequencing and analyses. Barcode counts among vector DNA and transgene transcripts revealed three variants that displayed strong transduction in muscle, resulting in over 400x higher levels than conferred by AAV2. We then evaluated their transduction performances in mice. The three variants showed over 12x better transduction than achieved by AAV2, and comparable to those of AAV1. This data suggests that the variants' remarkable transduction of muscle is exclusive to NHPs.In conclusion, our research has identified three AAV2 variants with enhanced transduction of non-human primate skeletal muscle. Subsequent investigations will focus on a detailed analysis, comparing the amino acid sequences of these high-performance variants, and delving into the mechanisms that

permit improved tropism in muscle. This effort aims to advance our understanding of AAV capsid biology and ultimately improve muscle targeting for gene therapy. G.G. and P.T. are corresponding authors.

216. Novel Neurotropic and Myotropic AAV Capsids for Translational Gene Therapy Applications

Irvin T. Garza[1], Vijayashree Ramesh[1], Hye Ri Kang[1], Erik A. Lykken[1], Mehmet Takar[1], Matthew C. Rioux[1], Ashwani Kumar[1], Peter Kunach[1], Ruhar Singh[1], Daniel J. Kieffer[1], Cynthia B. Trygg[2], Chao Xing[1], Lukasz Joachimiak[1], Stephen Braun[2], Steven J. Gray[1]

[1]UT Southwestern Medical Center, Dallas, TX,[2]Tulane National Primate Research Center, Covington, LA

Adeno-associated viral (AAV) vectors are generally safe and effective gene delivery vehicles. Hundreds of capsids have been identified and engineered through various means, but AAV9 remains a dominant vector with superior properties to treat neurological, neuromuscular, and muscular diseases, as demonstrated with Zolgensma, one of the first FDA approved gene therapies. While clinical trials continue to show success utilizing AAV capsids, efficiency and specificity of AAVs continue to pose a major caveat of their successful use. Manufacturing costs remain a major barrier to the translational use of AAV, and high doses of AAV particles or unfavorable biodistribution can also result in liver and DRG toxicity. These issues can be addressed with more efficient and better targeted capsid technology. We generated a novel AAV9-based library using random mutagenesis targeted to multiple specific regions across the entire capsid gene. We administered our libraries systemically (IV) and directly CNS-targeted by lumbar intrathecal (IT) administration, to mice and non-human primates (NHPs). To efficiently identify capsids with improved transduction to the CNS, we used single molecule real-time (SMRT) sequencing of capsid amplicons derived out of isolated nuclei from several tissues of the CNS and peripheral organs. To guide our hit selection for downstream validation and characterization, we developed a custom bioinformatics pipeline to analyze our large datasets and utilized computational protein modeling tools. Our lead capsid variant harbors two amino acid alterations in respect to AAV9 that are located in two distinct variable regions of the CAP gene, which was enriched following injection in both mice and NHPs. Our characterization of this lead capsid, as well as other variants, is ongoing. The lead candidate has significantly higher production yields compared to AAV9. Initial in vitro characterization, compared to AAV9, shows that in Lec2 cells, it has reduced cell surface binding kinetics, but greater overall binding capacity. It shows superior transduction, up to 6-fold of all immortalized mouse and human cell lines and iPSC-derived primary human cells including SH-SY5Y, Neuro-N2A, HEK293, HELA, induced atrial myocytes, rat ventricular myocytes, mature human cardiomyocytes, and mature human cortical neurons. We also highlight the significance of biophysical and biochemical alterations to the capsid surface in regards to viral stability (pH 7- pH 4) and zeta potential, which suggest mechanisms for increased manufacturability and decreased propensity for particle aggregation. In vivo we demonstrate notably and significantly improved transduction to the CNS and several muscle tissues in mice by either IT and IV administration. The transduction pattern was mapped in detail using two-photon tomography of the mouse brain from both IT and IV injected mice compared to AAV9. We leveraged machine learning methodologies to aide in further characterizing the molecular mechanism of action. Finally, to verify structural differences, we resolved the structure using Cryo Electron Microscopy. In summary, our novel lead candidate has enhanced manufacturability, and improved transduction in vitro and in vivo while retaining AAV9's ability to spread throughout the CNS. As we continue to collect data on this lead candidate as well as other novel capsid variants, our results highlight the advantages of whole capsid engineering and how we can utilize basic AAV biological findings to further generate novel AAVs. While our initial library screen in mice and NHPs suggests the enhanced performance of these variants across species, studies are ongoing to address this specific question.

217. An AAV Capsid Programmed to Bind Human and Macaque Receptors Mediates Enhanced Gene Delivery to the CNS and Skeletal Muscle *In Vivo*

Jason Wu, Nuria R. Botticello-Romero, Ken Y. Chan, Chin-Yen Lin, Qin Huang, Thomas Beddow, Pamela Brauer, Yujia A. Chan, Benjamin E. Deverman

Broad Institute of MIT and Harvard, Cambridge, MA

Gene therapies for multisystem disorders require efficient gene delivery to many organs. However, natural adeno-associated viruses (AAVs) have limited extrahepatic tissue tropisms, and capsid engineering has largely focused on targeting specific organs such as the central nervous system (CNS), liver, retina, or muscle. To target multiple organs, we used our recently described receptor-targeting platform to target peptide-modified AAV9 capsids to a human receptor that is broadly expressed across diverse cell types, including the CNS and muscle. These receptor-targeting capsids exhibited enhanced binding and transduction of cells in transgenic mice that expressed the human receptor. Two of the capsids, BI-TBA1 and BI-TBA2, efficiently transduced the CNS to an extent comparable to AAV-PHP.eB, a mouse CNS-targeting capsid, when intravenously administered to mice overexpressing the human receptor in the brain microvasculature (Fig. 1A). This enhanced tropism was absent in transgenic mice treated with wild type AAV9 or in mice not expressing the human receptor. When BI-TBA1 was intravenously administered to transgenic mice ubiquitously expressing the human receptor, it achieved substantially enhanced CNS and muscle transduction compared to wild type mice or transgenic mice injected with AAV9 (Fig. 1B). BI-TBA1 was also dramatically de-targeted from the liver compared to AAV9, even in animals where the human receptor was ubiquitously expressed (Fig. 1B). Notably, we demonstrated that BI-TBA1 can more efficiently transduce cells that express human or macaque, but not mouse, orthologs of the targeted receptor (Fig. 1C). Our findings show that BI-TBA1 has the potential to be a cross-species receptor-targeting AAV that can mediate enhanced in vivo gene delivery in a receptor-dependent manner. Based on the broad expression of the receptor in humans, BI-TBA1 and similar capsids may mediate enhanced gene delivery to multiple organs after systemic administration.

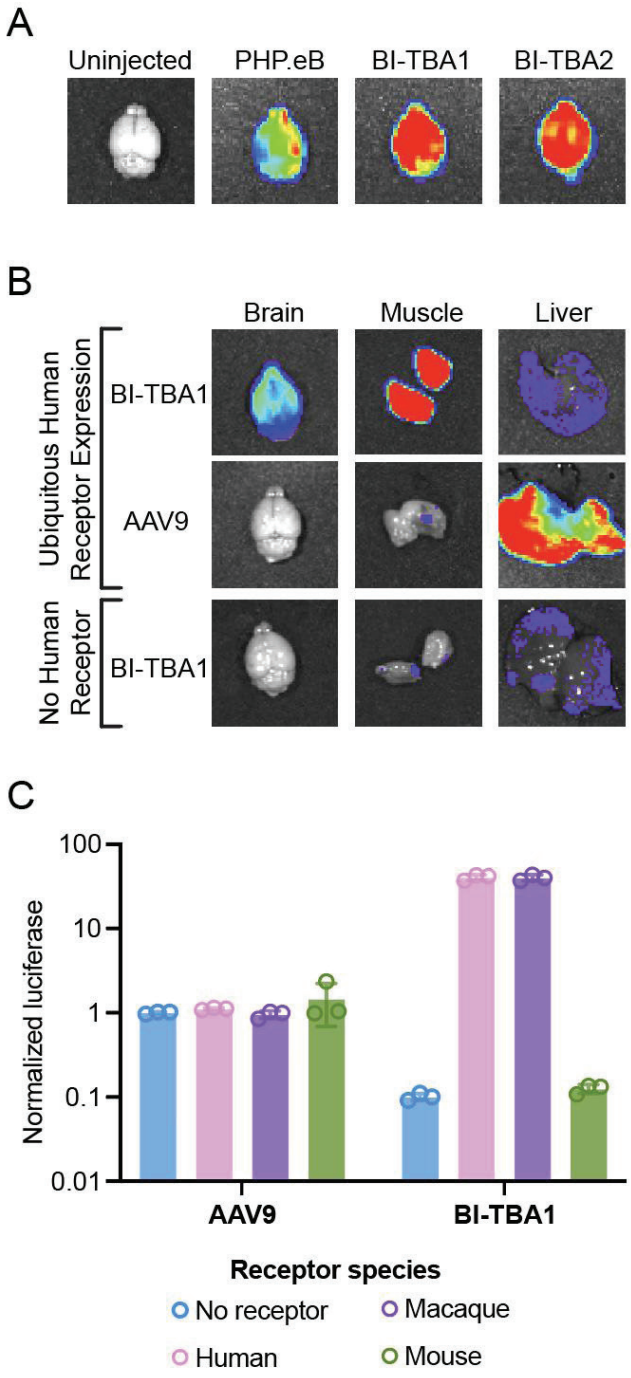


Figure 1. Human receptor-targeted AAVs efficiently transduced the brain and muscle but were de-targeted from the liver in transgenic mice. (A) Representative images show the luciferase signal in brain tissue from transgenic mice expressing the targeted human receptor in the brain vasculature injected with ssAAV-CAG-NLS-mScarlet-P2A-Luciferase-SV40pA packaged into human receptor-targeting capsids (BI-TBA1 or BI-TBA2) or AAV-PHP.eB. (B) Representative images show the luciferase signal in brain, muscle, and liver tissue from wild type mice or transgenic mice ubiquitously expressing the human receptor that were injected with BI-TBA1 or AAV9. (C) BI-TBA1 transduced CHO cells stably expressing the human or macaque orthologs of the targeted human receptor more efficiently than AAV9.

218. Retargeting of AAV Using Bispecific Antibodies

Chun Wai Yip[1], Tri Nguyen[2], Valerie Le Rouzic[3], Naveen Khan[3], Laith Zaki Alyass[1], Michael Golabek[1], Iryna Labinskyy[1], Kristen Tramaglini[4], Michael Stec[3], Yang Shen[2], Christos Kyratsous[1], Sven H. Moller-Tank[1]

[1]Regeneron Genetic Medicines, Regeneron, Tarrytown, NY,[2]Bispecifics, Regeneron, Tarrytown, NY,[3]Muscle & Metabolism, Regeneron, Tarrytown, NY,[4]Research Program Management, Regeneron, Tarrytown, NY

Adeno-associated virus (AAV)-based gene therapies offer potential treatments for a wide range of genetic diseases through the delivery of therapeutic cargo that correct or replace defective genes. However, effective delivery of AAV to peripheral tissues with natural serotypes remains a challenge and often requires very high doses that carry risks of cardiac and liver toxicity. To address this, Regeneron has developed platforms to target AAV to specific tissues using antibodies. Antibodies can bridge AAVs to target receptors specifically expressed on cells and tissues of interest, thereby enhancing AAV binding and uptake. When combined with capsid mutations to ablate glycan binding, significant detargeting from liver can be achieved, thereby improving the safety profile. Targeting receptors for which expression is conserved across species also preserves translatability of this approach from small animal models to NHPs and humans. Previously, we demonstrated AAV targeting to CNS and muscle with our covalent antibody-retargeting platform using Transferrin receptor 1 (TfR1) and calcium voltage-gated channel auxiliary subunit gamma 1 (CACNG1) as target receptors. We have validated these receptors for AAV targeting in humanized mice, diseased mice, and non-human primates. In parallel to the successful engineering of our covalent antibody-AAV platform, we have developed a platform to target these receptors with anti-AAVxCACNG1 and anti-AAVxTfR1 bispecific antibodies. As of today, there has been very limited use of bispecifics to target therapeutics *in vivo*. With intensive screening of antibodies, development of novel antibody formats, and identification of robust targeting receptors, we have engineered bispecifics capable of effective AAV targeting to CNS and skeletal muscle in mice. By incubating our bispecifics with AAV prior to administration, AAV:antibody complexes can achieve greater than 10-fold increased on-target transduction as compared to AAV alone. Enabled by our broad serotype binding anti-AAV arms, the same bispecific can similarly improve transduction of multiple different serotypes. This represents a significant milestone for the bispecific targeting approach. Importantly, this platform has the unique property of being "plug and play" and can be readily combined with existing AAV programs to improve on-target transduction efficacy.

Exosomes, Virus like Particles, and LNPs

219. Durable DNA-Based Gene Therapy Using the Non-Viral Fusogenix Proteolipid Vehicle Platform

Douglas Brown[1], Arun Raturi[1], Ping Wee[1], Prakash Bhandari[2], Amirali Bukhari[2], Maryam Hejazi[1], Jitendra Kumar[2], Roy Duncan[3], John Lewis[2]

Genetic medicines hold great promise to treat a wide array of diseases, yet success in the clinic has been hindered by limitations in the tolerability, biodistribution, scalability, and immunogenicity of current delivery platforms. We developed a novel delivery platform that overcomes these limitations by combining aspects from viral and non-viral platforms. The Fusogenix™ proteolipid vehicle (PLV™) incorporates fusion-associated small transmembrane (FAST) proteins isolated from fusogenic orthoreoviruses into a well-tolerated lipid formulation using a scalable microfluidic mixing approach. Incorporation of FAST protein into an optimized lipid formulation was found to significantly increase the expression of plasmid DNA (pDNA) *in vitro* and *in vivo*, without accompanying increases in toxicity. Utilizing the FAST-PLV platform for systemic delivery of pDNA, we confirmed successful pDNA delivery to numerous extra-hepatic tissues, such as muscle, lungs, and kidneys, in both murine and non-human primate models. This led to significant gene expression, as confirmed via histological examination and PCR analysis. To establish a suitable benchmark, we compared the systemic delivery of pDNA to a clinically approved lipid nanoparticle (LNP) formulation. The FAST-PLV platform displayed exceptional tolerability, without displaying any signs of liver toxicity or elevated cytokine levels that were observed with the LNP formulation - all without sacrificing pDNA expression. Importantly, the FAST-PLV platform displayed low immunogenicity and sustained efficacy, establishing it as an ideal candidate for durable gene therapy approaches. Here we report two gene therapies whereby pDNA vectors encoding follistatin (pDNA-FST) and leptin (pDNA-Lep) are encapsulated and delivered systemically using the FAST-PLV platform. A single intravenous injection of wild-type mice with pDNA-FST increased circulating follistatin levels, leading to significant enhancements in hindlimb grip strength and body weight three months post-injection. Eight months after pDNA-FST administration, post-mortem analysis confirmed notable gains in muscle mass compared to control animals. Similarly, intravenous injection of leptin-deficient mice with pDNA-Lep resulted in a sustained increase in circulating leptin levels, extending beyond a three-month duration. This was associated with significant improvements in body weight and metabolic function relative to control animals. The favorable activity and safety profile of the FAST-PLV platform defines a new standard for redosable gene therapies and genetic medicines.

220. Engineered Virus-Like Particles for Transient Delivery of Prime Editor Ribonucleoprotein Complexes *In Vivo*

Meirui An[1,2,3], Aditya Raguram[1,2,3], Samuel W. Du[4,5], Samagya Banskota[1,2,3], Jessie R. Davis[1,2,3], Gregory A. Newby[1,2,3], Paul Z. Chen[1,2,3], Krzysztof Palczewski[4,5,6,7], David R. Liu[1,2,3]

[1]Merkin Institute of Transformative Technologies in Healthcare, Broad Institute, Cambridge, MA,[2]Department of Chemistry and Chemical Biology, Harvard University, Cambridge, MA,[3]Howard Hughes Medical Institute, Harvard University, Cambridge, MA,[4]Gavin Herbert Eye Institute, Center for Translational Vision Research, Department of Ophthalmology, University of California, Irvine, CA,[5]Department of Physiology and Biophysics, University of California, Irvine, CA,[6]Department of Chemistry, University of California, Irvine, MA,[7]Department of Molecular Biology and Biochemistry, University of California, Irvine, CA

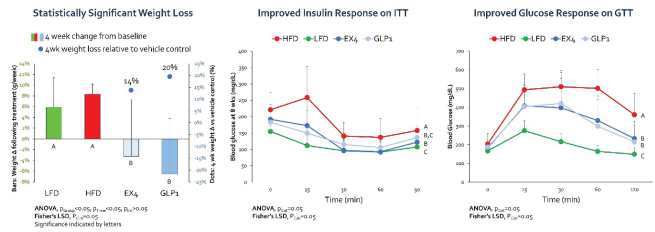
Prime editing enables precise installation of genomic substitutions, insertions and deletions in living systems. Efficient in vitro and in vivo delivery of prime editing components, however, remains a challenge. Here we report prime editor engineered virus-like particles (PE-eVLPs) that deliver prime editor proteins, prime editing guide RNAs and nicking single guide RNAs as transient ribonucleoprotein complexes. We systematically engineered v3 and v3b PE-eVLPs with 65- to 170-fold higher editing efficiency in human cells compared to a PE-eVLP construct based on our previously reported base editor eVLP architecture. In two mouse models of genetic blindness, single injections of v3 PE-eVLPs resulted in therapeutically relevant levels of prime editing in the retina, protein expression restoration and partial visual function rescue. Optimized PE-eVLPs support transient in vivo delivery of prime editor ribonucleoproteins, enhancing the potential safety of prime editing by reducing off-target editing and obviating the possibility of oncogenic transgene integration.

221. New Biological Insights into Extracellular Vesicle Associated AAV Help Improve Vector Yield and Provides Rational for Intraluminal AAV Packing

Ming Cheng[1], Demitri de la Cruz[1], Carrie Ng[1], Zachary Elmore[2], Aravind Asokan[2], Casey A. Maguire[1]

[1]The Massachusetts General Hospital, Charlestown, MA,[2]Duke University, Durham, NC

Introduction. Extracellular vesicle-associated adeno-associated virus vectors (EV-AAV) represent a unique population of vectors generated during production in 293 cells, in contrast to conventional non-enveloped AAV capsids. Several studies have provided experimental evidence that EV-AAV provides desirable gene delivery aspects such as greater resistance to antibody neutralization and transduction of organs and tissues *in vivo* in mice. Despite these promising data, there is a great deal of characterization of the EV-AAV system that needs to be performed. Free conventional AAV vectors co-isolating with EV-AAV has hampered the definition of accurate yields and functional activity of EV-AAV. **Results.** Here we use an optimized density gradient to answer some outstanding questions regarding EV-AAV characteristics, as well as using it to assess optimization of the production system.



Using a variety of molecular biology and biochemistry methods, we determined that gradient fractions 1-6 contained EV-AAV and fractions 7-10 conventional AAV. First, we quantitated the percentage of AAV genomes on the gradient were in the EV-AAV fractions of AAV serotypes 1, 2, 5, 6, and 9. We found the average value ranged from 2.4% (AAV5) to 11.95% (AAV6). AAV6 and AAV9 had the highest total yields of genomes in the EV-AAV fractions. Next, we assessed whether intraluminal EV-AAV9 could mediate functional transduction of cells (as opposed to AAV9 bound to the surface of EVs, or co-isolating free AAV9 capsids). To do this we performed an immunoprecipitation using an anti-AAV9 antibody conjugated to magnetic beads. Interestingly, we observed that approximately 20% of AAV genomes in the EV-AAV9 pooled fractions were resistant to AAV9-pulldown, suggesting a substantial portion of EV-AAV9 are intraluminal (with no bound AAV on the EV surface). To understand if these membrane-encapsulated vectors could transduce cells and resist antibody neutralization we performed neutralization assays using intravenous immunoglobulin (IVIg) and HeLa cells. We compared transduction in the presence or absence of IVIg with conventional AAV9, purified EV-AAV9, and EV-AAV9 with all surface-bound or free AAV removed by anti-AAV9 pulldown (ultra-pure EV-AAV9, UP-EV-AAV9). Interestingly, we found that in the absence of IVIg, UP-EV-AAV9 gave slightly higher (1.3-fold) transduction efficiency to EV-AAV9 and 2.5-fold higher transduction efficiency than conventional AAV9. UP-EV-AAV9 was similarly resistant to antibody neutralization to EV-AAV9 and much more resistant (6-fold at a 1:500 dilution of IVIg) to conventional AAV9. Finally, we tested whether heterologous expression of membrane associated accessory protein (MAAP) from AAV8 (MAAP8) with an AAV9 Cap (AAV9 MAAP null) production system would alter yields of EV-AAV9. Interestingly, we found that MAAP8/AAV9 Cap increased yields of EV-AAV9 by 3-fold compared to the cis-expression of AAV9 Cap/AAV9 MAAP. **Conclusions.** Gradient purification allowed us to accurately quantitate EV-AAV and conventional AAV yields in producer cell media. Our anti-AAV9 pulldown assay suggests that AAV9 capsids inside EVs are functional at transduction and therefore do not require AAV9 on the EV surface to mediate transgene expression. The antibody neutralization data also suggests that surface bound AAV9 capsids are not required for antibody evasion by EV-AAV as UP-EV-AAV9 was similarly resistant to IVIg as EV-AAV9. Thus, strategies aimed at increasing AAV packing inside EVs are warranted. The experiments with heterologous expression of MAAP8 suggest that yields of EV-AAV9 can be improved using this approach. In sum, these data provide important information for the further development of the EV-AAV vector system.

222. Development of a First-in-Class Adjustable Dose Gene Therapy Platform and its Application to the Treatment of Type 2 Diabetes and Obesity

Alexei Goraltchouk[1], Jared Lourie[2], Judith Hollander[1], Francesco Luppino[1], Alexey Seregin[1], Kai Zou[2]

[1]Remedium Bio, Inc., Needham, MA,[2]University of Massachusetts Boston, Boston, MA

Introduction: Despite enormous therapeutic potential, gene therapy is limited by an inability to adjust the dose following initial administration, high cost, antigenicity, and systemic toxicity. To overcome these challenges, we developed the first dose adjustable gene therapy platform with optimized specificity, localization, biocompatibility, and cost profile. The purpose of the study was to examine the efficacy of the new gene therapy and its application in a mouse model of Type 2 Diabetes (T2D). **Methods:** A novel, lipid nanoparticle (LNP) delivery vector was designed and characterized by dynamic light scattering for size, zeta potential, and polydispersity. System transfection efficiency and cytocompatibility was assayed *in vitro* using primary human adipocytes and preadipocytes. Biodistribution was characterized by in vivo imaging (IVIS), qPCR, and immunohistochemistry in C57BL/6N and B6N-*Tyr*$^{c\text{-}Brd}$/BrdCrCrl albino mice received subcutaneous injections of LNP. Durability, immunogenicity, and dose adjustability were confirmed via bioluminescent reporter transgene quantification. Efficacy was confirmed in a high fat diet (HFD) and low-dose (40mg/g BW) streptozotocin (STZ) induced T2D model by quantifying body weight, food intake, insulin sensitivity, and glucose tolerance following treatment with LNP-DNA-Exenatide or LNP-DNA-GLP1 relative to vehicle controls. **Results:** The optimized system demonstrated high transfection efficiency of primary human adipocytes and pre-adipocytes, reaching 81.3% +/-8.3% without compromising cytocompatibility. The vector was able to efficiently encase and deliver a broad range of genetic cassette sizes (1,871-6,203 bp) without impacting critical physico-chemical parameters including size, zeta potential, and polydispersity. Durable, localized, and adipocyte-specific expression was observed *in vivo* over 6 months, with no detectable transgene in the liver, heart, spleen, or kidney. Transgene expression was adjustable using several physical and pharmacological means, including cryolipolysis, focused ultrasound, and an inducible suicide gene system. A single treatment regimen expressing Exenatide or GLP1 produced pronounced weight loss, improved insulin response, and glycemic control in T2D mice relative to baseline and vehicle control. **Conclusion:** We report, for the first time, the development of a novel, ultra-low-cost, dose adjustable gene therapy platform and its application to the treatment of type 2 diabetes and obesity in a rodent model of disease.

223. Exosome-Mediated Intracellular Delivery of Arginase 1: A Potential Application for the Treatment of Arginase 1 Deficiency

Li-En Hsieh, Mafalda Cacciottolo, Michael LeClaire, Christy Lau, Kristi Elliott, Minghao Sun

Capricor Therapeutics, San Diego, CA

Arginase 1 deficiency (ARG1-D) is a rare genetic disorder caused by the loss of arginase 1 (Arg1), the final enzyme in the urea cycle. Hepatocytes of ARG1-D patients are impaired in converting ammonia into urea, resulting in elevated arginine and ammonia in blood and cerebrospinal fluid, which leads to progressive neurological symptoms. Current therapeutic strategies mainly focus on managing the plasma

arginine and ammonia but the long-term outcomes remain poor. Currently, there is no approved treatment specific for ARG1-D available in the United States. Exosomes, small extracellular vesicles involved in cell communication, are emerging as a powerful therapeutic vehicle. Using Capricor's Stealth-X™ platform, human Arg1 enzyme was engineered for expression on exosome membrane with either intra- or extra-exosomal orientation. The produced Arg1-exos were evaluated for their in vitro functionality as a disease-specific approach for the treatment of ARG1-D. Incorporation of Arg1 protein into the exosomes was confirmed by flow and Jess Western Blot. Regardless its localization on the exosome membrane, Arg1 was biologically active and able to convert arginine into urea. Surprisingly, nanograms of Arg1 delivered by exosomes were as potent as micrograms of human recombinant Arg1 protein. In addition, engineered exosomes carrying intra-exosomal Arg1 were capable of delivering Arg1 protein into 293F and HepG2 cells in a time and dose-dependent manner, contrary to human recombinant Arg1 protein alone. The data suggest that Arg1 exosomes were able to not only catalyze arginine efficiently at a lower dose but also protect the Arg1 protein to be delivered into target cells and retain its enzymatic activity in vitro. Taken together, Stealth-X™ platform engineered Arg1 exosomes have the potential to serve as an enzyme replacement therapy to deliver Arg1 to the target cell, the hepatocytes, and possibly have broader clinical benefits for the ARG1-D patient. The in vivo activities of Arg1 exosomes are currently under evaluation.

224. Engineering Endogenous Loading Methods for Therapeutic RNA Cargo into Extracellular Vesicles

Steven M. Jay

Fischell Department of Bioengineering, University of Maryland, College Park, MD

Extracellular vesicles (EVs) are an exciting platform for the delivery for a variety of therapeutic RNAs, but a major limitation is their low level of native RNA content. Strategies to improve RNA loading into EVs have been heavily investigated, as doing so would improve efficacy and reduce the need for repeated dosing, thus limiting the potential for immunogenicity and increasing the safety profile. Initial investigations of exogenous approaches such as electroporation or sonoporation have been expanded in recent years to include endogenous strategies that involve genetic engineering of EV producer cells. These latter methods are expected to be more scalable and cost-effective, but it has been difficult to match the effectiveness of exogenous loading to date. Our group has pursued development of novel endogenous loading methods across the spectrum of therapeutic RNAs, with successful adaptations for both small RNAs such as microRNAs (miRNAs) as well as for long non-coding RNAs (lncRNAs). With respect to lncRNAs, we have shown that RNA affinity sequences can be effectively adapted to increase EV loading of these large molecules. We have successfully delivered lncRNA HOTAIR and demonstrated increased efficacy in vivo in a wound repair model and we have further refined our approach to improve loading by >200 fold over a simple transfection approach. We have further demonstrated that this benefit can be retained for a wide variety of lncRNAs, including CARINH which we are currently testing in an animal model of colitis. With respect to miRNAs, we have engineered the microRNA biogenesis pathway for enhanced EV loading of miR-146a-5p by manipulating its interactions with the miRNA biogenesis enzymes RNA Polymerase, Drosha, Exportin-5, Dicer, and Ago2. We found that independence from interaction with either Dicer or Drosha (but not both) enabled increased EV localization of miR cargo. We also showed that altering the non-seed nucleotide sequence of miRs to allow for efficient transcription under the U6 promoter preceded by a cytomegalovirus (CMV) enhancer in an expression plasmid increases EV miR loading. Overall, these advances bring endogenous loading of cargo into EVs closer to parity with exogenous methods and generally increase the translational potential of EVs.

225. Utilizing the Endogenous NF1 Promoter for Widespread Cell Specific Expression

Rrita Daci[1], Simon Wentworth[2], Tyler Mola[3], Ana Rita Batista[2], Miguel Sena-Esteves[2]

[1]Neurosurgery, UMass Chan Medical School, Worcester, MA,[2]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[3]Neurology, UMass Chan Medical School, Worcester, MA

Introduction: Neurofibromatosis Type 1 (NF1) is among the most common human monogenetic diseases. These patients suffer from benign and malignant tumors, namely neurofibromas, gliomas, and malignant peripheral nerve sheath tumors (MPNST), among other cancers and diseases. While the monogenetic nature of NF1 makes it a good candidate for gene replacement therapy, there has been a paucity in its development for a variety of reasons. First, the NF1 coding sequence is ~8.5 kb, vastly exceeding the packaging capacity of adeno-associated virus (AAV) vectors. Secondly, neurofibromas are diffusely distributed throughout the body and arise from Schwann cells, which reside inside the avascular endoneurium making access of AAV to the cells challenging. Thirdly, neurofibromatosis affects patient's cerebrovasculature, as exemplified by the higher incidence of Moya-Moya in this group, and affects patients neurocognitive state, as exemplified by the higher presence of intellectual disabilities in these patients. Previous data in the literature has shown that the ubiquitously used Cag promoter is weak or non-functional in Schwann cells after systemic delivery of AAV9 vectors. In contrast, the rat P0 (from *Mpz* gene) promoter in AAV9 drives high efficiency gene expression in peripheral nerve by systemic administration. **Methods:** To overcome the obstacle associated with cell specific targeting and to better target both Schwann cells and neurons, the Sena-Esteves lab has analyzed publicly available single cell ATACseq data to identify regions of open chromatin with exceptionally high homology in NF1 genes across species. We have selected two sequences that incorporate human sequences with high homology to the mouse gene and identify them hereafter as NF1pL (long) and NF1pS (short). Ideally, we would use a promoter capable of driving gene expression in both Schwann cells and elsewhere in the body to mimic the ubiquitous expression profile of the NF1 gene. Five AAV9-GFP vectors were created utilizing the Cag, rat p0, Mecp2, and the novel NF1pL and NF1pS promoters. Adult mice were injected with $2x10^{12}$vg via tail vein injection with each vector-promoter combination (n=6 per group; 5 groups). There were equal numbers of male and female mice in each group. Endpoint was 6 weeks post injection, at which point the mice were necropsied. Analysis of liver, heart, brain, spinal cord, sciatic nerve and muscle was done with immunohistochemistry for GFP protein expression and RT-qPCR for GFP RNA expression. **Results:** As expected, all promoters had higher expression of liver than in any other organ. However, the

Cag promoter showed higher expression in the liver than all other promoters examined. Relative to the Cag promoter, other promoters appear to de-target the liver. The p0 promoter showed the least amount of expression in all tissue, except spinal cord and sciatic nerve, where the expression was similar across promoters. The novel NF1pL and NF1pS promoters showed similar expression profiles to the Mecp2 promoter across all organ groups. Immunohistochemistry of the brain of mice treated with AAV9-Cag-GFP showed a strong characteristic glial pattern of staining. However, immunohistochemistry in the brain of mice treated with other promoters showed predominantly neuronal staining. **Conclusion:** Due to widespread disease affecting multiple organ systems, treatment of NF1 requires targeting of several specific cell types including Schwann cells, endothelial cells, and neurons. Our preliminary results from treatment of 30 mice with 5 different promoters suggest that expression can be guided by unique and novel endogenous *NF1* promoters.

Cancer Immunotherapy and Cancer Vaccines

226. Interferon Alpha Gene Therapy Alters Tumor Metabolism in Bladder Cancer

Sharada Mokkapati[1], Alberto Martini[1], Come Tholomier[1], Seppo Yla-Herttuala[2], Nigel R. Parker[3], David McConkey[4], Colin P.N. Dinney[5]

D. Anderson Cancer Center, Houston, TX

Introduction IFNα gene therapy (Nadofaragene firadenovec) has been approved by the FDA in BCG Unresponsive Non-Muscle Invasive Bladder Cancer (NMIBC). Understanding and targeting mechanisms of resistance and identifying biomarkers predictive of response is a top priority. Using cell lines, preclinical models, and clinical samples we identified changes in the tumor metabolic pathway involved in fatty acid biosynthesis as one of the key pathways altered in end-stage tumors. FASN is a key enzyme in this biosynthetic pathway and was downregulated in both murine models and in human bladder tumors. To define the role of this gene in IFNα gene therapy, we generated conditional knockout cells for FASN in two bladder cancer cell lines: UC14 and RT112. We characterized these cells to better understand mechanisms that drive acquired resistance to IFNα gene therapy. We generated lipid profiles of urine from patients enrolled in phase 2 clinical trial to identify lipid biomarkers predictive of response. **Methods** Murine bladder cancer (BLCA) cell lines were treated with recombinant IFN (rIFNα) or Lentiviral IFNα (LV-IFNα) and sequencing was performed to identify differentially altered genes/pathways. Subcutaneous and intravesical tumor models were used to assess the effect of IFNα on tumor metabolism. Lipidomics, glucose uptake, and lactate levels were measured following treatment with IFNα in murine models. Lipidomics was carried out on phase 2 Nadofaragene firadenovec urine samples. We **Results** We identified several genes involved in fatty acid synthesis that were downregulated and several genes involved in glycolysis that were upregulated following treatment with IFNα in cell lines, in mouse models, and in human tumors treated with Nadofaragene. Q-PCR analysis was used to confirm changes in these genes. We performed lipidomics on mouse tumors treated with poly (I:C), an IFNα surrogate, and identified 79 lipids that were upregulated and 12 lipids that were downregulated. Three major classes of lipids were upregulated; phosphotidyl choline, spingomyelin and phosphotidyl ethanolamine; and one major class of lipid cardiolipin was downregulated. We also performed a preliminary analysis of lipidomics on urine samples collected from patients enrolled on the phase 2 Nadofaragene trial. We selected 7 responders and 6 non-responders and subjected urine samples collected at day1 (pre-treatment) and day12 (post-treatment) for lipidomics analysis. >592 lipids were detected in the urine samples tested. Our results show that the lipid profile is distinct between the responders and non-responders before treatment (day 1 samples) and the lipid profile is altered in non-responders after treatment. Finally, we found increased glucose uptake, and lactate levels suggesting increased glycolysis in BLCA cells treated with IFNα. **Conclusion** We uncovered a novel mechanism by which IFNα modulates tumor cell metabolism which may contribute to the development of resistance. Combining IFNα-based therapy with approaches targeting tumor cell metabolism might further facilitate in improving survival and overcome resistance.

227. Targeting AML with Naturally Occurring CD7 Negative T Cells Expressing CD7 CAR

Unmesha Thanekar[1], Chris Nevitt[1], Jaquelyn T. Zoine[1], Maksim Mamonkin[2], Masayuki Umeda[3], Jeffery Klco[3], M. Paulina Velasquez[1]

[1]Bone Marrow Transplant and Cell Therapy, St. Jude Children's Research Hospital, Memphis, TN,[2]Center for Cell and Gene Therapy, Baylor College of Medicine, Houston, TX,[3]Pathology, St. Jude Children's Research Hospital, Memphis, TN

Introduction: Finding the most effective surface antigen to develop chimeric antigen receptor (CAR) T cells for acute myeloid leukemia (AML) is challenging due to the high degree of overlap in antigen expression between AML blasts and normal hematopoietic progenitor cells (HPCs), leading to potential myelotoxicity. CD7 is a promising target as it is expressed in 30% of AML cases, correlates with worse prognosis yet is not expressed on HPCs. However, its expression on normal T and NK cells introduces the risk of fratricide. To bypass this fratricide, we have devised a strategy to select naturally occurring CD7-negative T cells and genetically modify them to express CD7CARs ($CD7CAR^{CD7-}$ T cells). Here we show that $CD7CAR^{CD7-}$ T cells effectively target AML. **Methods:** We mined a pediatric AML dataset to determine differential gene overexpression of CD7 in AML. We isolated CD7-negative T cells from peripheral mononuclear blood cells using a two-step magnetic bead separation process followed by selection of $CD3^+$ T cells from the CD7-negative fraction. These T cells were subsequently transduced with a CD7.CD28z retroviral vector and expanded with IL7-/IL15. Non transduced (NT) and CD19 CAR expressing CD7 negative T cells served as controls. We performed immunophenotypic analysis using flow cytometry and assessed effector function *in vitro* and *in vivo*. **Results:** We determined differential gene

overexpression of CD7 in a pediatric AML dataset comprising 887 TARGET and St. Jude cases and confirmed CD7 surface expressions in a panel of AML cell lines, PDX and pediatric AML blasts. We genetically modified CD7-negative T cells to express CD7 or CD19 CAR, with CAR expression ranging from 62.90% to 95.30% (N=4). CD7CAR^{CD7-} T cells predominantly showed CD4+ effector memory immunophenotype. They maintained viability over 85% and exhibited expansion kinetics similar to that of CD19-CAR and NT groups (N=4, p=ns), indicating the absence of fratricide. To assess effector function, we co-cultured CD7CAR^{CD7-} T cells with CD7+ AML cells (KG1a and THP-1). CD7CAR^{CD7-} T cells recognized and killed AML cells *in vitro*, as evidenced by consistent tumor lysis in 24-hour and repeat stimulation assays and by increased cytokine secretion in the presence of CD7+ targets ($p<0.0001$, N=4). To test anti-tumor activity of CD7CAR^{CD7-} T cells in an *in vivo* KG1a model, mice received a single iv dose of 3x10e6 T cells 7 days after tumor injection. CD7CAR^{CD7-} T cells substantially reduced tumor burden and showed significant survival advantage ($p<0.0001$) compared to tumor-only and control CAR T cells (CD19CAR^{CD7-}). **Conclusion:** Here we demonstrate that CD7 is overexpressed at a transcriptomic and protein level in a cohort of pediatric AML blasts. We show, for the first time, that naturally occurring CD7-negative T cells expressing CD7 CARs can effectively recognize CD7+ AML and have robust anti-tumor activity *in vitro* and *in vivo,* presenting a promising strategy for AML therapy.

228. A mRNA Lipid Nanoparticle Incorporated Nanofiber-Hydrogel Composite Generates a Local Immunostimulatory Niche for Cancer Immunotherapy

Yining Zhu, Zhi-Cheng Yao, Shuyi Li, Jingyao Ma, Christine Wei, Xiaoya Lu, Hai-Quan Mao

Johns Hopkins University, Baltimore, MD

Introduction: Immunotherapy has witnessed a paradigm shift recently with the advent of mRNA LNPs as an accelerated approach to combat cancer. The success of the two mRNA vaccines has demonstrated the effectiveness of stabilized mRNA constructs to deliver the encoded antigen(s) and the safety and potency of LNPs in delivering the gene therapeutics and vaccines to relevant cells in vivo. Nonetheless, the realization of the full potential of mRNA LNP cancer vaccines requires further optimization of LNP immune activation profiles and delivery strategies for more efficient programming of immune responses for potent efficacy. Herein, we propose an off-the-shelf mRNA LNP-loaded nanofiber-hydrogel matrix (LiNx), which promotes endogenous immune cell infiltration and creates a programmable immunostimulating microenvironment, therefore maximizing antigen presentation. Previously, we analyzed 1,080 LNPs to boost transfection efficiency in antigen-presenting cells (APC).[1] Our findings indicate that precise tuning of LNP composition enables the modification of transgene expression in both APCs and non-APCs, thereby influencing the elicited immune activation profile. In this study, we further loaded the selected D6 LNP into a previously developed nanofiber-hydrogel composite (NHC).[2] This configuration yields a more robust immune response with a single-dose vaccination in mouse colon carcinoma and melanoma models (**Fig. 1a**). **Methods:** To prepare LiNx, the synthesized NHC microgel (G′ of ~250 Pa) was combined with LNPs using a syringe extrusion method.[2] The kinetics of host cell recruitment was examined following injection of LiNx on C57BL/6 mice (30 μg mOVA per mouse, s.c.). To assess cell transfection, Ai9 mice were s.c. administered with LiNx (30 μg mCre per mouse). For tumor inhibition studies, mice aged 6-8 weeks were injected with MC38-OVA or B16-OVA cells (s.c.). Tumor growth was monitored every two days. **Results:** To investigate host cell recruitment in LiNx, we injected mOVA LiNx into mice and harvested composites at 3- and 7-days. Incorporating D6 LNP significantly increased host immune cell recruitment compared to LiNx itself (**Fig. 1b**). A substantial number of APCs, particularly macrophages, were detected on day 3 (**Fig. 1c**). We further assessed the delivery efficacy of LiNx using Ai9 mice and found that D6 LNPs loaded in the LiNx resulted in substantial tdTom$^+$ APCs in composites (**Fig. 1d**). The anti-tumor effect of D6 LiNx was investigated in MC38-OVA and B6-OVA therapeutic tumor models (**Fig. 1e**). D6 LiNx demonstrated potent tumor suppression, resulting in a median survival time of 75 days with 50% of mice remaining tumor-free beyond 100 days (**Fig. 1f**). Notably, D6 LiNx outperformed free LNPs (three doses, median survival time of 37.5 days), emphasizing the superior efficacy of this single-dose hydrogel vaccine. Additionally, D6 LiNx was assessed in a prophylactic melanoma model (**Fig. 1g**), showing a prolonged median survival time of 30 days (**Fig. 1h**).

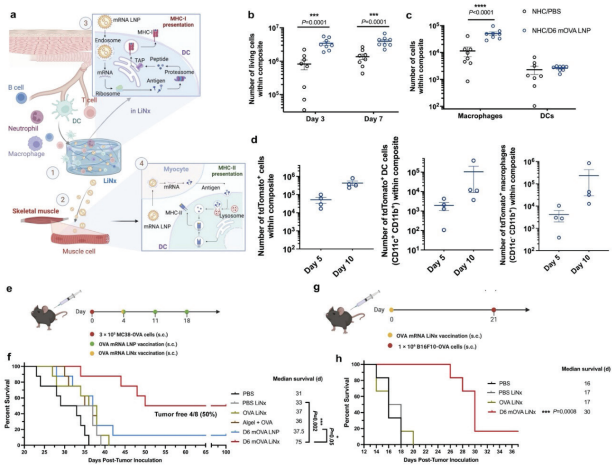

Fig. 1 | a, Schematic of the LiNx vaccination platform. **b-c,** The kinetics of host cell recruitment following injection of LiNx. **d,** Transfection of immune cells in the composite was analyzed using Ai9 mice. **e–h,** Schematic and results of therapeutic or prophylactic cancer vaccine models.

Conclusion: We engineered an mRNA LNP-incorporated microgel matrix as a programmable immunostimulating matrix that is capable of potentiating antigen expression, presentation, and immune cell cross-talks, and delivering potent antigen-specific immune responses and efficacy in murine cancer models. **Reference:** 1. 229. Targeting EphA3 on Glioblastoma Stem Cells with CART Cell Therapy to Overcome GBM Recurrence

Ekene J. Ogbodo[1], Reona L. Sakemura[1], Elizabeth L. Siegler[1], Claudia Manriquez-Roman[1], Truc Huynh[1], James H. Girsch[1], Jennifer M. Feigin[1], Olivia L. Sirpilla[1], Kun Yun[1], Carli M. Stewart[1], Hong Xia[1], Omar Gutierrez Ruiz[1], Lionel Kankeu Fonkoua[2], Mehrdad Hefazi[1], Michael W. Ruff[3], Saad S. Kenderian[1]

[1]Hematology, Mayo Clinic, Rochester, MN,[2]Medical Oncology, Mayo Clinic, Rochester, MN,[3]Neurology, Mayo Clinic, Rochester, MN

Glioblastoma (GBM) is the most lethal and common form of brain cancer, with a median survival of < 2 years. Despite aggressive treatment strategies including surgical resection, radiation, and chemotherapy, GBM is often resistant to or recurs after these standard therapies. GBM stem cells (GSCs) have been demonstrated to be the major player in the recurrence and maintenance of GBM tumors. Ephrin receptor A3 (EphA3), a member of the Eph family, is overexpressed in multiple cancers, including GBM. Additionally, EphA3 has been shown to be expressed on GSCs. Given the strong expression of EphA3 on GBM and GSCs and minimal expression on healthy tissue, we sought to develop a targeted therapy by engineering chimeric antigen receptor T (CART) cells against EphA3. CART cell therapy has shown remarkable outcomes in certain hematological cancers, but clinical success in solid tumors remains a challenge. We hypothesized that targeting GSCs with EphA3-CART cells will result in durable antitumor efficacy in preclinical models of GBM. We first isolated GSCs from GBM patient-derived xenografts (PDX) and confirmed high expression of EphA3 by flow cytometry (>90% EphA3$^+$). We generated a CD28-costimulated EphA3-CART cells through lentiviral transduction of healthy donor T cells (>90% transduction efficiency). We then evaluated *in vitro* effector functions of EphA3-CART cells in cocultures with GSCs. EphA3-CART cells demonstrated potent anti-GSC activity compared to untransduced T cell negative control (UTD), as determined by CART cytotoxicity ($p<0.0001$, Fig. 1A), proliferation ($p<0.0001$, Fig. 1B), degranulation ($p<0.0001$, Fig. 1C), and cytokine production ($p<0.01$, Fig. 1D). We then assessed the anti-GSC of EphA3-CART cells *in vivo* by orthotopically implanting 1 x 10^4 luciferase$^+$ GSCs into the brains of NOD-SCID-$\gamma^{-/-}$ mice. Tumor engraftment was confirmed by bioluminescence imaging (BLI), and mice were randomized and treated intravenously with 5 x 10^6 EphA3-CART or UTD control. Tumor burden was monitored by serial BLI, and T cell expansion was determined through peripheral blood sampling. This *in vivo* orthotopic model showed that treatment with EphA3-CART cells resulted in a significant reduction in tumor burden ($p<0.0001$, Fig. 1E), increased CART cell expansion ($p<0.01$, Fig. 1F), and prolonged survival ($p<0.01$, Fig. 1G) compared to UTD treatment. In conclusion, we established efficient targeting of GSCs with EphA3-CART cell therapy. Given the importance of GSCs in contributing to GBM resistance to and recurrence after conventional therapies, EphA3-CART cell therapy demonstrates significant promise in overcoming these challenges in GBM treatment.

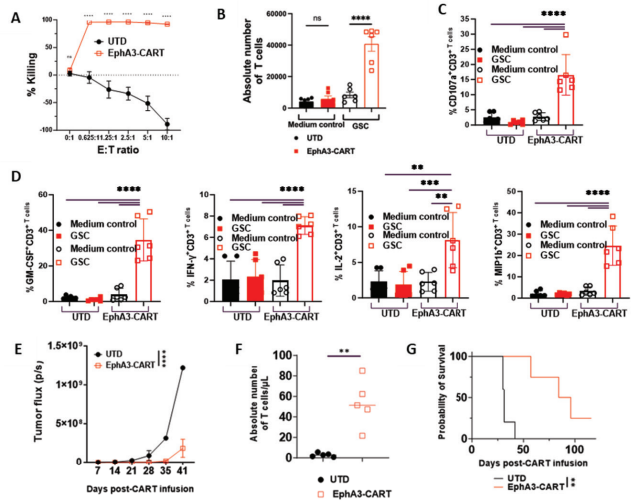

Fig 1. A. EphA3-CART or UTD were cocultured with luciferase$^+$ GSCs, and cytotoxicity was assessed by luminescence at 48 hours. **B.** Proliferation of EphA3-CART or UTD after a 5-day cocultured with GSCs was assessed by absolute counts of CD3$^+$ cells on flow cytometry. **C.** Degranulation of EphA3-CART or UTD after a 4-hour coculture with GSCs was assessed by CD3$^+$ CD107a$^+$ cells on flow cytometry. **D.** Cytokine production of EphA3-CART or UTD after a 4-hour coculture with GSCs was assessed by GM-CSF, IFN-γ, IL-2, or MIP1β on CD3$^+$ cells by flow cytometry. **E.** Antitumor activity of UTD or EphA3-CART was assessed by serial BLI as a measure of tumor growth. **F.** *In vivo* human T cell expansion in the peripheral blood was determined by absolute murine CD45$^-$ human CD45$^+$ human CD3$^+$ cell counts on flow cytometry. **G.** Kaplan-Meier survival curves of UTD- or EphA3-CART-treated mice are shown.

230. Combining the Anti-Viral and Anti-Tumor CD8+ T Cell Response Facilitates Immune Checkpoint Blockade Therapy and Oncolytic Virotherapy

Thanich Sangsuwannukul[1], Benjamin Kendall[1], Mason J. Webb[1], Jacob V. Vloten[1], Laura Evgin[1], Jason M. Tonne[1], Jill Thompson[1], Muriel Metko[1], Madelyn Moore[1], Maria P. Chiriboga Yerovi[1], Mark McNiven[1], Monga Satdarshan Pal Singh[1], Mitesh Borad[2], Roberts R. Lewis[1], Richard G. Vile[1]

[1]Mayo Clinic, Rochester, MN,[2]Mayo Clinic Cancer Center, Scottsdale, AZ

We tested the hypothesis that the heavily pro-inflammatory activity of vesicular stomatitis virus expressing interferon ß (VSV-IFNß) would convert the immune suppressive Tumor Micro-Environment (TME) of Hepatocellular carcinoma (HCC) to an immune stimulatory environment. In turn, this would recruit/prime/activate potentially anti-tumor T cells, the activity of which anti-PD-L1 Immune Checkpoint Inhibition (ICI) therapy would be able to potentiate further, thereby generating superior anti-tumor therapy to either therapy alone. This hypothesis is consistent with the model that inflammatory killing of tumor cells through viral oncolysis will recruit antigen presenting cells (APC) to the tumor site, release high loads of tumor associated antigens (TAA), and facilitate presentation of these TAA to CD8 and CD4 T cells in the draining lymph nodes, thereby generating systemically active anti-tumor T cell immunity. To test this hypothesis, we used a slow developing model of HCC, which resembles the etiology of human HCC, in which a Sleeping Beauty transposon integrates ß-catenin and hMet oncogenes into the livers of neonatal mice resulting in multi-focal tumor formation (SB-HCC) over 100-150 days. Tumor bearing mice were partially susceptible to anti-PD-L1 therapy (~50% long term cures), thereby mimicking at least one aspect of the human disease and current therapy. To our surprise, rather than observing even additive

benefit to therapy, and irrespective of the relative timings of both treatments, the addition of VSV-IFNß to anti-PD-L1 therapy largely abolished the therapeutic effects of anti-PD-L1 ICI alone. We show that VSV-IFNß treatment generated a highly significant expansion of one, or a few, dominant anti-viral effector $CD8^+$ T cell populations with the concomitant relative disappearance of those putative anti-tumor T cell populations which are the target of anti-PD-L1 treatment. We hypothesized that it would be possible to amalgamate the potent anti-viral response with an anti-tumor T cell response by expressing immunologically relevant tumor associated antigens from within the virus. Here we show that by expressing a multitude of putative, uncharacterized, tumor antigens within VSV using a cDNA library derived from three different SB-HCC explants (VSV-SB-HCC1,2,3) we observed highly significant improvements compared to anti-PD-L1 ICI alone - even in the absence of added anti-PD-L1 treatment. Our data provide a cautionary message for the use of highly immunogenic viruses as tumor-specific immune-therapeutics. We show that oncolytic virotherapy can induce anti-viral T cell responses which can actively inhibit, or obscure, weak anti-tumor T cell responses leading, potentially, to decreased anti-tumor therapy. However, by chimerizing anti-viral and anti-tumor T cell responses through encoding tumor antigens within the virus, at least a proportion of the anti-viral T cell response is co-opted into an anti-tumor response. In this way, oncolytic virotherapy can be purposed for very effective immune based tumor clearance and can generate anti-tumor T cell populations upon which immune checkpoint blockade can effectively work.

231. Adenovirus Capsid-Based Anti-Fentanyl Vaccine Protects Against Fentanyl-Induced Cardio-Respiratory Depression

Stephen M. Kaminksy[1], Isabelle Wilson[1], Cheyenne McKnight[1], Bishnu P. De[1], Tristan H. Lambert[2], Dolan Sondhi[1], Ronald G. Crystal[1]

[1]Genetic Medicine, Weill Cornell Medical College, New York, NY,[2]Chemistry and Chemical Biology, Cornell University, Ithaca, NY

Exposure to fentanyl, a highly potent synthetic opioid analgesic, resulted in the majority of the estimated 80,000 deaths caused by drug overdose in 2023. Fentanyl is not only associated with opioid use disorder due to its highly addictive qualities but also is added to other addictive drugs, resulting in an increase in deaths due to inadvertent use. Fentanyl causes bradycardia and respiratory depression in a dose-dependent fashion, often resulting in death. There is a need for a therapeutic that prevents the respiratory depressive effects of fentanyl and protects against overdose. We have developed a novel vaccine platform that sequesters fentanyl from mu-opioid receptors in the central nervous system to protect against lethal doses of the drug. The vaccine is based on direct covalent conjugation of a fentanyl analog (Hapten3) to the highly immunogenic serotype 5 $E1^-E3^-$ adenovirus after heat and detergent disruption (dAd5). dAd5-Hapten3 is produced by chemically crosslinking Hapten3 to the dAd5 hexon, fiber, and penton capsid proteins, thereby leveraging the adenovirus' naturally immunogenic properties to induce an immune response against fentanyl. Female C57BL/6J mice were administered dAd5-Hapten3 (8 μg, intramuscular) formulated with Adjuplex adjuvant at 0, 3, and 6 weeks. Serum collected prior to each vaccination was assayed for anti-fentanyl antibody titers. Vaccination generated titers $>10^6$ after a single dose and held steady after subsequent boosts. During weeks 8 to 13, mice were administered with fentanyl (2 mg/kg, intraperitoneal) and assayed for respiratory health parameters via pulse oximetry. Following fentanyl administration, unvaccinated controls had a decrease in heart rate (decrease 28.0 ± 14.1%), respiratory rate (decrease 42.8 ± 9.7%) and O_2 saturation (decrease 19.3 ± 7.9%). In contrast, vaccinated mice had less suppression of heart rate (fentanyl-induced decrease 13.0 ± 8.9%, $p<0.05$ compared to unvaccinated), respiratory rate (14.7% ± 16.6%, $p<0.01$) and O_2 saturation (9.3 ± 9.3%, $p< 0.05$). The vaccinated mice also demonstrated a decrease in fentanyl-induced mortality (44% unvaccinated, 80% vaccinated) despite the fact that the LD50 in mice is >100-fold greater than humans. In summary, capitalizing on the highly potent immunogenicity of adenovirus capsid proteins, we have developed a vaccine that produces antibodies specific to fentanyl, that can be used as a prophylactic against fentanyl-induced respiratory depression and resulting death.

232. The Novel Autologous AML Vaccine, TriLeukeVax, Stimulates Robust Anti-Leukemic Patient T Cell Responses

Karin L. Gaensler, Jacob Du, Uthpala N. Wijayaratna, Belinda Huang

UCSF, San Francisco, CA

There is an urgent need for more effective therapies for acute myeloid leukemia (AML), as relapse is frequent after chemotherapy. Evidence for the efficacy of immunotherapy is provided by the improved outcomes after hematopoietic stem cell transplantation (HSCT). However, this involves significant risks and toxicity, rendering many patients ineligible. To provide another strategy for stimulating anti-leukemic immunity, we developed a novel autologous cell vaccine (TriLeukeVax/TLV) by genetically engineering patient AML cells to express the co-stimulatory protein CD80 and the cytokine IL-15, with its receptor IL-15-receptor-α. Transduced AML can become potent antigen-presenting cells, capable of stimulating leukemia-specific responses, without the risks and toxicity of HSCT. Studies in leukemic mice showed 80% curative outcomes with serial TLV vaccination alone. In mice with advanced high-burden leukemia, non-curative chemotherapy followed by serial TLV vaccination eradicated residual disease in 40-50% of subjects. Ex vivo stimulation assays were used to test the efficacy of TLV in stimulating anti-leukemic activity in autologous patient T cells. TLV was generated by lentiviral transduction of diagnostic bone marrow or peripheral blood samples from five patients (47-69 y.o.). These cells were irradiated at 30 Gy and co-cultured with autologous post-remission T cells at an effector-to-target (E:T) ratio of 1:2, for 5 days. Controls to assess background levels of activation included co-culture of T cells with unmodified autologous AML. Proliferative responses were measured by flow cytometric analysis of effectors (CellTrace Violet) and targets (CFSE) stained with supravital dyes (Fig. 1). Primary co-culture with TLV stimulated greater CD4+ and CD8+ T cell proliferative responses than did co-culture with unmodified AML cells (Fig. 1). In our planned Phase 1 clinical trial, peripheral T cells in transplant ineligible AML patients in remission will be primed by serial vaccination with TLV. To recapitulate the induction of leukemia-specific cytolytic responses by primed T cells in patients, secondary ex vivo T cell stimulation assays were developed. Proliferating T cells previously co-cultured with TLV (primed T cells) in primary

stimulation assays were purified by fluorescence-activated cell sorting (FACS) and expanded in culture for 7-10 days. To determine whether TLV stimulation increased leukemia specific cytolytic activity, primed T cells were harvested and cocultured with unmodified autologous AML (E:T 2:1 for 24 hours). Background levels of cytolytic activity in non-primed T cells were compared with responses by primed T cells after co-culture with unmodified autologous AML (E:T 2:1 for 24 hours). Primed T cells showed significantly higher cytolytic activity against unmodified, autologous AML than did non-primed T cells (Fig. 2). These studies demonstrate that TLV mediates induction of robust proliferative and anti-leukemic cytolytic responses in autologous post-remission T cells. Investigational New Drug (IND)-enabling studies to support a future Phase 1 trial of TLV are currently underway.

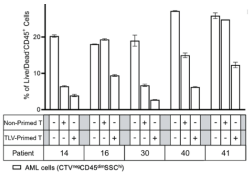

Figure 2. TLV enhances anti-leukemic responses in autologous T cells ex vivo. In secondary stimulation assays, the frequency of AML cells ($CTV^{neg}CD45^{dim}SSC^{hi}$) was quantified as % live $CD45^+$ cells in autologous AML cultured alone, or in AML co-cultured with TLV-primed T cells or non-primed T cells. In the 3 cultures performed per sample in triplicate, the left most bar indicates the frequency of AML cells as a % of total bone marrow or peripheral blood cells normalized to a 33% target cell plating frequency. The 2nd and 3rd bar in each set of samples depicts % live AML cells after co-culture with non-primed T cells (2nd) or TLV-primed T cells (3rd). Responder cells are shown in the table below the graph.

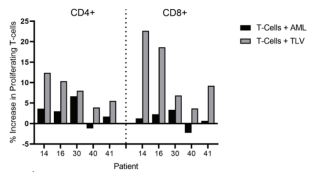

Figure 1. Increased T cell proliferation after primary co-culture with TLV versus unmodified autologous AML. Rested patient T cells were stained with CellTrace Violet (CTV) and co-cultured for 5 days with irradiated, carboxyfluorescein succinimidyl ester (CFSE)-stained AML or TLV at an effector-to-target ratio of 1:2. The frequency of proliferating cells (CTV^{dim}) was quantified in CD4+ or CD8+ T cells (Live $CFSE^-CTV^+$) cultured alone or co-cultured with autologous AML or TLV. The increase in proliferation is the % dividing T cells co-cultured with AML or TLV minus the %dividing T cells in the absence of target.

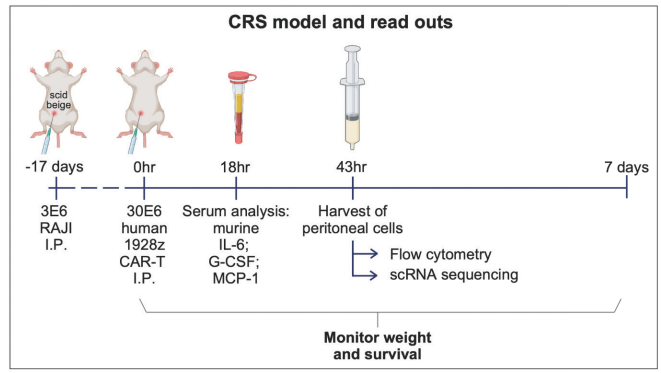

Pharmacology Toxicology Studies and Analytics Assay Development

233. CAR T-Cell-Derived TNF Drives Cytokine Release Syndrome and Enhances M1 Macrophage Differentiation

Pieter L. Lindenbergh[1], Theodoros Giavridis[1,2], Ophélie Vivier[1], Michael Lopez[1], Anton Dobrin[1], Michel Sadelain[1]

[1]Memorial Sloan Kettering Cancer Center, New York, NY,[2]Mnemo Therapeutics, New York, NY

Background: The pathophysiology of CAR T-cell-induced Cytokine Release Syndrome (CRS) is driven by cytokines and biochemical mediators produced by activated T-cells and macrophages. TNF serum levels are elevated in patients suffering from CRS and pre-clinical work from our group shows that CRS can be abated by TNF-blockade. To elucidate the role of TNF in CRS, we set out to identify its cellular source and its effect on macrophage activation. We tested the effect of TNF-blockade on the efficacy of several CAR T-cell designs to assess if TNF is a potential target for CRS prevention in the clinic. **In vivo models:** To study the role of TNF in CRS, we blocked TNF in a previously established model for CRS in which human 1928z CAR T-cells induce inflammatory cytokine release, weight-loss and occasional lethality (see figure). To assess the effect on therapeutic efficacy, we blocked TNF in a NALM6-leukemia model treated with 1928z, 19BBz or 1928z/4-1BBL CAR-T cells.

Results: To identify the cellular source of CRS-driving TNF, we treated the CRS model with clinically utilized agents that block human and murine TNF (etanercept) or only human TNF (infliximab). We observed that blockade of human TNF alone was sufficient to prevent cytokine release, weight-loss and lethality. Consistently, flow cytometric analysis of myeloid cells at the tumor site showed that human TNF-blockade abated CRS-induced macrophage accumulation. Because CD4 CAR T-cells produce more TNF than CD8 CAR T-cells, we hypothesized that CD4 CAR T-cells would be stronger inducers of CRS. We administrated sorted CD4 or CD8 CAR T-cells but observed no significant difference in cytokine release, weight-loss and lethality. Furthermore, CRS induced by both subsets was abated by etanercept. We used scRNA sequencing and the MacSpectrum annotation system to assess the effect of CRS and TNF on the M0/M1/M2 differentiation of macrophages at the tumor site. We found that CRS-induction universally polarized the macrophages towards a M1-like state, which was epitomized by the upregulation of *Nos2* (encoding the iNOSynthase of vasodilating NO). TNF-blockade attenuated the M1-like differentiation of these macrophages and significantly reduced *Nos2* expression. We assessed the effect of prophylactic TNF-blockade on CAR T-cell efficacy in a leukemia model treated with CAR T-cells. Mice received an induction dose of etanercept prior to CAR T-cell treatment and bi-weekly follow-up doses over the course of three weeks, covering the time window in which CRS occurs in the clinic. Whilst TNF-blockade reduced the efficacy of 1928z and 19BBz CAR T-cells, we observed that 1928z CAR T-cells modified to co-express 4-1BBL were not affected by TNF-blockade. **Conclusions:** Our results support a model in which CD4 and CD8 CAR T-cell-derived TNF is a crucial, positive regulator of CRS and enhances the differentiation of macrophages towards a proinflammatory state. The results of the preclinical efficacy experiments indicate that CAR T-cells can be modified to have uncompromised efficacy in the presence of long-term TNF-blockade. Thus, TNF is not only a nexus in the pathophysiology of CRS, but also a potential target for its prevention.

234. Identification of Cellular Factors that Contribute to Peripheral Blood-Derived CAR-NK Cell Mediated Inflammatory Toxicities

Supreet Khanal, Nirjal Bhattarai

FDA, Silver Spring, MD

Chimeric antigen receptor-expressing NK (CAR-NK) cells are increasingly being developed to treat a wide variety of human diseases. While CAR-T cells are known to activate bystander myeloid cells,

contributing to inflammatory toxicities such as cytokine release syndrome (CRS) and immune effector cell-associated neurotoxicity syndrome (ICANS), the potential of CAR-NK cells to induce similar effects remains uncertain due to limited clinical data. Here we studied human peripheral blood-derived CAR-NK cells and assessed their ability to cause inflammatory toxicities. Primary NK cells were isolated from healthy donors and activated using PMA/Ionomycin as well as using target cells such as Daudi and K562. Cell-free activated supernatants were collected and added to THP-1 cells and primary monocytes to assess myeloid activation, that was measured by the secretion of IL-6 and IL-1β using ELISA. Cytokine arrays were used for the identification of cellular factors. We found that following activation, NK cells secrete fewer inflammatory cytokines at lower levels compared to T cells obtained from the same donor, resulting in lower levels of myeloid cell activation and secretion of inflammatory cytokines IL-6 and IL-1β by myeloid cells. Nevertheless, activated NK cells demonstrated notable myeloid cell activation across all donors studied compared to resting NK cells. To assess the mechanism by which CAR-NK cells activate bystander myeloid cells, we analyzed the inflammatory cytokine profile of activated NK cells. Comparative analysis of secreted cytokines from activated and resting primary NK cells and NK cell lines identified key inflammatory factors with potential to cause myeloid cell activation. Antibody-mediated neutralization studies identified four NK cell factors, which, upon neutralization, significantly reduced NK-cell-mediated myeloid cell activation. This observation was confirmed through siRNA-mediated knockdown studies as knockdown of these four factors in peripheral blood-derived CAR-NK cells significantly reduced myeloid cell activation. Importantly, neutralization or knockdown of these four inflammatory factors in NK cells did not affect potency of CAR-NK cells. Together, these data suggest that peripheral blood-derived CAR-NK cells can activate bystander myeloid cells and contribute to inflammatory toxicities during CAR-NK cell therapy. Furthermore, this study identified four major inflammatory factors secreted by activated NK cells, which, upon inactivation, can significantly reduce CAR-NK cell-mediated inflammatory toxicities without affecting their potency.

235. Pharmacokinetics and Vector Shedding in NHPs Following a Single Intravenous Infusion of a CD20-Targeted Engineered Lentiviral Vector

Lentiviral vector (LVV) based *ex vivo* cell therapy is well established, and in this setting the carryover of infectious LVV particles into patients is low for clinical-grade material (Cesani et al. 2015). The *in vivo* administration of LVV to generate CAR cells inside the patient has the potential to circumvent manufacturing and administration challenges presented by *ex vivo* cell therapies but presents a potential risk of environmental contamination through shedding of infectious vectors in patient excreta. We developed an engineered replication-incompetent LVV clinical candidate (INT2104) that directs *in vivo* production of CD20-directed CAR-T and CAR-NK cells following a single-dose intravenous (IV) infusion. Here we report pharmacokinetics of vector capsid protein and RNA genomes in blood, and shedding of vector RNA genomes in urine, feces, and saliva of cynomolgus macaques after IV administration of 2 x 10^9 transducing units of INT2104. This dose represents the highest dose proposed for a FIH study planned to start in 4Q2024. We used ELISA and RT-qPCR methods to detect vector capsid protein and RNA genomes respectively in several LVV studies in cynomolgus macaques, including the GLP-Toxicology study. In all studies, LVV drug product was administered in a single-dose IV infusion. LVV capsid protein peaks in the blood 1 day after vector administration and is then rapidly cleared. Vector RNA genomes are cleared more rapidly than protein and are detected at much lower levels than expected if the all the capsid protein measured in circulation were associated with intact LVV particles. These data indicate that clearance of intact and therefore potentially infectious vector particles from circulation is rapid after IV administration of our replication-incompetent LVV. Shedding of vector RNA genomes into feces, saliva and urine was detectable in some animals at very low levels in the first 3 days following vector administration, suggesting very limited and transient LVV shedding. Taken together these data demonstrate rapid clearing of an in vivo-administered replication-incompetent LVV, with limited shedding in animal excreta indicating low risk of environmental contamination.

236. Characterization of Preclinical Models for Systemically Delivered Vectors Based on Human Adenoviruses HAdV-B3, HAdV-B11, HAdV-C5, HAdV-C6, and HAdV-D26

Margarita Romanenko, Jill Schappa Faustich, Kazuho Inoko, Sacha Robert, Melanie Graham, John P. Carney, Julia Davydova

University of Minnesota, Minneapolis, MN

Oncolytic adenoviruses (OAds) are promising cancer therapy agents that selectively lyse cancer cells while sparing healthy tissues. They also promote antitumor immunity by inducing immunogenic cell death and disrupting immunosuppressive microenvironment. Notably, their intravenous delivery targets metastases, enabling systemic treatment. However, OAds' clinical progress is hampered by the absence of reliable animal models that can predict OAds' therapeutic and immunomodulatory responses, particularly upon systemic administration. Ideally, preclinical models should support OAd replication, mimic OAd-induced immune responses, and represent OAd interactions with blood components. However, standard murine models don't support replication of human Ads, resulting in nonfunctional progenies. Furthermore, both mice and hamsters do not allow for the binding of species B Ads (e.g., HAdV-B3 and HAdV-B11) due to the absence of CD46 and human desmoglein-2, hDSG2, receptors. This limitation extends to chimeric OAd vectors targeting these receptors (e.g., HAd5/3). This study seeks to identify and characterize preclinical models for OAds evaluation. Our recent work shows porcine cells and tissues effectively support the binding, transduction, and replication of HAdV-C5- and chimeric HAd5/3-based vectors, at a level similar to human tissues. Here, we compared these findings across mammals, assessing binding, transduction, and replication of species B, C, and D Ads in mice, hamsters, pigs, and non-human primates. Focusing on systemic delivery, we explored Ads' interaction with blood factor X (FX), a pivotal element influencing

adenoviral transduction. Prior research has established that human FX binding notably augments cell transduction for species C Ads. In this study, we explored whether FXs derived from a diverse array of mammalian sources—including human, porcine, murine, canine, and cynomolgus monkey—could enhance the transduction efficacy of both wild-type and chimeric Ads, specifically HAdV-B3, HAdV-B11, HAdV-C5, HAdV-C6, and HAdV-D26, as well as the chimeric variants HAd5/3 and HAd5-RGD. We showed that porcine and canine FXs significantly improve the transduction efficacy of HAdV-C5, HAdV-C6, and chimeric HAd5/3 in CAR-, hDSG2-, and CD46-deficient CHO cells, matching human FX levels. Interestingly, while HAdV-B3 transduction remains unaffected by the presence of any FX variant tested, in the case of HAdV-B11, significant enhancement of transduction efficiency was observed when human and porcine FX was introduced. Unexpectedly, FX derived from cynomolgus did not exhibit any enhancement in the transduction capabilities across the Ad types we tested. We are currently examining Ad types' hemagglutination with red blood cells, RBCs, sourced from humans, porcine, hamsters, mice, rhesus macaque, and cynomolgus monkeys. Preliminary results indicate that porcine, murine, and hamster RBCs don't hemagglutinate with any of the explored Ad types (HAdV-B3, HAdV-C5, HAdV-C6, HAdV-B11, HAdV-D26, HAd5/3, HAd5-RGD), unlike human RBCs, which do with HAdV-C5, HAdV-C6, HAdV-D26, and HAd5-RGD. Notably, non-human primate (cynomolgus and rhesus macaque) RBCs do hemagglutinate with only HAdV-B11. Based on our current and previous research on the porcine model, we conclude that pigs represent a promising candidate for the preclinical evaluation of OAds, particularly for chimeric HAd5/3-based vectors. In light of these findings, the FDA has permitted the exclusive use of pigs for IND-enabling toxicology studies of the oncolytic HAd5/3 vector.

237. Potency Assay Enabling Both *Ex Vivo* and *In Vivo* Genome Editing Therapeutics for Sickle Cell Disease

Utku Goreke[1], Dipti H. Kamath[1], Yaw O. N. Ansong-Ansongton[1], Nathan M. Perez[1], Umut Gurkan[2], Petros Giannikopoulos[1], David N. Nguyen[1]

[1]Innovative Genomics Institute, University of California Berkeley, Berkeley, CA,[2]Mechanical and Aerospace Engineering, Case Western Reserve University, Cleveland, OH

Sickle cell disease (SCD) stems from a point mutation of the two β subunits in adult hemoglobin (HbA) that leads to nucleated polymerization of sickle hemoglobin (HbS) under hypoxia. A critical unmet need for using gene editing-based genomics therapies to cure sickle cell disease is the ability to characterize red blood cell (RBC) quality to assess the potency, regardless of the editing modality. The standard DNA sequencing methods can assess the safety of the product, and conventional hematologic assays such as high-performance liquid chromatography (HPLC) can measure the abundance of various hemoglobin variants in a sample. There is sparse knowledge of the *in vitro* functional characterization of RBCs. Still, these could assess the biophysical and rheological properties of RBCs derived from genome-edited SCD HSPCs at the single-cell level. We delivered CRISPR Cas9 RNPs targeting the BCL11a enhancer locus (or controls) to commercially obtained healthy donor peripheral blood mobilized (CD34+) HSPCs to enhance fetal hemoglobin expression. Edited HSPCs were differentiated into erythroid cells using a 21-day 3-phase cytokine cocktail system (including IL-3, SCF, and erythropoietin). Differentiation, proliferation, and enucleation were compared between control and gene-edited samples with flow cytometry. Adhesion and deformability of enucleated RBCs were studied using the SCD-Biochip Assay, a suite of microfluidic devices capable of functionally characterizing several biochemical and biomechanical phenotypes of RBCs namely: adhesion, deformability, and sickling under hypoxic and normoxic conditions [1, 2, 3]. Editing efficiency was estimated as high as ~60% via electroporation. The mean cell amplification of CD34+ cells reached a 695-fold expansion by Day 16. Differentiation of the immature erythroblasts into mature RBCs continued from day 16 to 21, marked by the progressive loss of CD71 expression; ~50% of CD235a+ cells were enucleated. We observed more microfluidic occlusion index (a surrogate for deformability) with glutaraldehyde crosslinked RBCs compared to untreated controls. We found that RBC occlusion and adhesion (to fibronectin) are significantly greater under hypoxia than under normoxia for HbSS RBCs. Here, we present a matrix-type potency assay to address the critical need for a universal potency assay for editing-based SCD treatments. The assay will be anchored by a suite of novel microfluidic biochip devices that can functionally assess the health of individual RBCs in a clinically relevant human capillary model in unprecedented sensitivity for precision diagnostics. We demonstrate the feasibility of adopting the SCD-Biochip platform to evaluate pertinent biomechanical functions of RBCs derived from CRISPR-edited HSPCs. The application of these functional assays could result in a robust and accurate precision diagnostic that addresses the critical need for a universal potency assay for editing-based SCD treatments. 238. Association Between Potency Critical Quality Attributes and Clinical Efficacy Across Lentiviral Vector Cell and Gene Therapy Products

Ilya A. Shestopalov, Hancheng Jiang, Marisa Gayron, Marc d'Anjou, Kelly Kral, Francis J. Pierciey, Richard Colvin

bluebird bio, Somerville, MA

Introduction: Identifying drug product Critical Quality Attributes (CQAs) that associate with clinical efficacy has been a challenge with cell and gene therapy (CGT) products. Betibeglogene autotemcel (beti-cel), lovotibeglogene autotemcel (lovo-cel), and elivaldogene autotemcel (eli-cel) are distinct CGT products with differentiated safety and efficacy profiles that leverage lentiviral gene addition in CD34+ hematopoietic stem and progenitor cells for treatment of severe genetic diseases. Beti-cel and lovo-cel utilize an LVV construct

with a tissue-specific promoter to address β-thalassemia and sickle cell disease, whereas eli-cel has a constitutive promoter to treat cerebral adrenoleukodystrophy. The choice of promoter contributes to distinct safety profiles. A matrix of potency assays has been developed for each of these drug products to capture their multi-faceted mechanisms of action. **Objective:** To identify common potency-related CQAs that are associated with clinical safety and efficacy of beti-cel, lovo-cel, and eli-cel. **Methods:** This post-hoc, exploratory analysis included data from a total of 155 patients across 6 clinical studies: beti-cel, 41 patients from HGB-207 (NCT02906202) and HGB-212 (NCT03207009); lovo-cel, 47 patients from HGB-206 (NCT02140554) and HGB-210 (NCT04293185); eli-cel, 67 patients from ALD-102 (NCT01896102) and ALD-104 (NCT03852498). Potency-associated attributes studied were vector copy number (VCN), percentage of transduced cells (lentiviral-vector positive cells, %LVV+ cells), vector copy number per transduced cell (VC/TC), therapeutic protein expression, percent colony forming cells (%CFC), and disease-specific potency assays that measure changes in biological function related to the mechanism of action of the product (red blood cell (RBC) differentiation for beti-cel, RBC morphology for lovo-cel, and metabolism of very long chain fatty acids for eli-cel). Univariate logistic regression analyses were preformed between potency-associated attributes and clinical outcomes: occurrence of vaso-occlusive events (VOEs) for lovo-cel; development of major functional disabilities (MFD) or myelodysplastic syndrome (MDS) for eli-cel . For beti-cel, a multi-variate approach was used to predict achievement of a peripheral blood VCN ≥0.75 copies per diploid genome, a stringent surrogate biomarker of transfusion independence (TI). Associations between CFC activity and engraftment were also studied. **Results:** Measures of transduction efficiency (VCN and %LVV+ cells) were significantly associated with clinical endpoints across the products, including preventing MFDs in eli-cel, resolution of VOEs in lovo-cel, and achievement of a stringent surrogate biomarker of TI in beti-cel. Transduction efficiency based on protein expression (% of cells positive for therapeutic adrenoleukodystrophy protein ALDP) was also associated with preventing MFDs in eli-cel. VCN and %LVV+ cells were not associated with cases of MDS that are unique to eli-cel. VC/TC was not associated with efficacy or safety-related outcomes and CFC had no association with time to engraftment in all three products. In contrast to transduction efficiency measurements, product-specific functional potency assays had variable associations with clinical outcomes. **Conclusion:** Our findings indicate that all three products (beti-cel, lovo-cel, and eli-cel) share measures of transduction efficiency as the common potency-associated CQAs that highly correlate with product efficacy. These results highlight the value of transduction efficiency assays as surrogate potency measurements and can help guide the establishment of rigorous and meaningful product quality acceptance criteria for complex CGT products.

239. Transcriptional Changes in Non-Human Primate Tissues After Intrathecal Delivery of Serotype 9 Adeno-Associated Viral Vector: Insights into Organ Toxicities

Fumiaki Aihara[1], Matthew Mardo[2], Vera Ruda[1], Megumi Onishi-Seebacher[1], Philippe Couttet[1], Keith Mansfield[1], Kelley Penraat[1], Eloise Hudry[1]

[1]Novartis, Cambridge, MA,[2]University of Colorado, Aurora, CO

Adeno-associated virus (AAV) based gene therapy has brought transformative therapeutic benefits to patients with otherwise untreatable genetic diseases. Despite these life changing effects, AAV-driven organ toxicities remain a safety concern in the clinic and the mechanism of action remains unknown. To gain further insights into the potential molecular mechanisms underpinning organ toxicity, we conducted RNAseq analysis in non-human primates administered scAAV9-CB-GFP intrathecally as well as empty viral particles and 'promotorless' AAV particles. Tissues primarily transduced by the viral vector (liver, dorsal root ganglia, heart, skeletal muscle, and spleen) were collected and processed. Initial pathway analysis confirmed that many of the upregulated pathways were related to a viral immunological response towards the full AAV, which persists at least a month after dosing across liver, dorsal root ganglia, and heart tissues. Evaluating the top upregulated genes after AAV dosing revealed several immunological genes associated with interferon signaling, phagocytic activity, antigen presentation, and T cell/B cell activity. Several of these significantly upregulated genes were expressed across the three organs of interest, suggesting that there is a common response towards the AAV's transgene expression. We have also observed a striking difference in transcriptional signals between fully functional AAV and the empty viral particles and 'promotorless', with far more significant changes seen in the group given the fully functional AAV. This distinction was most prominently seen in the dorsal root ganglia, liver, and heart, where there was the highest expression of the transgene within the organ. This suggests that lasting transcriptional changes are mostly observed when the transgene is expressed (early capsid-dependent transcriptional alterations were not captured in our analysis). Taken together, this study provides clearer insight into the transcriptional responses, with distinct signatures for interferon signaling and antigen presentation, within key tissues following administration of high-dose AAV.

Cell Therapy and Cell-Based Gene Therapy Trials

240. FVIII Expression through Autologous CD34+ Hematopoietic Stem Cells Transduced with a Lentiviral Vector with a Novel F8 Transgene for Gene Therapy of Hemophilia A - A First-in-Human Clinical Trial

Alok Srivastava[1,2], Aby Abraham[1], Fouzia Aboobacker[1], Gurbind Singh[2], Tulasi Geevar[1], Uday Kulkarni[1], Sushil Selvarajan[1], Anu Korula[1], Rutvi Dave[1], Mohanashankar Mahalingam[2], Ramachandran Shaji[1,3], Sukesh Chandran Nair[1], Gabriela Denning[4], Pete Lollar[4,5], Christopher Doering[4,5], H. Trent Spencer[4,5]

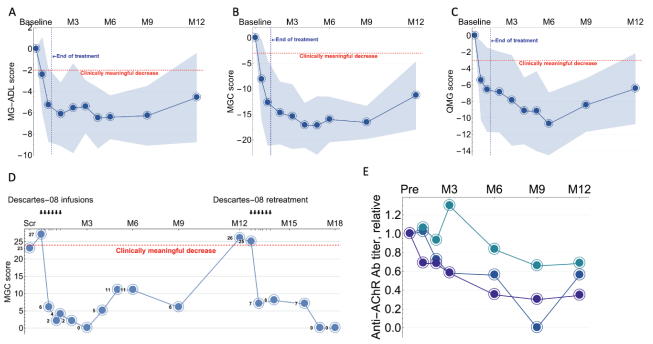
Liver directed adeno-associated virus (AAV) vector-based gene therapy for hemophilia A has several limitations: age and anti-AAV antibody

related eligibility restrictions, inter-individual variation in FVIII:C expression and its durability as well as unexplained transaminitis. We demonstrated sustained FVIII expression from hematopoietic stem cells (Doering *et al Hum Gene Therapy 2018; 29:1183*) using a self-inactivating lentiviral vector (LV) encoding a novel *F8* transgene designed for enhanced FVIII secretion (ET3) and driven by a CD68 promoter. The vector, designated as CD68-ET3-LV, is being evaluated in a first-in-human clinical trial of this novel gene therapy approach for severe hemophilia A (NCT 05265767; CTRI/2022/03/041304). This report describes the outcome of the first 4 treated participants. $CD34^+$ cells selected from mobilized peripheral blood stem cell harvests were transduced *ex-vivo* with the CD68-ET3-LV vector and cryo-preserved targeting a final cell dose of $>5x10^6$ $CD34^+$ cells/kg. Transductions for the first two participants (G1) were without enhancer while for the next two participants (G2) transductions were with enhancer and a 50% reduction in vector dose. Conditioning for the hematopoietic stem cell transplant (HSCT) consisted of treosulfan and fludarabine. The cytopenic period was supported with rFVIII along with other standard of care measures for HSCT. As engraftment ensued and blood counts normalized, rFVIII replacement was gradually stopped. Post engraftment, FVIII:C levels were measured by one-stage and chromogenic substrate assays. The genomic integration profile of the CD68-ET3-LV vector was also assessed. The four treated participants ranged between 22-34 years and had >100 prior exposures to FVIII with a median annual bleeding rate of 33 (range:20-120). $CD34^+$ cell doses administered for HSCT ranged from 5.3-6.2 x 10^6 cells/kg. The vector copy numbers (VCN) in the therapeutic products were 0.57 & 1.02 in G1 and 0.62 & 1.49 in G2. The HSCT procedure was well tolerated. Neutrophil and platelet engraftment occurred at 10-12 and 12-15 days after HSCT and the duration of severe neutropenia and thrombocytopenia was 7-11 and 1-4 days, respectively. There were no bleeding episodes. No Grade >2 non-hematological toxicities occurred during the engraftment period. The last day of rFVIII replacement ranged from 11-20 days after HSCT. FVIII:C levels peaked between days +30 to 60 after HSCT and then remained stable within a small range. The median FVIII:C after day +30 at last follow-up for G1 participants are 5.2% (18 mo.) and 1.7% (12 mo.), while for those in G2 was 32.6% (6 mo.) and 11% (4 mo.) with comparable one stage and chromogenic substrate assays. The peripheral blood VCN at day +30 was 0.12 and 0.25 in G1 and 1.45 and 2.5 in G2 correlating with the measured FVIII:C levels. The vector integration profile showed no safety concerns. None of the participants reported any bleeds post-HSCT through the last follow-up. FVIII mRNA levels in blood cells were highest in $CD14^+$ cells, lower in $CD15^+$ cells and none in $CD3^+$ cells. This ongoing first-in-human clinical trial of a lentiviral vector transduced HSC-based gene therapy for hemophilia A establishes feasibility of this approach with no early safety signals, and very promising therapeutic efficacy with clinically significant stable levels of circulating FVIII:C within a month after treatment.



241. Investigation of mRNA Cell Therapy as a Treatment for Autoimmune Disease in Patients with Myastenia Gravis

James F. Howard[1], Tahseen Mozaffar[2], Tuan Vu[3], Nizar Chahin[4], Gregory Sahagian[5], Marc H. Feinberg[6], C. Andrew Stewart[7], Metin Kurtoglu[7], Milos D. Miljkovic[7], Christopher M. Jewell[7]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC,[2]University of California Irvine, Irvine, CA,[3]University of South Florida, Tampa, FL,[4]Oregon Health and Sciences University, Portland, OR,[5]Neurology Center of Southern California, San Diego, CA,[6]SFM Research, Boca Raton, FL,[7]Cartesian Therapeutics, Gaithersburg, MD

Autoimmune diseases occur when the immune system mistakenly attacks host tissue. Myasthenia gravis (MG) is an autoimmune disease in which auto-antibodies attack the neuromuscular junction. We recently reported on the safety and preliminary clinical activity of an mRNA-engineered chimeric antigen receptor (CAR) T-cell therapy in patients with MG. This strategy is differentiated from DNA-based approaches in the use of mRNA to encode the CAR, which results in transient expression and avoids permanent genomic integration. As a result, this therapy is administered in the outpatient setting and does not require lymphodepleting chemotherapy. In particular, these engineered cells target the B-cell Maturation Antigen (BCMA) expressed on PC that produce the pathogenic autoantibodies during MG and many other autoimmune diseases. In the Phase 2a part of our study, 7 participants (4 acetylcholine receptor [AChR]+, 2 muscle-specific kinase [MuSK]+, 1 seronegative, by history) who received six weekly infusions of Descartes-08 exhibited clinically meaningful improvement in common MG severity scales at Month 3. Further, three of the 7 participants achieved minimal symptom expression (MSE). Here, we report the results of the final per-protocol one year follow-up. Descartes-08 maintained a favorable safety profile, with no new product-related adverse events reported during the 12-month follow-up period. At Month 9 follow-up - approximately 7 months after the final infusion - all participants continued to experience substantial clinical responses as measured by the MG Activities of Daily Living Score (Figure 1A), MG Composite Score (Figure 1B), Quantitative MG scores (Figure 1C), and others. Notably, at Month 12, 5 of the 7 participants maintained clinically meaningful improvement, including one with MSE. Two participants exhibited worsening disease at Month 12 and became eligible for retreatment. One opted for retreatment, which led to a rapid decrease in MG-specific clinical scores and MSE. The MSE is ongoing at Month 6 of retreatment follow-up (Figure 1D). All three participants with detectable anti-AChR levels at baseline also showed lasting reductions in these auto- antibody levels (Figure 1E). In summary, we observed continued clinical improvement and autoantibody reductions after BCMA-directed rCAR-T treatment that persisted through the one-year follow-up period. A patient with clinical relapse at Month 12 again achieved MSE after redosing. The favorable safety profile of this mRNA CAR-T treatment contrasts with DNA-based CAR-T treatments, which require lymphodepletion chemotherapy with potential hematologic toxicities and oncogenic risk from genomic integration of CAR DNA. Our observations suggest that using rCAR-T therapy to target BCMA-positive cells—including PCs—can result in durable depletion of autoantibodies and clinically meaningful improvement in MG severity scores without severe toxicity,

agammaglobulinemia, or increased risk of infection. These data support continued development of Descartes-08 in myasthenia gravis and other autoantibody-associated autoimmune disorders.

242. Safety, Tolerability, and Clinical Assessment of Bemdaneprocel for Parkinson's Disease: Results up to 18 Months from a Phase 1 Study

Claire Henchcliffe[1], Harini Sarva[2], Andres Lozano[3,4], Alfonso Fasano[4,5,6], Suneil Kalia[3,4], Kenny Kwok Hei Yu[7], Cameron Brennan[7], Whitney Stemple[8], Nauman Abid[8], Marcus Yountz[8], Ahmed Enayetallah[8], Antoine Lampron[8], Viviane Tabar[7]

[1]Department of Neurology, University of California, Irvine, Irvine, CA,[2]Department of Neurology, Weill Cornell Medicine, New York, NY,[3]Division of Neurosurgery, University of Toronto, Toronto, ON, Canada,[4]Krembil Brain Institute, Toronto, ON, Canada,[5]Division of Neurology, University of Toronto, Toronto, ON, Canada,[6]Edmond J Safra Program in Parkinson's Disease, Morton and Gloria Shulman Movement Disorders Clinic, Toronto Western Hospital, Toronto, ON, Canada,[7]Department of Neurosurgery and Center for Stem Cell Biology, Memorial Sloan Kettering Cancer Center, New York, NY,[8]BlueRock Therapeutics LP, Cambridge, MA

Background: Bemdaneprocel is an investigational cellular therapy comprising pluripotent stem cell-derived dopaminergic neuron precursor cells under development for the treatment of Parkinson's disease. This first-in-human phase 1 study assesses the safety, tolerability, and clinical outcomes of bemdaneprocel in participants with Parkinson's disease. **Methods**: In this open-label, 24-month, non-controlled study, 12 participants received 1 of 2 doses of bemdaneprocel bilaterally delivered to the post-commissural putamen and a 1-year immunosuppression regimen. The primary objective was safety and tolerability at 1 year. Exploratory clinical outcomes were also evaluated. **Results**: In the primary analysis at 1 year (previously presented), 2 serious adverse events (SAEs) unrelated to bemdaneprocel were reported, 1 in each cohort: a hospitalization due to COVID-19 and a transient seizure 1 day after surgery. Treatment-emergent adverse events (TEAEs) reported by 11/12 participants were mostly mild or moderate in severity (65/66), and none were considered related to bemdaneprocel. Early trends toward clinical improvement (median [Q1, Q3] change from baseline) at 12 months included: Movement Disorders Society-Unified Parkinson's Disease Rating Scale (MDS-UPDRS) Part III OFF scores and patient-reported Good ON times of 1.0 (−26.0, 13.0) and +0.7 (−0.4, 1.0) hours, respectively, in the low-dose cohort, and −13.0 (−20.0, −4.0) and +2.2 (−0.4, 2.2) hours, respectively, in the high-dose cohort. Median (Q1, Q3) change from baseline in patient-reported OFF time was −1.6 (−1.7, −0.4) and −1.9 (−2.2, 0.4) hours in the low-dose and high-dose cohorts, respectively. **Conclusions**: Bemdaneprocel was well tolerated, with no major safety issues in all 12 participants through 1 year. Exploratory clinical measures suggested improvements in MDS-UPDRS Part III OFF scores and patient-reported Good ON time and OFF time. Safety and clinical outcomes with 18 months of follow-up, 6 months post discontinuation of immunosuppression, will be presented.

243. Eighteen-Year Follow-Up of GD2 Chimeric Antigen Receptor-Cytotoxic T Lymphocyte Therapy in Patients with Neuroblastoma

Che-Hsing Li[1,2,3], Sandhya Sharma[1], Andras Heczey[1,3], Chrystal Louis[1], David Steffin[1,3], Bambi Grilley[1,4], Sachin Thakkar[1], Mengfen Wu[4], Tao Wang[4], Cliona Rooney[1,4], Malcolm Brenner[1,4], Helen Heslop[1,4]

[1]Center for Cell and Gene Therapy, Baylor College of Medicine–Texas Children's Hospital–Houston Methodist Hospital, Houston, TX,[2]Program in Immunology & Microbiology, Baylor College of Medicine, Houston, TX,[3]Center for Advanced Innate Cell Therapy, Department of Pediatrics, Baylor College of Medicine, Houston, TX,[4]Dan L. Duncan Comprehensive Cancer Center, Baylor College of Medicine, Houston, TX

In a clinical trial open to accrual from 2004 to 2009 (NCT00085930) we treated children with neuroblastoma using immune effector cells genetically modified with chimeric antigen receptors (CARs) directed to the GD2 antigen expressed by neuroblastoma cells. We administered two different types of immune effector cells: EBV-specific cytotoxic T lymphocytes and CD3 activated T cells - each genetically modified with one of two distinguishable barcoded transgenes encoding the same CAR. We previously reported the initial and 5-year follow-up of this study in 19 patients with high-risk neuroblastoma: 8 (42.1%) in remission at infusion and 11 (57.9%) with active disease; we now report a median follow-up of 13.9 years (range 8.7 - 18.2 years) post-infusion for surviving patients. Of the 11 patients with active disease at the time of infusion, 3 patients achieved a complete response. One subsequently relapsed but two had sustained responses with one for 8 years until lost to follow-up and one for 18+ years. Of 8 patients with no evidence of active disease (NED), 5 had a history of relapsed disease and 3 were infused after completing therapy for high-risk disease. Five of these patients are disease free at their last follow-up with a median follow-up of 13.9 years (range 10.1 - 14.0 years) post-infusion. The median overall survival was 2.5 years (95% CI: 0.5 - NA years for all patients) (0.8 year, 95% CI: 0.2 - 6.8 years for patients with active disease, but not reached for patients with NED, $p = 0.019$, **Figure 1**). The median event-free survival was 0.9 year (95% CI: 0.2 - NA years for all patients) (0.3 year, 95% CI: 0.1 - 4.9 years for patients with active disease, but not reached for patients with NED, $p = 0.044$). The toxicities observed during this long-term follow-up were attributable to previous chemotherapy, with sensorineural hearing loss the commonest. One patient developed invasive ductal carcinoma of the breast 12 years after infusion. We detected low levels of GD2CAR transgene in the tumor

sample likely representing long-persisting CAR-T cells, an observation consistent with reports that breast cancer stem cells may express their targeted antigen, GD2. In conclusion, patients with refractory/relapsed neuroblastoma achieved long-term disease control after receiving GD2 CAR-T cell therapy including a patient in remission of relapsed disease for >18 years without subsequent therapy.

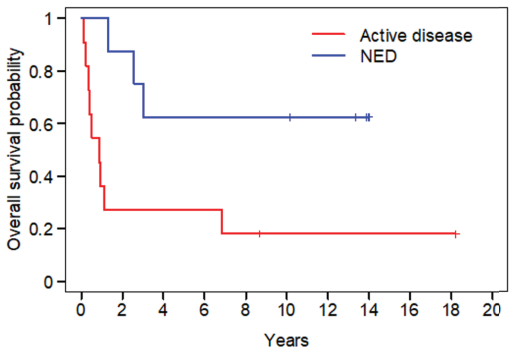


Figure 1. The median overall survival is 2.5 years (95% confidence interval 0.5 - NA years for all patients; 0.2 – 6.8 years in patients with active disease and not reached in patients with no evidence of active disease; $p = 0.019$, Log-rank test).

244. Efficacy and Safety of BRL-101, CRISPR-Cas9-Mediated Gene Editing of The BCL11A Enhancer in Transfusion-Dependent β-Thalassemia

Biao Zheng[1], Rongrong Liu[2], Xinhua Zhang[3], Bin Fu[4], Yajing Xu[4], Jun Shi[5], Xiaoqin Feng[6], Dali Li[1], Yuxuan Wu[1], Mingyao Liu[1], Yongrong Lai[2]

[1]BRL Medicine Inc., Shanghai, China,[2]The First Affiliated Hospital of Guangxi Medical University, Nanning, China,[3]923rd Hospital of the People's Liberation Army, Guangxi, China,[4]Xiangya Hospital, Central South University, Hunan, China,[5]Institute of Hemalology & Blood Diseases Hospital, Chinese Academy of Medical Sciences, Tianjin, China,[6]Nanfang Hospital Southern Medical University, Guangzhou, China

BACKGROUND: β-Thalassemia is an inherited hemolytic disease that is prevalent worldwide. Over 200 mutations in the HBB gene, which encodes adult hemoglobin (HbA), result in β-thalassemia. Hereditary persistence of fetal hemoglobin (HbF) can alleviate the symptoms of anemia. CRISPR-Cas9-mediated disruption of the BCL11A erythroid enhancer results in the reduction of BCL11A expression and the induction of fetal γ-globin, which is a practicable therapeutic strategy for treating transfusion-dependent β-thalassemia (TDT). ***METHODS:*** We obtained mobilized autologous CD34$^+$ cells from 9 TDT patients sponsor initiated in phase I/II clinical trial (NCT05577312) and 6 TDT patients in investigator initiated clinical study(NCT04211480, NCT04205435)respectively. These cells were edited with CRISPR-Cas9 RNP at the +58 erythroid specific enhancer region of the BCL11A gene and then reinfused after the patients had undergone myeloablative busulfan conditioning. We subsequently monitored adverse events, neutrophil and platelet engraftment. ***RESULTS:*** Between October 15, 2019, and August 24, 2023, 15 patients with TDT were enrolled and received BRL-101 with a median age of 11.5 years (6-26). Among all the treated patients, 8 patients were β^0/β^0 phenotype, 3 patients were β^0/β^+ phenotype,3 patients were β^+/β^+ phenotype, and 1 patient was β^0/β^E phenotype. As of November 27, 2023, the median follow-up was 9.8 months (3.2-43.6 m) (Tab.1). The longest duration of TI was 41.6 months. The levels of mean HbF increased significantly from 2.1 to 150.2 g/L and the mean total hemoglobin inceased from 114.1 to 152.0 g/L after BRL-101 infusion (Fig.1). At 5 months after BRL-101 infusion, the proportion of HbF-expressing red blood cells in peripheral blood had reached 96.5%, and then continued to rise and remained around 98-99% (Fig.2). Treatment-related adverse events were typical of those associated with myeloablation and autologous stem-cell transplantation, mainly manifested as hematological toxicities (Tab.2, Tab.3). 3 patients experienced adverse events (AEs) grade ≥3 which related to BRL-101. 4 patients experienced serious AEs (SAEs), including decreased platelet count, shock, febrile infection, soft tissue infection, and veno-occlusive liver disease. Only decreased platelet count may related to BRL-101, the others were due to busulfan treatment. All the SAEs were resolved. No study drug-related withdrawals or deaths occurred during treatment. ***CONCLUSIONS:*** Whether genotype was β^0/β^0 or non-β^0/β^0, BRL-101 demonstrated clinically meaningful increases in total Hb and HbF which occurred early and have been maintained over time, the safety profile of BRL-101 is generally consistent with that of myeloablative conditioning and autologous hematopoietic stem cell transplant. The updated data with 15 patients reported here are consistent with previous reports and support continued investigation of BRL-101 as a potential functional cure for patients with TDT.

Fanconi anemia (FA) is an inherited deoxyribonucleic acid repair disorder that results in progressive bone marrow failure (BMF) within the first decade of life in 80% of patients. Allogeneic hematopoietic stem cell transplant is curative for FA-related BMF with survival that exceeds 80% in experienced transplant centers, however adverse effects including 100-day mortality, severe infections, graft-vs-host disease and increased cancer risk present persistent limitations. We previously reported that autologous hematopoietic stem and progenitor cells (HSPCs) transduced with a lentiviral vector carrying the *FANCA* gene (RP-L102), administered without antecedent conditioning, conferred genetic and phenotypic correction as well as hematologic stability in at least 6 patients with FA-A treated in Rocket-sponsored studies with ≥1 year of follow up. Given that insertional mutagenesis is a potential risk associated with lentiviral (LV)-mediated gene therapy, we now provide data from longitudinal integration site analyses (ISA) conducted to assess clonal diversity and insertion site genomic location within patients' hematopoietic cells following RP-L102 administration. Patients with *FANCA* mutations, age ≥ 1 year, no HLA-matched sibling donor and ≥30 CD34+ cells/μL in bone marrow (BM) were eligible. Peripheral blood (PB) cells were collected via leukapheresis. Following CD34+ enrichment, HSPCs were transduced with a LV vector carrying the *FANCA* gene, and infused without cryopreservation or conditioning. Patients are followed for 3 years in the parent study and then in a long-term follow-up study. Peripheral blood mononuclear cell (PBMC) ISA was conducted regularly in a central laboratory to assess for overall clonality and any potentially predominant clonality, defined as an integration site with a VCN-normalized relative contribution ≥10%. Data are presented for all 23 patients treated with RP-L102 across Rocket-sponsored studies and FANCOLEN-I, a prior Investigator Initiated Study. As of Sept, 2023, mean [SD] follow-up was 3.57 [1.96] years (range: 0.4-7.7). Overall clonality and diversity indices (Gini, Shannon and UC50) indicated predominantly polyclonal integration patterns (range: oligoclonal to highly polyclonal). There was no evidence of RP-L102 related oncogenesis in any patient. Sequential ISA in patients treated with RP-L102 for up to 7.7 years demonstrated no insertional oncogenesis. These data contribute to the continuing favorable overall benefit:risk profile of RP-L102 as an *ex vivo* LV gene therapy for treatment of FA-A.

246. Autologous *Ex-Vivo* Lentiviral Gene Therapy for Pediatric Patients with Severe Leukocyte Adhesion Deficiency-I Provides Sustained Efficacy with a Favorable Safety Profile

Background: Severe leukocyte adhesion deficiency-I (LAD-I) is a primary immunodeficiency caused by mutations in the *ITGB2* gene that encodes the common subunit of β2-integrins (CD18), which is essential for neutrophil adhesion to inflamed endothelium and migration into tissues. Severe LAD-I, predominantly defined as <2% of normal CD18 polymorphonucleocyte (PMN) expression, is characterized by frequent and often refractory bacterial and fungal infections, and significant pediatric mortality in the absence of allogeneic hematopoietic stem cell transplant (alloHSCT) which is curative but limited by donor availability, graft-versus-host disease, and graft failure. The gene therapyRP-L201 employs autologous CD34+ cells transduced with a lentiviral vector carrying *ITGB2* to restore CD18 expression. **Methods:** Patients ≥3 months old with severe LAD-I were enrolled in this Phase I/II study (NCT03812263). Hematopoietic stem cells, collected via apheresis after mobilization with G-CSF and plerixafor, were transduced *ex-vivo* with Chim-CD18-WPRE-LV (RP-L201, marnetegragene autotemcel). Myeloablative therapeutic drug-monitored busulfan conditioning preceded RP-L201 infusion. Patients were followed for safety and efficacy, including survival in the absence of alloHSCT to ≥1 year post-infusion and to 2 years for patients <1 year old at enrollment; peripheral blood (PB) PMN CD18 expression; PB vector copy number (VCN), leukocytosis improvement

and decreased infection-related hospitalizations. **Results:** Nine patients (age 5 months to 9 years) received RP-L201with median (range) follow-up of 29.3 (21.7-44.8) months; eight patients have completed ≥2 years follow-up. RP-L201 cell doses ranged from $2.8x10^6$to $10x10^6$ CD34+ cells/kg with a drug product VCN of 1.8 to 3.8. AlloHSCT free survival is 100%. No patients have had graft failure or graft-versus-host disease. Pre-treatment leukocytosis improved uniformly. Infection-related hospitalizations and prolonged hospitalizations (≥7 days)were markedly reduced ($p < 0.0001$) following therapy. All nine patients had sustained restoration of PMN CD18 expression (median over 18 to 42 months post-infusion: 17.4%to 87.4%) with concomitantly sustained genetic markings (median VCN/PBMC over 18to 42 months: 0.7-4.0). No RP-L201-related serious adverse events were reported. No evidence of replication-competent lentivirus has been observed. Insertion site analyses indicate highly polyclonal integration patterns across the entire cohort. **Conclusion:** RP-L201 has a favorable safety profile and confers durable correction of the severe LAD-I phenotype in all nine pediatric patients treated, eight of whom have ≥2 years of follow-up, as demonstrated across all relevant clinical and laboratory parameters.

AAV Vectors - Preclinical and Proof-of-Concept: Technology Focus

247. S/MAR-Containing AAV Vectors Result in an Increase in AAV Episomes & a Reduction in AAV Integration Sites in a Mouse Model with a High Rate of Hepatocyte Proliferation

Andrea Llanos-Ardaiz[1], Aquilino Lantero[1], Marina Ruiz de Galarreta[1], Leire Neri[1], Itsaso Mauleón[2], Martin Bilbao[2,3], Blanche Tamarit[4], Veronica Ferrer[4], Anne M. Douar[4], Jean-Philippe Alex Combal[4], Rafael Aldabe[2], Gloria Gonzalez-Aseguinolaza[1,2]

[1]Vivet Therapeutics, Pamplona, Spain,[2]DNA & RNA Medicine Division, Centre for Applied Medical Research (CIMA), University of Navarra, Pamplona, Spain,[3]IdISNA, Navarra Institute for Health Research, Pamplona, Spain,[4]Vivet Therapeutics, Paris, France

Scaffold/matrix attachment regions (S/MARs) are highly conserved ubiquitous DNA sequences that are involved in chromatin organization and gene regulation. Studies have shown that these sequences are able to increase expression and facilitate nuclear retention of exogenous DNA that contain them, allowing the exogenous DNA to replicate in synchrony with the host genome. Adeno Associated Viruses (AAVs) are single stranded DNA vectors broadly used for gene therapy (GT) due to their good safety profile and therapeutic efficacy. AAVs have a very low integration rate, although some integration events have been observed with both wtAAVs and rAAVs. Due to the non-integrative nature of AAV, their genomes, that remain as episomes, are lost upon division of the transduced cells, and thus therapeutic efficacy in growing organs, such as the infant liver, is transient. Hereditary tyrosinemia type I (HT1) is an autosomal recessive disease arising from mutations in the fumarylacetoacetate hydrolase (FAH) coding gene resulting in disruption of the tyrosine catabolism pathway. This leads to the accumulation of toxic metabolites that cause liver failure as well as kidney damage. The standard of care consists of daily dosing of 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) that prevents the production of toxic metabolites and ultimately of liver transplant. Using an HT1 mouse model (Fah1R Tyrc/RJ), in which corrected hepatocytes have a selective advantage, we questioned whether the presence of a S/MAR sequence in an AAV expressing hFAH would favour maintenance of the AAV genome as an episome while inducing its replication in synchrony with hepatocyte regeneration, leading to a sustained therapeutic effect in damaged livers. Mice were injected with a subtherapeutic dose (1E11 vg/kg) of either a control AAV (AAV-FAH) or an AAV with the S/MAR sequence inside (AAV-FAH-S/MAR-pA) or outside (AAV-FAH-pA-S/MAR) the transcriptional unit. NTBC was withdrawn 2 weeks post AAV injection (p.i.) and body weight (BW) and serum biomarkers (SB), were followed periodically until 20% BW loss or to 70 days p.i., at which point the mice were sacrificed. Viral genomes and hFAH expression levels in liver were quantified by qPCR. FAH^+ liver area was detected by IHC, and viral integration was analysed by S-EPTS/LM-PCR. Results showed that AAV-FAH-S/MAR-pA achieved higher therapeutic effect (66.7% survival), than either the control (15% survival) or the AAV-FAH-pA-S/MAR vector (40% survival). Three different phenotypes were observed upon NTBC withdrawal based on BW and SB: failed, recovered, and stable mice. Survivors showed BW and SB normalization after approximately 50 days p.i. and the number of viral genomes and hFAH expression levels were similar between experimental groups. IHC showed FAH expression in clusters of positive hepatocytes in recovered mice, suggesting potential AAV integration and clonal expansion. Importantly, S-EPTS/LM-PCR studies revealed higher presence of episomal AAV genomes, read as vector-vector junctions, in the group treated with AAV-FAH-S/MAR-pA (2-fold difference vs. the control group), furthermore the number of integration sites was reduced in comparison to the other two groups. These results indicate that not only the presence of the S/MAR sequence, but also its position within the therapeutic vector, influence the fate of the viral genome in the transduced cell.

248. A Durable Gene Therapy with a Robust AAV-LNP Delivery System Allowing for a Reduced AAV Dose

Matthew Nitzahn, Bernard Kok, Oscar Alvarez-Garcia, David Ebeid, Lucas Homa, Khalid Hajj, Zhibo Ma, Alicia Davis, Cindy Negron, Joshua Rychak

Poseida Therapeutics, San Diego, CA

Adeno-associated virus (AAV) vectors have strong potential for treating genetic diseases but can face dose-related toxicity hurdles, especially when a high proportion of cellular correction is needed. Achieving lifelong expression of the therapeutic transgene is also challenging with AAV, particularly when treating children. Technologies that enable genomic integration of a therapeutic transgene have the potential to provide durability and possibly boost transgene expression. Our piggyBac™ DNA insertion system is unique in its ability to integrate large cargo into regions of the genome that support robust expression. Super piggyBac (SPB) is an enhanced transposase that enables highly efficient genome integration. In the current studies, we explored the feasibility of combining existing AAVs with SPB and demonstrate substantial reduction in AAV dose in two animal models of disease.

We first developed a lipid nanoparticle (LNP) for SPB mRNA delivery and an AAV transposon vector for liver-targeted gene expression. *In vivo* tolerability and pharmacology studies were conducted in rodents and non-human primates to characterize novel LNPs in combination with liver-tropic AAV capsids (AAV8, AAV9, or KP1). Integrated vector copies were dose-responsive (1-3 per cell) with a genomic insertion profile similar between human and mouse cells, and no bias toward exon sequence. We next tested this hybrid system in neonatal and adult mouse models of Ornithine Transcarbamylase Deficiency (OTCD) and Phenylketonuria (PKU), respectively. Using a mouse model of PKU (B6.BTBR-*Pah*^{enu2}/MalnJ), adult animals were dosed an AAV-PAH transposon vector, or the same vector co-administered with SPB-LNP. We observed a striking increase (>10-fold) in the frequency of hepatocytes expressing the PAH transgene following AAV+LNP treatment relative to AAV-alone at matched dose levels. Subsequent multi-dose studies demonstrated correction with the AAV+LNP system at AAV doses 3 to 10 times lower than non-integrating AAV alone, demonstrating that piggyBac-mediated integration can enable excellent efficacy at reduced AAV dose levels. We separately evaluated the hybrid platform in a mouse model of severe OTCD to explore the feasibility of utilizing this system to treat early-onset disease. Mice were dosed on day 1 of life with an AAV-OTC transposon vector or the same vector co-administered with SPB-LNP. High (>2E13 vg/kg) doses of AAV alone did not enable survival into adulthood; in contrast, co-administration of 0.25 mg/kg of the SPB-LNP with ten times lower AAV dose (3E12 vg/kg) enabled 100% survival. Liver immunostaining showed broad (>55% cells) hepatocyte expression of OTC protein persisting for at least 6 months in hybrid-treated mice, while AAV-only treatment yielded <1% of hepatocytes expressing OTC protein ~6 weeks after treatment. These data demonstrate the utility of the hybrid platform for enabling treatment at lower AAV dose levels. Additionally, we demonstrate how the platform can extend the utility of AAV for treatment of disease early in life. The piggyBac DNA insertion system can be deployed effectively with a variety of AAV capsids and used to expand the utility of AAV-based gene therapy.

249. Novel Micro-Dystrophin Constructs for DMD Gene Therapy

Ruchita Selot, Subhradeep Sarkar, Chitra Gopinath, Riya Patra, Arkasubhra Ghosh

Center for Genetics and Gene Therapy, Grow Lab Narayana Netralaya Foundation, Bangalore, India

Introduction Duchenne Muscular Dystrophy is caused by loss of the Dystrophin protein essential for muscle function. Due to its large size, the native Dystrophin gene cannot be packaged into AAV vectors for gene therapy. Hence, smaller, truncated versions called Micro-Dystrophins have been designed and tested in animal models and clinical trials. Although such a Micro-Dystrophin therapy has received conditional approval, the results of the trial indicate that despite high doses, the functional improvement in patients is low, necessitating better designs. We have therefore tested a set of new Micro-Dystrophin vectors that differ by domain designs. **Methods** Four micro-Dystrophin constructs were designed with ubiquitous (CAG) or muscle-specific (Spc5-12) promoters and codon-optimized. The constructs GL1 (ΔR4-R15/R19-R22/H3/CTD), GL2 (ΔH2/R4-R15/R19-R23/H3/CTD), GL3 (ΔH2/R3-R15/R19-R23/H3/CTD) and GL4 (ΔH2/R3-R15/R19-R22/H3/CTD) had common N-terminal, Hinge 1 and 4, nNOS binding domains, and the cysteine rich domain. They differed in their sequences for binding to distinct domains for sarcolemmal lipoprotein interactions and microtubule-binding. Each micro-gene was packaged in AAV9 capsids and delivered to *mdx* mouse TA muscles at a dosage of 1x10^9vg/muscle. GL3 was further injected systemically at a dosage of 3.5x10^{13}vg/kg with AAV9.eGFP as control in *mdx* mice via tail vein. Post-sacrifice, muscle tissues were analyzed for transgene expression, DAG complex, immune infiltration, and centro-nucleation. **Results** Expression of Dystrophin was observed in all four constructs, with GL1 (65.5±3.89%) and GL3 (70.71±3.08%) exhibiting significantly higher levels compared to GL2 (42.79±5.08%) and GL4 (38.47±3.536%) [***=p<0.0001, one-way ANOVA]. Furthermore, GL1 (42.266±0.039%) and GL3 fibers (36.0±7.69%) displayed minimal aggregation of nuclei in muscle, in contrast to the control (69.65±0.08%). Additionally, GL1 (10.1±1.62%) and GL3 (8.3±1.60%) constructs demonstrated lower levels of macrophage infiltration compared to the control (24.80±2.059%) and significantly higher levels of nNOS and Dystroglycan restoration (p<0.05). This observation was supported by a significant increase (***=p<0.0002) in both distance and time on the treadmill for *mdx* mice with GL3 systemic injection compared to sham-injected mice, indicating enhanced muscle function. **Discussion and Conclusion** Our findings indicate that the strategic choice of Dystrophin domains [GL1(ΔR4-R15/R19-R22/H3/CTD) and GL3(ΔH2/R3-R15/R19-R23/H3/CTD)] facilitated efficient Dystrophin expression, and resulted in sarcolemmal localization resulting in restoration of DAG complex. We anticipate that GL1 and GL3 constructs will contribute favorably towards ameliorating the DMD phenotype.

250. Addressing the Translational Potential of Neurotropic AAVs Using Functionally Mature Human Stem Cell-Derived Blood-Brain Barrier Organoids

Angelo Iannielli[1], Martina Greco[1], Serena G. Giannelli[1], Mirko Luoni[1,2], Benjamin E. Deverman[3], Vania Broccoli[1,2]

[1]Ospedale San Raffaele, Milan, Italy,[2]Institute of Neuroscience, CNR, Milan, Italy,[3]Broad Institute, Cambridge, MA

Novel AAV9 engineered capsids have been selected for their superior ability to cross the blood-brain barrier (BBB) and diffuse into the brain parenchyma after intravascular administration. However, their behaviors have been assessed in mice up to non-human primates, but whether the same capacity remains unchanged in a human setting remains unknown. To address this, we established improved procedures to differentiate human pluripotent-stem cells (hPSCs) into endothelial, mural and astroglial cells by defining an original combination of small molecule cocktails with the expression of cell lineage-specific master regulators. To assemble the three cell types together we decided to generate organoids that recapitulate the spatial organization of the BBB on a transwell filter (fBBBOs). We demonstrated that fBBBOs display a tight and homogeneous endothelial cell layer with well-organized cell junctions clustering key endothelial cell junction components including Glut1 and Occludin. BBBOs developed high functional properties with high values of trans-epithelial electric resistance (TEER) and

impermeability to high molecular mass dyes. Furthermore, we tested the fBBBO endothelial integrity by assessing any eventual crossing of AAV2 and lentiviruses (LVs) that notoriously are incapable to trespass this biological barrier in vivo. Indeed, the fBBBOs effectively blocked the diffusion of both LVs and AAV2. In contrast, the AAV-PHP.B was able to efficiently transverse the fBBBOs only when expressing its transcytosis receptor Ly6A. These results demonstrate that BBBOs have acquired a highly selective permeability. Altogether, the deployment of cell lineage master improves the consistency of cell differentiation and subsequent maturation state. Spatially-defined cultures of endothelial, mural and astroglial cells produced a robust in vitro neurovascular model with long-lasting stability and functions. Human fBBBOs offer a neat system for testing the translational potential of new brain shuttling agents, including the new AAV engineered variants exploited in animals or in vitro.

251. *In Situ* Biodistribution and Localization of Bidridistrogene Xeboparvovec (SRP-9003) in LGMD2E/R4 Mice

Young Seo, Stephen Fasul, Chrissy Hopkins, Akansha Pradhan, Jasmine Wu, Alex Haile, Rachael Potter, Sarah Lewis, Stephen Baine, Louise Rodino-Klapac

Sarepta Therapeutics, Inc., Cambridge, MA

Background Limb-girdle muscular dystrophy type 2E (LGMD2E/R4) is caused by mutations in the β-sarcoglycan (*SGCB*) gene resulting in loss of functional SGCB protein, progressive muscle degeneration, and shortened lifespan. Bidridistrogene xeboparvovec (SRP-9003, rAAVrh74.MHCK7.hSGCB) is an investigational adeno-associated virus (AAV)-based gene therapy designed to restore functional SGCB expression in muscle and improve clinical outcomes in patients with LGMD2E/R4. RNAscope™ has recently emerged as a technology capable of determining tropism, transduction efficiency, and in-situ localization of targeted gene therapies. Here we report the use of RNAscope™ to elucidate the spatial biodistribution, cellular tropism, transgene expression, and durability of SRP-9003 following intramuscular (IM) and intravenous (IV) administration in LGMD2E/R4 mice. **Methods** The RNAscope™ in-situ hybridization (ISH) probes were designed to be non-overlapping for two-plex ISH. One probe detected AAVrh74 vector DNA only (anti-sense strand), while a second probe captured *hSGCB* transgene mRNA (sense strand) allowing evaluation of subcellular localization of vector genome DNA and *hSGCB* RNA for spatial analysis. Mouse tissues were assessed at 24 hours, 7 days, 14 days, 21 days, and 28 days following a single IM administration (3×10^{10} total vector genomes) and up to 240 days after single IV administration of bidridistrogene xeboparvovec (7.41×10^{13} vector genomes per kilogram [vg/kg]). Importantly, timepoints evaluated in the systemic study included day 60, which corresponds to the timepoint for biopsy procedure utilized in clinical studies. For RNAscope™, vector genome DNA and *hSGCB* RNA were quantitively analysed using fluorescence in-situ hybridization (FISH) and FISH- immunofluorescence (IF) algorithm with the HALO® Image Analysis Platform. Vector DNA was also quantified using digital droplet polymerase chain reaction (ddPCR) (copies per nucleus), *hSGCB* mRNA was measured using reverse transcription (RT)-ddPCR, and hSGCB protein expression was assessed using IF (as percent beta-sarcoglycan positive fibers [%PβPF] quantified with HALO® Muscle Fiber FL algorithm). **Results** Proof of principle for in-situ detection of bidridistrogene xeboparvovec was established following IM evaluation. Vector genome copies were detected in all bidridistrogene xeboparvovec-dosed animal tissues by both RNAscope™ and ddPCR 24 hours after injection with DNA levels decreasing at day 7. In contrast *hSCGB* mRNA transcript levels plateaued at day 14 using both RNAscope™ and RT-ddPCR. IF results showed consistent SCGB protein expression at day 14 through day 28 (average PβPF 54.9% and 47.6%, respectively). Systemic administration (7.41×10^{13} vg/kg) of bidridistrogene xeboparvovec revealed significant vector DNA and mRNA levels at day 60 in muscle tissue, which corresponded to robust hSGCB transgene expression and reinforced the day-60 biopsy to assess maximal SGCB expression following treatment. In addition, IV administration of bidridistrogene xeboparvovec led to significant vector DNA and mRNA expression up to 120 days post dosing in skeletal and cardiac muscle. Limited off-target effects of bidridistrogene xeboparvovec were demonstrated by lack of DNA or mRNA probe signal in selected organs (kidney, brain; D14-D120) highlighting the preferential targeting of muscle and durable efficacy of bidridistrogene xeboparvovec in LGMD2E/R4 mice. **Conclusion** This study demonstrates the applicability of RNAscope™ to determine the spatial, cellular organization, and molecular trafficking of bidridistrogene xeboparvovec. These data may be useful to inform future application of RNAscope™ for biodistribution evaluation of AAVrh74 gene therapy.

252. Transgene Protein Evolution as a Novel Strategy for Next-Gen Gene Therapy in Canavan Disease

Sarah Foley[1], Morgan Mooney[2], NhatAnh B. Nguyen[2], Anoushka Lotun[2], Guangping Gao[2,3,4], Dominic J. Gessler[2,4], Lee Coffey[1,5]

[1]Pharmaceutical and Molecular Biotechnology Research Centre, South East Technological University, Waterford, Ireland,[2]Horae Gene Therapy Centre, UMass Chan Medical School, Worcester, MA,[3]Li Weibo Institute for Rare Diseases Research, UMass Chan Medical School, Worcester, MA,[4]Co-corresponding author, Worcester, MA,[5]Co-corresponding author, Waterford, Ireland

Canavan Disease (CD) is characterised as a progressive neurodegenerative disease caused by the accumulation of N-acetylaspartate (NAA) as a result of the deficiency of aspartoacylase (ASPA) enzyme associated with mutations in the ASPA gene. ASPA is responsible for the supply of acetate for the oligodendrocytes and is essential for normal myelination. Recombinant adeno-associated (rAAV) gene therapy (rAAV9-ASPA) has been shown to rescue the CD knock-out mouse model from premature death. This has been supported by the normalisation of NAA levels and growth, improved motor function, and ASPA gene expression detected in the CNS of the treated CD mice. The advancements in the design of rAAV as a gene therapy delivery vehicle have provided significant potential for numerous rare diseases with unmet therapeutic options. One of the remaining challenges for rAAV gene therapies for CNS disorders is the high dose required to achieve sufficient transgene protein levels. The high cost associated with rAAV production and the risk of systemic toxicity is further exacerbated by the vector dose required. To offer solutions to the dosage-associated toxicity and costs, we have hypothesised that the amino acid sequence translated from the rAAV-delivered transgene can be evolved and optimised for

enhanced transgene protein activity. To explore if specific mutation(s) in the wild-type ASPA (WT-ASPA) amino acid sequence could achieve increased ASPA enzyme activity, we constructed a random mutant ASPA library (~10^3) using an optimised directed evolution approach to maximise mutation distribution and diversity. The use of a prokaryotic expression system allowed for ease of microscale protein expression and high throughput functional screening by a spectroscopic method benchmarked against the recombinant human WT-ASPA enzyme. This led to the identification of several evolved ASPA (ev.ASPA) enzyme candidates with increased enzymatic activity. Subsequently the ev.ASPA candidates underwent enzyme purification and secondary screening using a high-sensitivity chromatography method to confirm enhanced performance. To determine the *in vivo* performance of ev.ASPA, the leading candidate nucleotide sequences were cloned into rAAV9 (rAAV9-ev.ASPA) and delivered to CD mice on postnatal day 1 (P1) intravenously at a 3-fold lower dose than our clinical full dose vector expression WT-ASPA. Initial findings show disease rescue in the CD mouse model, supported by improvements in growth and motor function. In addition, none of the treated animals have succumbed to the disease. This contrasts with untreated animal's overall survival of around 24 days of age. Studies to directly compare ev.ASPA to our clinical vector is underway to determine the side-by-side *in vivo* performance of our transgene evolution approach. This approach could be a critical contribution to rAAV genome design for therapeutic applications. In terms of rAAV delivery to the CNS, this would allow for potential viral vector dose reduction, all while maintaining the therapeutic efficacy - providing a novel solution to CD and other gene therapy applications and benefiting the wider gene therapy research community.

253. Antibody Gene Therapy for Rabies Encephalitis

Jyoti Yadav[1,2], Amanda L. Gross[2], Giovanna Panepinto[2], Ywh-Min Tzou[2], S. Satheshkumar Panayampalli[3], L. Claire Godino[3], Kent R. Van Kampen[4], Nicholas J. Jones[5], April D. Davis[5], Miguel Sena-Esteves[6,7], Henry J. Baker[2], Douglas R. Martin[1,2]

[1]Department of Anatomy, Physiology, & Pharmacology, Auburn University, Auburn, AL,[2]Scott-Ritchey Research Center, Auburn University, Auburn, AL,[3]Centers for Disease Control and Prevention, Atlanta, GA,[4]The Van Kampen Group, Payson, UT,[5]Department of Health, Wadsworth Center Laboratory, Albany, NY,[6]Department of Neurology, University of Massachusetts Medical School, Worcester, MA,[7]Horae Gene Therapy Center, Worcester, MA

Introduction. Rabies virus is a neurotrophic virus with almost 100% fatality. Vaccination strategies currently used to prevent rabies infection majorly rely on the generation of the host serum neutralizing antibodies. The major caveat of these antibody-based therapy is that while the rabies virus penetrates the CNS, antibodies cannot cross the blood brain barrier, making them largely ineffective in the treatment of symptomatic encephalitis. We designed a recombinant AAV9 (rAAV9) vector to traverse the blood brain barrier and express a neutralizing human antibody against rabies glycoprotein in the brain. The goal is to produce antibody-mediated protection in the CNS, independent of the host immune system. Methods. A rAAV9 vector expressing a broadly neutralizing human antibody against rabies (CR57) was used as pre- or post-exposure treatment to determine the effect of single-dose intravenous (IV) delivery on prevention or rescue of the infection in rabies-challenged mice. C57BL/6J mice were treated with low and high IV doses (1x10^{12} and 1x10^{13} vg/kg, respectively) of rAAV9, 14 days prior to rabies virus inoculation. For the rescue study, mice were immunized with 1x10^{13} vg/kg of rAAV9, 3 days after rabies inoculation, and monitored for 70 days. We analyzed rabies neutralizing antibodies in serum using Fluorescent Antibody Virus Neutralization (FAVN) and in brain by IHC. Additionally, 4-month-old cats were treated with low (2x10^{12} vg/kg) or high (1x10^{13} vg/kg) IV doses of rAAV9 and tissues were analyzed. Results. The IV delivery of rAAV9 14 days prior to rabies inoculation prevented disease in 100% (16 of 16) and 88% (14 of 16) of mice in the high- and low-dose cohorts, respectively. Rabies-inoculated, saline treated control mice (6 of 7) reached a predetermined humane endpoint within 11 days and tested positive for the rabies virus in postmortem samples. The rabies neutralizing antibody level in mouse serum from the end of study was >1000 times higher than the protective titer recommended by the WHO (0.5 IU/ml) after the high dose of rAAV9 vector. The expression of neutralizing antibodies was further tested in brain cells by IHC. In the post-exposure study, 92% (11 of 12) of mice survived when treated with the high dose of rAAV9 3 days after rabies inoculation (*Fig 1*). In rAAV9-treated cats, the high-dose treatment group showed significant levels of neutralizing antibodies in serum for at least 15 months and in CSF for 3 months post-injection. The decline in rabies neutralizing antibodies in feline serum after 15-months is due to the development of cat immune response against human CR57. Nonetheless, rabies neutralizing antibodies were detected in the feline brain of the high-dose treatment group at endpoint by IHC (*Fig. 2*). Conclusions. An AAV9 vector injected intravenously in rabies-challenged mice expresses broadly neutralizing antibodies in brain cells and protects against rabies infection in mice. Cats treated by IV injection of the same rAAV9 vector express rabies neutralizing antibodies in serum and brain for at least one year.

Fig. 2: Analysis of broadly neutralizing rabies antibodies (represented by brown stained neurons) in the brain section of rAAV9 treated cats 24 months post injection.

On- and Off-Target Method Development

254. Precise Measurement of CRISPR Genome-Editing Outcomes through Single-Cell DNA Sequencing

Ayal Hendel[1], Nechama Kalter[1], Michael Rosenberg[1], Saurabh Gulati[2], Shu Wang[2], Benjamin Schroeder[2], Alex Li[2]

[1]The Institute for Advanced Materials and Nanotechnology, The Mina and Everard Goodman Faculty of Life Sciences, Bar-Ilan University, Ramat-Gan, Israel,[2]Mission Bio, South San Francisco, CA

CRISPR-Cas genome-editing technology is rapidly integrated in diverse clinical applications for the treatment of various diseases. However, the clinical utilization of this technology encounters a bottleneck in the form of off-target activity, the inadvertent cleavage of the Cas nuclease at genomic loci beyond the intended targets. Off-target activity results in the formation of insertions and deletions (inDels) and structural variations (SVs), potentially driving oncogenic mutations. Many studies have characterized off-target activity at a cell-population level using bulk-sequencing-based methods. Nevertheless, these approaches lack sufficient sensitivity to study the off-target implications at the resolution of individual cells. To address this gap, we have harnessed the Tapestri technology, a single-cell DNA sequencing (scDNA-seq) platform which enables the sequencing of CRISPR-edited cell products at a single-cell level. This technology offers high-resolution insights into the co-occurrence of on-target and off-target editing, zygosity of editing profile, precise editing activity measurement per cell and per allele, and cell clonality. Furthermore, unlike conventional amplification-based bulk sequencing methods, which only report SVs presence, single-cell data enables the capture of the SVs frequency while integrating the inDels data. The enhanced resolution is primarily pivotal in CRISPR experimental designs aimed to simultaneously edit multiple biological targets, to ensure a genome-editing product that is edited at all specified targets. Hence, we have engineered human primary T-cells donors using a multiplex three guide RNAs (gRNAs) complex, designed to knock-out the *PDCD1*, *TRAC*, and *TRBC* anti-cancer targets. To address the off-target activity of these guides, we created a panel comprising of 111 putative off-target sites based on prior GUIDE-seq experiments, and sequenced these sites using the Tapestri platform, generating output data of ~10,000 edited cells per donor. Next, we evaluated the inDel profile at each allele, and quantified the CRISPR editing activity. Interestingly, different gRNAs showed different ratios of mono-allelic versus bi-allelic editing. Furthermore, only a minority of the cell population harbored bi-allelic frameshift mutations across all on-target sites. Single-cell analysis also revealed a heterogenous spectrum of CRISPR outcomes, with a unique on-target and off-target profile per cell, highlighting the importance of thoroughly characterizing the genome-engineered cell product. We also identified translocations and long-deletions between on-target and off-target loci. CRISPR editing-activity and translocations results were validated using bulk DNA sequencing using rhAmp-Seq technology, attesting to a high degree of reproducibility. In summary, the utilization of single-cell DNA sequencing for the assessment of off-target activity outperforms prevailing standards by (1) facilitating precise measurement of editing activity at both on- and off-target sites; (2) comprehensive profiling of the editing outcomes, encompassing the co-occurrence of editing outcomes; and (3) sensitive SVs identification. This comprehensive high-resolution methodology represents a leap forward in our understanding of CRISPR outcomes, while also serving as a platform for a highly sensitive quality control assessment of genome-engineering products, holding the potential to enhance and optimize therapeutic applications of the CRISPR-Cas platform.

255. Heterogeneous On-Target Genomic Rearrangements Occur upon Long Range Gene Editing in T-Cells

Daniele Canarutto[1], Claudia Asperti[1], Stefano Beretta[1], Chiara Gaddoni[1], Gabriele Pelosi[1], Elisabetta Rovelli[1], Simona Porcellini[1], Samuele Ferrari[1], Chiara Brandas[2], Maria Carmina Castiello[1,3], Anna Villa[1,3], Marina Radrizzani[1], Luigi M. Naldini[1,4]

[1]SR-TIGET Telethon Institute for Gene Therapy, Milan, Italy,[2]Translational and Molecular Medicine (DIMET), University of Milano-Bicocca, Monza, Italy,[3]UOS Milan Unit, Istituto di Ricerca Genetica e Biomedica (IRGB), CNR, Milan, Italy,[4]Vita-Salute S. Raffaele University, Milan, Italy

Introduction Long-range gene editing by homology driven recombination (HDR) of primary haematopoietic cells is a promising and currently almost unique strategy for the targeted integration of long DNA sequences under clinically feasible conditions. HDR-based gene editing is expected to result in precise integration of a single copy of the donor template in the target locus, and bona-fide HDR is commonly assessed by droplet-digital PCR (ddPCR). However, this approach is blind to imprecise and heterogeneous structural outcomes. Here we unbiasedly assessed genomic outcomes with optical genome mapping (OGM) and Oxford Nanopore sequencing (ON) upon long-range HDR editing of T-cells with Cas9 and an integrase defective lentiviral vector (IDLV), overcoming the limitations of PCR-based technologies. **Methods** Human male CD4 T-cells were edited at the X-linked *CD40LG* locus with Cas9 ribonucleoprotein and IDLV donor template carrying a functional truncated CD40LG cDNA for corrective knock-in into the locus coupled with LNGFR reporter, in GMP-like conditions. Correctly edited cells were then enriched by immunomagnetic selection and expanded as previously reported. OGM effective coverage was >1400X; data was analyzed with the rare variant pipeline. For ON, up to 6 gRNAs were designed to frame a region of interest of 3.8-7kb in the *CD40LG* locus. High molecular weight DNA was extracted and processed with modified Oxford Nanopore Cas9 sequencing kit. Reads were aligned using the wf-aligment Epi2me pipeline and then annotated manually. **Results** Having previously validated OGM for assessment of genomic rearrangements, we first uncovered the presence of template concatemers at the target site upon editing. We then sought to sequence on-target outcomes by ON. After workflow optimization, we acquired ≈340k reads/sample with an on-target enrichment of ≈0.1% per run. Median on-target read length was 7kb (range 0.2-76). As expected, a small percentage of the reads mapped to the native locus with or without small indels. About half of the on-target reads spanned the entire locus and supported bilateral HDR events at both the 5' and 3' homology arms, and HDR frequency was found to be similar to that measured by ddPCR. Interestingly, IDLV concatemers containing up to 6 long-terminal repeats were found in about 1/8

of the reads. Moreover, about 10% of the reads were unique and contained heterogeneous rearrangements, involving the native locus, the donor template, and/or other chromosomal regions. Notably, as the cell product underwent purifying selection for reporter expression from the hemizygous targeted locus, the vast majority of outcomes were compatible with transgene expression and may thus represent a fraction of those generated in the editing process. **Conclusions** IDLVs may constitute concatemers that can be integrated on-target. Complex on-target rearrangements can occur upon HDR editing of T-cells, and occasionally include genomic sequences from distant loci. Such trapping of unexpected sequences may also occur also with Cas9 alone, alternative donor templates, and different primary cell types. While some of these outcomes may not raise safety concerns and even be compatible with the intended goal of editing, the extent and breadth of heterogeneity occurring at the targeted locus defies the expectation of precision engineering and supports coupling the process to a natural or engineered purifying selection for safe clinical translation.

256. Selecting Highly Conserved and Specific Guide RNAs for CRISPR/CasX-Mediated Gene Editing of the HSV-1 Genome

Meltem Isik, Kevin Luk, Nadia Amrani, TJ Cradick, Jennifer Gordon, Guoxiang Ruan

Excision BioTherapeutics, Watertown, MA

Herpes simplex keratitis (HSK), caused by herpes simplex virus type 1 (HSV-1) infection of the cornea, is a major cause of blindness worldwide. After the primary infection of the ocular surface, HSV-1 is transported into trigeminal ganglia (TG) and other ganglia to establish lifelong latency, from which reactivation of the virus causes recurrent disease. Current anti-HSV-1 therapies, such as acyclovir, valacyclovir, and famiciclovir, interfere with the replication of viral DNA. However, these antiviral agents do not eliminate the latent HSV-1 reservoirs, and thus are only suppressive rather than curative. CRISPR-Cas-mediated gene editing offers the potential to address the underlying causes of the disease by eliminating the latent HSV-1 reservoirs directly. CasX (type V Cas12e) from Planctomycetes (PlmCasX) has recently garnered significant attention because of its compact size (less than 1000 aa) and potential for high specificity. The large size (~152kb) of the HSV-1 genome and the genetic diversity of infections collected globally (1-4% variation in nucleotide identity between viral genomes) have made it challenging to fully understand the HSV-1 virus from a clinical genomics perspective. Many studies have examined the global genetic diversity of HSV-1, with ongoing research uncovering new genotypes as more viruses are sampled worldwide. Therefore, it is important to consider HSV-1 genetic diversity when selecting conserved lead guides for therapeutic genome editing of the HSV-1 genome. In this study, we used the CRISPR/CasX gene editing system to inactivate the latent HSV-1 virus by co-targeting two essential HSV-1 genes, ICP0 and ICP27. To perform conserved guide design, we built an Herpesviridae family CDS database using the VIPR database (version Feb, 2022; 46,027 strains and 62,554 Genbank IDs). This database was used to choose highly conserved guide RNAs. 22 PlmCasX guide RNAs targeting ICP0 and 20 PlmCasX guide RNAs targeting ICP27 were found with a perfect sequence match in over 70% of HSV-1 strains. They were also found with perfect match to the consensus sequences of ICP0 and ICP27. The 440 guide RNA pairs formed with these 42 PlmCasX guide RNAs were tested in tissue culture for DNA excision efficiency. The PlmCasX guide RNAs from the most efficacious guide RNA pairs were evaluated for possible off-target editing using homology-dependent methods (computational nomination, hybrid capture, and Amplicon-seq) and homology-independent methods (GUIDE-seq). The results were analyzed using in-house developed bioinformatics pipelines for GUIDE-seq and targeted amplicon sequencing. These pipelines are built using Nextflow, a workflow tool to run tasks across multiple compute infrastructures in a very portable manner, with direct integration of AWS S3 buckets for automated data ingestion and helps with maintaining a database for reproducible results. The off-target assessment identified several highly specific PlmCasX guide RNAs that showed no detectable off-target editing activity. In summary, our comprehensive bioinformatics platform has helped identify highly conserved and specific PlmCasX guide RNAs for inactivating the HSV-1 virus.

257. *In Silico* Prediction Tool for Meganuclease Off-Target Sites

Zhe Zhang, R. Jason Lamontagne, Jenny A. Greig, James M. Wilson

Gene Therapy Program, University of Pennsylvania, Philadelphia, PA

The disruption of genetic coding sequences via sequence-specific nucleases represents a promising genome editing approach to reduce specific protein levels for therapeutic benefit, or produce specific double-strand breaks for targeted gene insertion. We extensively evaluated the long-term safety profile of an engineered ARCUS meganuclease (M2PCSK9) expressed from an adeno-associated virus (AAV) vector in liver of rhesus macaques. The M2PCSK9 meganuclease recognizes and edits a 22-bp target site within exon 7 of the *PCSK9* gene. As part of our assessment of the safety and efficacy of the M2PCSK9 meganuclease, we have previously utilized a genome-wide assay called inverted terminal repeat sequencing (ITR-seq), to identify the M2PCSK9 meganuclease off-target sites within the macaque genome when it is delivered by an AAV vector. Following identification of off-target sites, we performed amplicon sequencing analysis to confirm and quantify editing at individual sites. In an effort to further characterize the activity of this meganuclease, we developed an *in silico* approach to predict potential off-target sites that were not detected in our ITR-seq datasets. Using this approach, an M2PCSK9 meganuclease recognition motif of 22 bases was established via a training data set of 2,530 unique off-target sites identified from 93 ITR-seq libraries. We searched for matches to this motif in both the rhesus macaque and human reference genomes and calculated a weighted matching score to each hit to measure its potential as M2PCSK9 meganuclease off-target site. Upon further investigation of the locations and matching scores of these predicted sites, we found that they were enriched around known genes. While most predicted off-target sites were not yet identified by ITR-seq training data, we did observe a strong correlation between M2PCSK9 meganuclease activity and the matching score to the 22-base motif at individual sites that have been identified. To further verify our findings, genome editing at a selection of top-scoring sites was directly assessed by amplicon sequencing in AAV-delivered, M2PCSK9 meganuclease-treated rhesus macaques. Together, this study demonstrates that the off-target activities of the M2PCSK9 meganuclease can be predicted

according to sequence similarity to a consensus motif and that *in silico* prediction of the off-target sites may be a novel and valuable tool for evaluating gene editing safety.

258. Validating EPI-321 Safety: A Comprehensive Off Target Characterization Platform for Epigenetic Gene Therapies

Linsin A. Smith[1], Tyler Borrman[1], Melanie R. Silvis[1], Emily Dabe[2], Kaitlin Pensabene[1], Siddaraju V. Boregowda[1], Abhinav Adhikari[1], Christopher Still[1], Tengyu Ko[1], Timothy Daley[1], Robin W. Yeo[1], Alexandra Collin de L'Hortet[1], Yanxia Liu[1]

[1]Epic Bio, South San Francisco, CA,[2]Excelra/BISC Global, Iselin, NJ

Genome and epigenome editing hold immense potential for precisely altering DNA and modulating gene expression, enabling therapeutic applications for previously untreatable diseases. However, there remain significant barriers to realizing this potential including developing highly precise genome and epigenome editing tools. One well-recognized obstacle is the risk of off-target effects associated with CRISPR-based editors, where unintended binding to non-target regions of the genome can lead to undesirable and potentially dangerous outcomes. Epic Bio is advancing the field of epigenetic editing to control gene expression and treat diseases that are beyond the reach of genome editing. Facioscapulohumeral muscular dystrophy (FSHD), which affects 800,000 globally with no available cure, is a prime example. FSHD is linked to hypomethylation of the D4Z4 microsatellite region on chromosome 4, which leads to the inappropriate expression of DUX4 and progressive muscle wasting in skeletal muscles. Leveraging our proprietary GEMS platform, Epic Bio has developed EPI-321, an epigenetic therapy treatment for FSHD that targets the D4Z4 region, permanently suppressing DUX4 expression by restoring DNA methylation to healthy levels. To validate the safety of EPI-321, we conducted genome-wide off-target characterization and found no direct off-target effects mediated by EPI-321. Unlike genome editing technologies employing double-strand breaks for off-target profiling, epigenome editing technologies demand more comprehensive characterization based on the intended epigenetic modification mechanism. Here, we present our all-encompassing platform for off-target evaluation and showcase its application in off target characterization of EPI-321. Our comprehensive platform integrates in silico off-target prediction, genome-wide expression profiling, genome-wide bisulfite sequencing, and targeted validation assays across various model systems in order to robustly identify putative off target effects. Application of the off-target characterization platform to EPI-321 revealed no direct off-target events caused by EPI-321 treatment, highlighting the safety and precision of our GEMS technology.

259. Off-Target Analysis Shows Favorable Safety Profile of Prime Editing

Maria Collier, Jacob Stewart-Ornstein , Marina Lilieholm, Matthew Irby, Hari Prasanna Subramanian, Jack M. Heath, Justin G. Tedeschi, Billy Law, Alan Wilhelm, Dewi Harjanto, Thomas Aunins, Deepak Reyon, Jennifer L. Gori, Jeremy S. Duffield

Prime Medicine, Inc., Cambridge, MA

Off-target assessment is critical for evaluating the precision and specificity of gene editing technology as it moves into the clinic. Compared to other gene editing approaches, Prime Editing may offer fundamental safety advantages at the target site and at potential off-target sites because double stranded breaks in DNA are not required and editing is gated on further homology recognition beyond the spacer sequence. Here we describe a comprehensive empirical evaluation of Prime Editing specificity that supports the theoretical arguments in favor of a superior safety profile of Prime Editing. We present a suite of assays developed specifically for Prime Editing to comprehensively assess off-target activity with high sensitivity and specificity. We will present data from two single-stranded nick based biochemical approaches developed at Prime Medicine to detect potential Prime Editor induced nicks across the genome: Library of In Silico Targets sequencing (LIST-seq) and 3-Prime End liGation sequencing (PEG-seq). In addition, we will show data from the Single End Extension sequencing (SEE-seq) assay developed at Prime Medicine for high precision detection of chromosomal alterations, such as large deletions and translocations. Such events are observed in CRISPR double-stranded break-based genome editors in typical culture conditions at 1-5%, and have not been observed with Prime Editing, therefore requiring the implementation of highly sensitive assays for assessment. In addition, we will show data from whole genome and transcriptome analyses of Prime Edited cells, which further highlight the minimal levels of genome-wide off-target activity. Finally, we will present results from the off-target analysis of the late-stage preclinical program for Chronic Granulomatous Disease (CGD) as well as preliminary analysis from other advanced preclinical programs at Prime. Collectively, our assessment supports the specificity and minimal, if any, off-target activity of Prime Editing, which has potentially important implications for patient safety.

260. Casmini-Tool: A Comprehensive Database for Efficient and Specific Guide RNA Design Using dCasMINI

Spencer Lopp[1], Tyler Borrman[1], Nishant Jha[2], Xiao Yang[1], Melanie Silvis[1], Gabriella Alvarez[1], Courtney Klappenbach[1], Ryan Swan[1], Yanxia Liu[1], Daniel O. Hart[1], Lei S. Qi[3], Timothy P. Daley[1], Robin W. Yeo[1]

[1]Epicrispr Biotechnologies, South San Francisco, CA,[2]Nitro Bio, Pasadena, CA,[3]Stanford University, Stanford, CA

The dCasMINI protein is a compact, nuclease-inactivated CRISPR-Cas system engineered for transcriptional modulation and epigenetic editing. The small size of dCasMINI (529 amino acids), less than half the size of comparable Cas9 molecules, makes it ideally suited for AAV-based therapies which are frequently limited by AAV's small cargo capacity. Unlike Cas9 or Cas12a, there are no available computational

tools for designing dCasMINI guides which presents a significant barrier to its ease-of-use by academic and industry researchers alike and limits its clinical utility as a potential tool for gene therapy. To facilitate and accelerate the development of dCasMINI-based applications, we synthesized knowledge regarding dCasMINI guide design and built a web application to assist researchers in designing optimal guides for dCasMINI-based experiments for transcriptional inhibition (CRISPRi) and activation (CRISPRa). Effective CRISPR-Cas targeting requires recognition of a protospacer adjacent motif (PAM) in the target DNA sequence; in the case of dCasMINI, previous studies have reported it recognizing a TTTR PAM. Considering that other PAMs may permit dCasMINI binding and subsequent target regulation, we developed a pooled PAM screening assay using a synthetic reporter, FACS, and NGS to evaluate all possible nucleotide arrangements of the PAM. In addition to the canonical TTTR PAM, dCasMINI was found to recognize several other relaxed PAMs, less potent than TTTR but sufficiently strong for target regulation. We incorporated canonical and relaxed PAMs into our guide design algorithm to expand the set of candidate on-target guides and increase the sensitivity of off-target prediction. Off-target guide binding can lead to undesirable and potentially dangerous therapeutic outcomes. It follows, accurate prediction of off-target regions is critical to successful guide selection. To address this, we experimentally evaluated nucleotide substitutions and deletions for each nucleotide position of the guide RNA in the context of CRISPRa. We identified a high fidelity 6 bp seed region in the guide which was intolerant to mismatches or deletions. Our off-target prediction algorithm integrates the seed region, relaxed PAMs, and gapped alignment to report a comprehensive list of high confidence off-targets. Overall, the casmini-tool supports guide design, selection, and off-target prediction with functions and parameters optimized for the dCasMINI CRISPR-Cas system. We anticipate that this web-based tool will be of value to the CRISPR-Cas research community and will allow researchers to more easily and quickly design CRISPRi/a experiments with dCasMINI. The tool is freely available at casmini-tool.com.

AAV Vector Biology and Development II

261. Multi-Step Engineered Adeno-Associated Virus Enables Whole-Brain mRNA Delivery

Weiya Bai[1], Yaqing Zhao[1], Zhen Liu[1], Dong Yang[1], Guoling Li[1], Haifeng Quan[1], Yingsi Zhou[1], Tong Li[1], Shaoran Wang[1], Xuan Yao[1], Alvin Luk[1], Linyu Shi[1], Hui Yang[1,2]

[1]HuidaGene Therapeutics Co., Ltd., Shanghai, China,[2]Institute of Neuroscience, Center for Excellence in Brain Science and Intelligence Technology, Chinese Academy of Sciences, Shanghai, China

Background: Messenger RNAs (mRNAs) have emerged as a new category of therapeutic agents to combat a wide range of incurable diseases. However, systemic injection of mRNA-delivering lipid nanoparticles (LNPs) or virus-like particles (VLPs) has limited therapeutic applications due to liver accumulation, a significant barrier in the development of therapeutically efficacious RNA drugs and limitation to deliver drugs to challenging tissue targets such as the brain due to the presence of the blood-brain barrier (BBB). Adeno-associated virus (AAV) vectors are commonly used for DNA delivery for gene therapy applications, with several advantages over other viral vectors. The use of naturally occurring or newly engineered AAV capsids is a promising strategy for targeting non-liver tissues, such as the brain, skeletal muscle, and heart. Here, we developed a system that enables the AAV shell to package mRNAs by introducing RNA-packaging components into the AAV production system (triple-plasmid system). **Methods:** We replaced the DNA packaging signal of AAV (inverted terminal repeat, ITR) with RNA packaging signals (RPSs) and enabled the binding of Rep78/68 proteins to RPS-harboring mRNAs to convert the AAV into an RNA-packaging virus. To improve the production efficiency and packaging specificity of the system, we conducted multi-step engineering of AAV Rep proteins. A comprehensive assessment of the properties of the resultant mRNA-carrying AAVs (RAAV) was further conducted. Furthermore, RAAVs were applied in gene editing. **Results:** Through multi-step engineering, we achieved a ~6000-fold increase in mRNA loading and a ~14,100-fold reduction in DNA loading with RAAV, compared to the conventional AAV (Fig. 1a). The RAAVs retained most properties of conventional AAVs, including capsid composition, virus morphology, and tissue tropism (Fig. 1b, c and Fig. 2). These RAAVs mediated mRNA transfer into the target cells and tissues, leading to transient expression of the functional protein (Fig. 1d, e). In addition, RAAVs enabled efficient CRISPR gene editing in cells with reduced off-target effects (Fig. 1f). Importantly, intravenously injected RAAV with capsid PHP.eB efficiently crossed the BBB and infected the whole mouse brain (Fig. 2). **Conclusions:** We have developed an efficient, engineered RAAV vector from the DNA virus AAV that specifically and safely delivers mRNAs for therapeutically relevant applications. The RAAVs combined the transient nature of mRNA with a variety of tissue tropism of the AAV capsid, making them ideal for either broad-spectrum or tissue-specific mRNA delivery. Our results demonstrate the feasibility of using rational engineering to change the virus genome type. Our strategy in developing RAAVs could be extended to other DNA viruses to endow them with mRNA packaging capability.

262. Optimization of RNA End Joining (REJ) to Safely and Efficiently Express Large Proteins

Lukas C. Bachmann[1], Kip J. Hermann[2], Ryan Hsu[3], Claire Williams[4], Samuel L. Pfaff[5]

[1]Gene Expression Laboratory (GEL-P), The Salk Institute, Vertuis Bio, and currently Insmed, La Jolla, CA,[2]The Salk Institute, La Jolla, CA,[3]Salk Institute & UC San Diego, La Jolla, CA,[4]Salk Institute for Biological Studies, La Jolla, CA,[5]Gene Expression Laboratory (GEL-P), The Salk Institute, La Jolla, CA

Background: Adeno-associated viruses (AAVs) have many favorable characteristics as a delivery vector for gene therapy, but have a limited cargo capacity of ~4.7 kb. Because many genetic diseases such as Stargardt, Usher 1F (Ush1F), and Duchenne Muscular Dystrophy (DMD) are caused by loss-of-function mutations in large genes, it has proven difficult to devise effective gene replacement strategies to treat these patients. Consequently a range of approaches are being undertaken including isolating functional mini-genes, re-engineering AAV capsids, and molecular strategies with DNA, RNA, and proteins that join smaller pieces together to produce larger proteins. Here we report an RNA based solution for safely and efficiently expressing large proteins by manipulating RNA trans-splicing. *Results:* Our studies to overcome the size constraints of AAV have focused on co-opting the cell's intrinsic RNA splicing machinery to join RNA fragments encoded by separate AAVs that coinfect target cells. This is achieved by breaking genes into fragment sizes compatible with efficient AAV packaging (<4.7kb) and appending the ends of each RNA segment with short ~250 nucleotide cis-element sequences termed RNA End Joining (REJ) modules that promote RNA trans-splicing (see Figure). REJ elements use the cell's intrinsic splice machinery to join separate RNAs, thereby generating long mRNAs capable of encoding proteins >300kd. The design features of this platform gene expression system include: (1) REJ modules are short; (2) REJ modules contain strong, but selective, RNA::RNA interaction elements to "trick" the spliceosome into splicing non-covalent RNAs; (3) the REJ system can be inserted at nearly any position, thereby allowing genes to be segmented without screening to account for protein domain structure; (4) REJ generates mRNAs that encode the exact endogenous protein without introducing a residual "scar"; (5) REJ functions without the need for foreign proteins, and (6) REJ modules are engineered to suppress translation of un-joined RNA fragments thereby preventing expression of truncated proteins that could oppose full length protein function by acting as dominant negatives. We find that the REJ system has a nearly undetectable level of off-target splicing using RNA sequencing, yields approximately 50% of the protein level compared to single linear RNAs, is a platform system that has reliably worked in >20 different genes tested in mouse and human cells, and has functioned well *in vivo* in every mouse tissue examined. *Conclusions:* The REJ system has shown excellent promise as a tool for treating genetic diseases with gene replacement (see Hsu et al. and Williams et al. abstracts) and *in vivo* gene editing with CRISPR. In addition the system is well suited for gene complementation, including applications involving intersectional genetics for precisely targeting specific cell populations. *Figure Legend:* REJ proof-of-concept. (A) The yellow fluorescent protein (YFP) gene was divided into 3 segments (green) and packaged into separate AAVs. Each RNA segment was appended with REJ domains (purple/blue). Viruses were mixed at equal concentration and injected into the tibialis anterior muscle of the mouse leg (B) Two weeks after virus injection YFP was detected.

263. Encapsidation of, and Transgene Expression from, Generation Z (Genz) Single-Stranded AAV Vectors is AAV Serotype Capsid-Specific

Keyun Qing[1], Jakob Shoti[1], Aneesha Nath[1], Geoffrey D. Keeler[1], Arun Srivastava[2]

[1]University of Florida, Gainesville, FL,[2]University of Florida College of Medicine, Gainesville, FL

We have previously reported the development of a generation Z (GenZ) ssAAV DNA genome in which the D-sequence in the AAV inverted terminal repeat (ITR) was replaced with a sequence obtained from a random nucleotide library (*Mol. Ther.*, 31: 234-235, 2023). The GenZ ssAAV genome overcomes the rate-limiting step of the viral second-strand DNA synthesis, and mediates significantly higher levels of transgene expression. Thus, it behaves more like a scAAV genome, but without the size-limitation. However, we observed that the extent of transgene expression from different GenZ AAV serotype vectors varied widely. For example, as shown in **Figures 1A** and **Figure 1B**, whereas the transduction efficiency of GenZ ssAAVrh74 and GenZ ssAAV3 vectors was ~20-fold and ~22-fold, respectively, compared with that of their wild-type (WT) counterparts, the transduction efficiency of GenZ ssAAV2 and GenZ ssAAV6 vectors was only ~3-fold and ~4-fold, respectively, compared with that of their WT counterparts (**Figures 1C** and **Figure 1D**). These observations prompted us to examine whether different AAV capsids modulate transgene expression. Previous studies by others have documented that AAV2 (*J Virol.*, 88:10711079, 2014; *J Virol* 2016;90:7196-7204) and AAV9 (*Mol. Ther.*, 28:1373-1380, 2020; *Hum. Gene Ther.*, 31:1155-1168, 2020) capsids indeed play a role in

transcription and second-strand DNA synthesis. To test our hypothesis that AAV2 and AAV6, but not AAVrh74 and AAV3 capsids, negatively impact the transgene expression from GenZ ssAAV vectors, the following strategy was used. GenZ ssAAVrh74 vectors were used to transduce HeLa cells in triplicates at $3x10^3$ vgs/cell, incubated with and without highly purified empty capsids of AAVrh74, AAV2, AAV3, and AAV6, either before or during transduction. Transgene expression was visualized under a fluorescence microscope 72 hrs post-transduction. These results are shown in **Figure 1E**. As is evident, whereas AAVrh74 and AAV3 empty capsids had no effect, both AAV2 and AAV6 empty capsids led to a significant decrease in transgene expression from GenZ ssAAVrh74 vectors. These data not only provide a mechanistic insight into the observed difference in the extent of transgene expression mediated my different GenZ ssAAV serotype vectors, but also further corroborate the studies cited above. However, given the absolute requirement of the D-sequence for the optimal rescue, replication, and packaging of the AAV genome (*Mol. Ther.*, 9: 2628-2630, 2021), we also observed that the efficiency of rescue and replication of the GenZ AAV genome from recombinant plasmids was significantly reduced, and depending on the AAV serotype capsid, the efficiency of GenZ AAV genome packaging ranged between ~10% to ~60% that of the AAV genome containing the D-sequence. Despite this limitation, which warrants further studies for its mitigation, the availability of the GenZ AAV genome has important implications for its potential use in achieving high-efficiency transgene expression from ssAAV vectors.

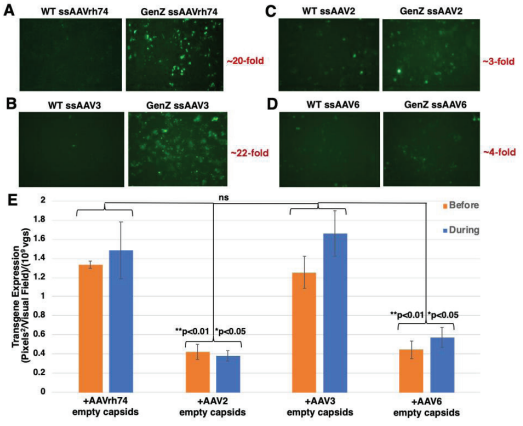

Figure 1: Transduction efficiency of WT and GenZ ssAAVrh74 **(A)**, AAV3 **(B)**, AAV2 **(C)**, and AAV6 **(D)** vectors in human HeLa cells *in vitro*. Cells were transduced with each vector at 1,000 vgs/cell and transgene expression was visualized under a fluorescence microscope 72 hrs post-transduction. **(E)** HeLa cells were transduced with WT and GenZ ssAAVrh74 vectors at 3,000 vgs/cell, with and without pre-incubation with AAVrh74, AAV2, AAV3, and AAV6 empty capsids, respectively. Transgene expression was visualized and quantitated by ImageJ analysis. ns=not significant.

264. Development of ITR-Modified AAVrh74 Vectors with Improved Transgene Expression in Primary Human Skeletal Muscle Cells *In Vitro* and in Murine Skeletal Muscles *In Vivo*

Jakob Shoti[1], Geoffrey D. Keeler[2], Keyun Qing[1], Dongsheng Duan[3], Arun Srivastava[4]

[1]University of Florida, Gainesville, FL,[2]University of Florida, Gainesville, FL,[3]University of Missouri School of Medicine, Columbia, MO,[4]University of Florida College of Medicine, Gainesville, FL

We have previously reported that the distal 10-nucleotides in the D-sequence in the the wild-type (WT) AAV2 inverted terminal repeat (ITR) share partial homology with the consensus ½ site of the glucocorticoid receptor-binding element (GRE), and that replacement of the distal 10 nts with a full GRE site leads to generation Y (GenY) ssAAVrh74 vectors that mediate up to 6-fold higher transgene expression in primary human skeletal muscle cells compared with those containing the WT D-sequence (*Mol. Ther.*, 30: 237-238, 2022). In the current study, we designed a modified AAV ITR, designated as DeltA ITR, in which the A-domain was made complementary to the GRE sequence, and the D-sequence was replaced with the GRE sequence (**Figure 1A**). This allowed the terminal resolution site (*trs*) to be conserved (**Figure 1B**), for AAV Rep-mediated resolution, rescue, replication of the AAV genomes. WT ITR and DeltA ITR genomes containing a muscle cell-specific promoter (CDK8)-driven hrGFP expression cassettes were packaged into AAVrh74 capsids. The extent of the transgene expression from the DeltA AAVrh74 vectors was ~34-fold higher than that from the WT AAVrh74 vectors in differentiated primary human skeletal muscle cells *in vitro* (**Figure 1C**). The transduction efficiencies of the WT and the DeltA AAVrh74 vectors were also evaluated in a mouse model *in vivo.* $1x10^9$ vgs of WT or DeltA-CK8-hrGFP AAVrh74 vectors were administered into gastrocnemius (GA) muscles in C57/BL6 mice (n=6 each). Cyro-sectioning and imaging of muscle tissues were performed 2 weeks post-injections. These results, shown in **Figure 1D**, document that DeltA-ITR AAVrh74 vectors averaged ~24-fold increased transgene expression than that from the WT-ITR AAVrh74 vectors. These data suggest that this novel ITR-modification subverts the need for the AAV D-sequence and is a useful strategy to achieve improved transgene expression from ssAAV vectors. However, since we have previously documented the essential role of the D-sequence in AAV genome encapsidation (*Mol. Ther.*, 9: 2628-2630, 2021), the deletion of this sequence significantly reduced the titers of the DeltA AAVrh74 vectors. Studies are warranted to further optimize the DeltA-ITR design to improve the vector titers. Additional studies are also underway to encapsidate the DeltA-ITR genomes into capsid-modified NextGen AAVrh74 vectors (*Mol. Ther. Meth. Clin. Dev.*, 31: 101147, 2023) leading to the generation of optimized DeltA-ITR vectors (OptΔ) AAVrh74 vectors for high-efficiency transduction as well as augmented transgene expression following systemic delivery, which has implications in the optimal use of these vectors in the potential gene therapy of muscular dystrophies in humans.

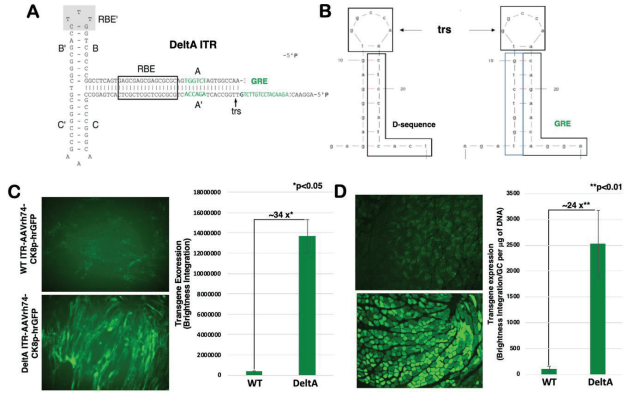

Figure 1: (A) Schematic structures of the DeltA AAV-ITR. **(B)** Secondary structures of the *trs* sites in the WT and the DeltA ITRs. **(C)** Transduction efficiency of WT and DeltA AAVrh74 vectors in primary human skeletal muscle cells *in vitro*. **(D)** Transduction efficiency of WT and DeltA AAVrh74 vectors in mouse gastrcnemius skeletal muscle cells *in vivo* following intramuscular injections. Data were quantitated using the Keyence software.

265. Transcriptional Crosstalk Between AAV Genomes Depends on Concatemer Formation and Enables Cell Type-Targeted Delivery of Oversized Cargo

Gerard M. Coughlin, Máté Borsos, Nathan Appling, Bre'Anna H. Barcelona, Acacia M. H. Mayfield, Elisha D. Mackey, Rana A. Eser, Xinhong Chen, Sripriya Ravindra Kumar, Viviana Gradinaru

California Institute of Technology, Pasadena, CA

Engineering of adeno-associated virus (AAV) capsids has enabled broad and efficient access to target organs following systemic administration. Inclusion of regulatory elements, such as enhancers mined from the host genome, can further refine the transduction profile of AAVs to target specific cell types. However, the limited packaging capacity of AAVs precludes use of enhancer-driven expression for delivery of certain large cargoes, including machinery for CRISPR-based gene editing and manipulation. Here we demonstrate that cell type-specific enhancer elements on one AAV genome can increase expression from minimal promoters present on another AAV genome. We term this behaviour "transcriptional crosstalk" and profile it across 11 different enhancers with cell type-specific activity in the mouse brain. To better understand the mechanisms of transcriptional crosstalk, we develop novel spatial genomics methods, AAV-Zombie and SpECTr, that enable high-resolution subcellular localization of AAV genomes and concatemers in cultured cells and in tissue. With these tools, we construct detailed views of the spatiotemporal dynamics of AAV genomes, concatemers, and cargo expression in primary neurons, and provide evidence that transcriptional crosstalk is dependent on AAV genome concatemerization. Lastly, we leverage transcriptional crosstalk for cell type-targeted delivery of a large Cas9 cargo following systemic administration of a BBB-penetrant engineered AAV. Using an established reporter assay, we demonstrate that this approach enables all-AAV cell type-specific gene editing. To demonstrate the efficiency of this approach, we disrupted *Cacna1a* in wildtype animals with Purkinje-cell specific Cas9 expression, recapitulating known phenotypes of genetic knockouts. Importantly, this paradigm does not require transgenic animals and thus can be used for cell type-specific gene disruption and manipulation in a range of models, including species that lack Cas9-expressing transgenic strains. This work synergizes with recent advances in AAV capsid engineering that have enabled genetic access to nervous systems of non-human primates, opening new directions for understanding cell type-specific gene function in a myriad of model organisms.

266. Newly Identified AAV Binders: Blood-Brain-Barrier Transcytosis Mediator LRP6 for Engineered AAVs and Immune Cytokine IL3 for AAV9-Host Interaction

Seongmin Jang[1], Timothy Shay[2], Tyler Brittain[1], Xinhong Chen[1], Beth Walker[3], Claire Tebbutt[3], Damien Wolfe[1], Cynthia Arokiaraj[1], Erin E. Sullivan[1], Xiaozhe Ding[1], Yaping Lei[1], Miguel Roberto Estella Chuapoco[1], Viviana Gradinaru[1]

[1]Division of Biology & Biological Engineering, Caltech, Pasadena, CA,[2]CLOVER Center, Caltech, Pasadena, CA,[3]Charles River Laboratories, Chinley, United Kingdom

Due to their native blood-brain barrier transcytosis ability, adeno-associated virus serotype 9 (AAV9) and its engineered derivatives have been used as potential gene therapy vectors for both basic science and clinical applications. However, AAV infection mechanisms remain poorly understood, thereby limiting further development and application. This is especially so for the many promising capsids engineered by mechanism-agnostic directed evolution. To address this problem, we screened wild type and engineered AAV capsids against the human extracellular proteome and secretome displayed as a cell microarray. Here, we report multiple newly-identified AAV interactions including two key findings: (1) low-density-lipoprotein-receptor-related-protein 6 (LRP6) as a lab-evolved receptor mediating blood-brain barrier transcytosis of AAV9-X1.1, AAV.CAP-Mac, and AAV-BI30, and (2) interleukin 3 (IL3) as a potential host immune reactor toward the natural serotype AAV9. Our screening effort also found other AAV binders outside of central nervous system that can help in understanding an AAV's off-target infection and side effects. This study provides a deeper understanding of AAV tropisms and the host's immune response to AAV, ultimately helping the engineering of highly brain-enhanced and safe AAVs for practical applications.

267. Creation of an AAV-Based Replication Origin for Novel AAV Vectors That Cannot Be Replicated in Nature

Leah R. Whitfield[1], Shani Inbari[1], R. Bryan Sutton[2], R. Jude Samulski[3], Matthew L. Hirsch[1]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC,[2]Department of Cell Physiology and Molecular Biophysics, Texas Tech University Health Sciences Center, Lubbock, TX,[3]UNC Gene Therapy Vector Core, Chapel Hill, NC

Recombinant AAV (rAAV) mobilization is the phenomenon in which rAAV spreads from the recipient's cells to additional cells within the patient and potentially the environment. This is facilitated by the wild-type (wt) AAV genome, either naturally present or provided as a contaminant in the vector preparation, and a helper virus which

allows rAAV replication in *trans* to create *de novo* rAAV. As wtAAV serotype 2 ITRs are currently used in all clinical AAV gene therapies and are replication targets for AAV Rep proteins of many natural serotypes found across many species, the objective of this work is to eliminate the potential for rAAV production in patients and therefore, excessive vector shedding and environmental spread. A previous report of AAV serotypes 2 and 5 Rep and ITR sequences identified the region between the Rep binding element and the base of the nicking stem and the length of the nicking stem as determinants that restrict ITR2 replication by Rep5 and vice versa. Additionally, analyses of the protein sequences reveal that Rep5 is truncated in the region implicated in ITR binding and nicking, with aa 135-160 reported as essential for ITR2/5 replication specificity. Given these insights, it was hypothesized that the addition of a single helical turn within Rep's nicking region would eliminate replication of wtITRs and confer replication of a unique ITR sequence selected from a mutant ITR library. First, Rep Y152 and Y156 were individually mutated to alanine to investigate their roles in replication. In contrast to previous reports which implicate Y156 as the endonucleolytic tyrosine, mutation of either residue eliminated AAV vector production. Next, mutations of Rep2 implicated in increased production titers were investigated. A S535A mutation showed no significant titer change compared to Rep2 while substitution of the Rep start codon to ACG resulted in a two-fold increase in production titers. Given these insights, mutated Rep proteins were rationally designed in the ACG context by extension of the nicking region through the addition of natural AAV alpha-helical turns. Using AlphaFold, repetition of the second turn of the endonucleolytic helix of multiple Rep serotypes failed to maintain the helix while inserting a corresponding endonucleolytic turn of Muscovy Duck AAV (mdRep) did and was used for further analyses. As desired, yet somewhat surprising, mdRep failed to produce wtITR2 containing vectors, despite the maintenance of both Y152 and Y156. Production runs using mdRep and capsid 2 on a mutant ITR library demonstrated rAAV production at relatively low titers. Currently, these mutant ITR genomes are being amplified through production cycling followed by nanopore sequencing. In addition to offering mechanistic determinants of ITR and Rep protein restriction, this work has the potential to create a capsid packaged mutant ITR flanked genome that can only be replicated in a laboratory environment thereby decreasing concerns associated with rAAV mobilization.

Neurologic Diseases III

268. AAV-Based Prion Protein-Lowering Gene Therapy for CJD

Jun Zhang[1], Manuel Camacho[1], Fengfeng Bei[2], Qingzhong Kong[1]

[1]Pathology, Case Western Reserve University, Cleveland, OH,[2]Neurosurgery, BWH, Boston, MA

Creutzfeldt-Jakob disease (CJD) is the most common human prion disease that is transmissible and always fatal, progresses rapidly and has no treatments. An effective and lasting treatment for CJD is urgently needed. The cellular prion protein (PrP) is essential for both prion replication and prion pathogenesis yet expendable for life, making it an ideal target for prion therapeutics development. Knocking down the PrP gene expression through RNA interference, such as with antisense oligonucleotides (ASOs), has been shown to be safe and effective against rodent prions in mouse models. But there has been no published report on PrP-lowering RNA interference or gene therapy for human prions. We designed a few shRNAs for the human PrP gene that showed ~90% knockdown of human PrP protein level in the M17 human neuroblastoma cell line. We created rAAVs carrying one of the shRNAs with the AAV.CAP-B10 (or B10) capsid. The rAAV.B10-shRNA was given as a systemic dose (1.6×10^{12} vg/mouse) via the retro-orbital route to a CJD-inoculated humanized CJD mouse model (Tg40h) at near clinical onset that led to a ~26% reduction of brain PrP level and a 9.6% extension of survival ($p=0.0003$), which is very significant given that the Tg40h mice overexpress human PrP at 3-4 fold of wild type level. We found that the same rAAV-shRNA packaged with the PHP.eB (or eB) capsid doubled the brain PrP knockdown (to 52.7%) at a much lower systemic dose (2.4×10^{11} vg/mouse) in the Tg40h mice, suggesting that a much more extensive survival extension of CJD-inoculated Tg40h mice or Tg40 mice (the hemizygous counterpart of Tg40h) should be achievable with a moderate systemic dose of rAAV.eB-shRNA. The recently reported AAV.CPP16 capsid (CPP16) that can effectively cross the BBB and transduce the brain tissues of both mice and macaques offers a good chance of translation for treatment of human CJD patients. Experiments treating CJD-inoculated Tg40 or Tg40h mice with a systemic dose of rAAV-shRNA packaged with the eB or CPP16 capsid are ongoing. Our data suggest that a single systemic dose of an optimized rAAV-shRNA targeting human PrP is a highly promising and realistic approach for effective CJD treatment when given at or near clinical onset. Acknowledgements: This study is supported by CJD Foundation. We are very grateful to Drs. Timothy Shay and Viviana Gradinaru at Caltech for sharing the plasmids for two AAV capsids.

269. Effective *In Vivo* Gene Silencing of HTR2A Reduces Anxiety and Enhances Memory Performance

Troy Townsend Rohn, Dean Radin, Tracy Brandmeyer, Peter Seidler, Barry Linder, Tom Lytle, John Mee, David Pyrce, Fabio Macciardi

Cognigenics, Boise, ID

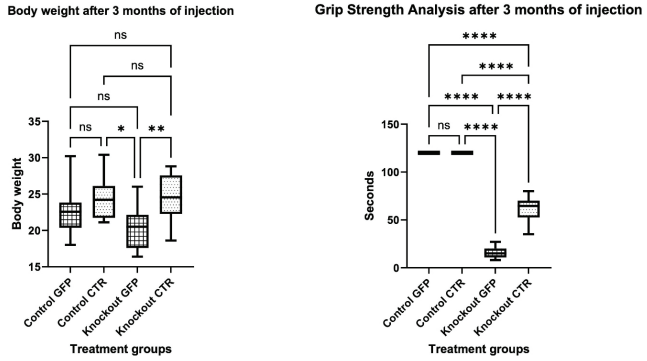
Short-hairpin RNA (shRNA) molecules, tailored for the targeted silencing of specific genes, offer substantial potential for the development of precise therapeutic interventions for a variety of neurodegenerative diseases. Yet, the capability of shRNA constructs to alter neuronal pathways that control certain behaviors remains to be investigated. We engineered shRNAs to silence the *HTR2A* gene *in vitro* within neurons derived from induced human pluripotent stem cells (iPSCs). Subsequent analysis with Multi-electrode arrays (MEA) indicated that suppression of the 5HT-2A receptor was associated with reduced spontaneous neural firing. In a mouse model, the intranasal administration of adeno-associated virus serotype 9 (AAV9) vectors encapsulating shRNA led to diminished anxiety-like behavior in mice, as well as a marked enhancement of memory performance, as evidenced by a 104% improvement in mice and a 92% improvement in rats over control groups. This research not only showcases a groundbreaking non-invasive shRNA delivery method that successfully circumvents the

blood-brain barrier but also has potential implications for the treatment of a multitude of neurological and psychiatric conditions. Particularly, the inhibition of the HTR2A gene emerges as a promising new strategy for managing chronic anxiety and combatting cognitive deterioration associated with mild-cognitive impairment patients.

270. Development of an Adeno-Associated Virus Gene Therapy for the Treatment of CDKL5 Deficiency Disorder

Janine M. Lamonica, Eileen Workman, Rachel S. White, Mariya Kostiv, Ralf S. Schmid, Juliette Hordeaux, James M. Wilson

Gene Therapy Program, University of Pennsylvania, Philadelphia, PA



Loss-of-function mutations in the X-linked cyclin-dependent kinase-like 5 (CDKL5) gene cause a severe neurodevelopmental condition known as CDKL5 deficiency disorder (CDD). CDD is characterized by early-onset epilepsy, intellectual disability, autistic features, and impaired motor function. Presently, there is no cure for CDD, and treatment options are limited to reducing seizure burden. Research has shown that restoring CDKL5 protein expression in Cdkl5-deficient mice leads to a reversal of behavioral phenotypes, pointing to *CDKL5* gene replacement as a possible therapeutic strategy for CDD. To this end, we are developing an adeno-associated virus gene therapy vector, a clade F AAVhu68 vector encoding a human codon-optimized *CDKL5*. We performed pharmacology and minimum effective dose studies following delivery of our vector via intracerebroventricular injection into neonatal *Cdkl5* knockout (KO) mice at four escalating doses, ranging from 7.5×10^9 to 9.75×10^{10} genome copies (GC). At 11 and 15 weeks of age, the mice underwent a series of behavioral tests. Compared with vehicle-treated KO mice, vector-treated KO mice exhibited improvements in locomotor activity, hindlimb clasping severity scores, and nest-building ability in a dose-dependent manner. We are currently performing Western blotting and immunohistochemical analyses to detect hCDKL5 protein levels and activity in the brain. We are also conducting a toxicological evaluation of our vector in rhesus macaques following intra-cisterna magna (ICM) administration. We administered our vector at low (4.5×10^{12} GC), intermediate (1.5×10^{13} GC), and high (4.5×10^{13} GC) dose levels. Three nonhuman primates (NHPs) per dose, plus one vehicle-treated control, will be euthanized at Day 90 post-injection, and three additional high-dose NHPs plus one vehicle-treated control will be euthanized at Day 180. This study will provide critical data regarding the safety, tolerability, and expression of our vector following ICM administration in NHPs. Ultimately, the goal of these studies is to provide a safe and efficacious treatment option for patients with CDD.

271. Validation of an AAV Gene Therapy Designed to Complement the Loss of TDP-43 Splicing Repression for ALS-FTD

Aswathy Peethambaran Mallika[1], Philip C. Wong[2]

[1]Pathology, Johns Hopkins University School of Medicine, Baltimore, MD,[2]Pathology & Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD

Background: Emerging evidence support the notion that loss of splicing repression by TDP-43, an RNA binding protein that was first implicated in ALS-FTD, underlies their pathogenesis. Previously, we showed that delivery of an AAV9 vector at early postnatal day expressing a fusion protein (AAV9.RAV1-3'UTR termed CTR) comprised of the N-terminal region of TDP-43 and an unrelated splicing repressor termed RAVER1 complemented the loss of TDP-43 in mice lacking TDP-43 in spinal motor neurons (*ChAT-IRES-Cre;tardbp$^{F/F}$* mice). To translate this potential therapeutic strategy to the clinic, it will be important to demonstrate benefit of such AAV delivery of CTR to motor neurons in adult mice. Here we validate a therapeutic approach using a recently developed AAV.PHP.eB vector that enables efficient transduction in central neurons, including motor neurons by an intra-venous (IV) administrative route. **Method:** Intra-venous injection of AAV.PHP.eB.RAV1-3'UTR [(*ChAT-IRES-Cre;tardbp$^{F/F}$* (n=12) and *ChAT-IRES-Cre;Tardbp$^{F/+}$* (n=8)] and AAV.PHP.eB.GFP [(*ChAT-IRES-Cre;tardbp$^{F/F}$* (n=10) and *ChAT-IRES-Cre;Tardbp$^{F/+}$* (n=8)] was carried out at 6 weeks old littermate animals. Histology and immunohistochemistry to show the infectivity, RT-PCR and RNA in situ hybridization to show the rescue of splicing repression and finally the grip strength analysis were performed. **Result:** We show that IV delivery of AAV.PHP.eB.RAV1-3'UTR to adult *ChAT-IRES-Cre;tardbp$^{F/F}$* mice efficiently transduced spinal motor neurons, repressed cryptic exon inclusion and attenuated muscle weakness. **Conclusion:** These data support validation of our AAV gene therapeutic strategy to attenuate motor neuron disease, including ALS and potentially extended to other human disorders harboring TDP-43 pathology. Other relevant results, including rescue of motor neurons and extension of life span will be presented.

272. ATAD1 Gene Rescue of Zellweger Spectrum Disorders via Targeting of Shared Common Mechanism

Tamara Stevenson[1], Esther Nuebel[2], Nettie Pyne[3], Allison M. Bradbury[3], Joshua L. Bonkowsky[1]

[1]University of Utah, Salt Lake City, UT,[2]Noorda College of Osteopathic Medicine, Saratoga Springs, UT,[3]Nationwide Children's Hospital, Columbus, OH

Peroxisomal biogenesis disorders (PBDs), of which Zellweger Spectrum Disorders (ZSDs) are the most severe, are caused by mutations in the peroxin proteins, coded by PEX genes. The birth incidence of ZSDs is ~1/50,000. ZSDs present with severe clinical features, including seizures, leukodystrophy, hepatomegaly, mitochondrial defects,

retinopathy, and ultimately lead to death in infancy or early childhood. There are no curative treatments for ZSDs, and only a few drug trials are being pursued. Gene replacement therapy is an appealing option, as the ZSDs are largely autosomal recessive monogenic conditions. However, a major limitation in the development of gene therapies for ZSDs is the size of the PEX genes, which exceed the AAV payload. Further, with 14 known PEX genes, each form of ZSD would require a lengthy and expensive gene therapy development process. We have developed a novel approach for treatment of ZSDs, through targeting of a shared mechanism common to ZSDs. Using a PEX3$^{-/-}$ patient-derived fibroblast line, we showed that mitochondrial mislocalization of peroxins (PEX) contributes to the phenotype of ZSDs. Further, we showed that we could rescue PEX localization, restore mitochondrial function, and restore peroxisome function by expression of ATAD1, a mitochondrial chaperone AAA+ ATPase (Nuebel et al., 2022). Use of ATAD1 has two important, appealing features for gene therapy for ZSDs. First, its small size (~1kb) allows it to package efficiently in AAVs. Second, ATAD1 could potentially rescue multiple different ZSDs. To establish generalizability across the ZSDs, we tested ATAD1 exogenous expression in a PEX1-/- patient-derived fibroblast line. We found that ATAD1 expression corrected mitochondrial deficits of ZSDs and also found that peroxisomal dysfunction was corrected. We observed normalization of very-long chain fatty acid levels (a marker of peroxisome metabolic function); and improvement in plasmalogen synthesis (a marker of peroxisome anabolic function). We are testing ATAD1 AAV9-mediated gene therapy in a PEX1 ZSD mouse model (G844D mutation). We are using PEX1 as a control to compare outcomes with ATAD1 gene supplementation. Genes (GFP, ATAD1, or PEX1) were subcloned into a single-stranded AAV plasmid. We used 2 different promoters: an EFS (shortened EF1-α) promoter; or the ubiquitous promoter chicken β-actin with a CMV enhancer (CAG). Due to the large size of the PEX1 transgene we could only use the small EFS promoter for the PEX1 construct. In contrast, because of the smaller size of the ATAD1 transgene (1 kb), we have generated 2 comparison promoters, EFS and CAG. All constructs were packaged in AAV9 capsids. P1 wildtype mice were injected by intracerebroventricular (ICV) or intravenous (IV) delivery. Mice were sacrificed at 1-month post-injection to evaluate expression and biodistribution via immunofluorescence staining. The AAV9-CAG-GFP construct resulted in high expression levels throughout the neuroaxis, with on average approximately 75% of the brain positive for GFP. Additionally, the intensity of expression was robust. When LUTs were normalized, expression and intensity of GFP driven by EFS was significantly lower. Our results suggest that ATAD1 gene therapy has potential to rescue mitochondrial and peroxisomal dysfunction and their downstream phenotypic effects in PEX1, PEX3, and potentially other ZSDs.

273. AAV-Based Anti-RAN Antibody Therapy for C9orf72 ALS FTD

Introduction: Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease that causes paralysis and death ~3-5 years after diagnosis. The most frequent, known, genetic cause of familial and sALS is the *C9orf72* (C9) G_4C_2 repeat expansion. Strong evidence indicates toxic proteins expressed by repeat associated non-AUG (RAN) translation contribute to disease. Our previous studies show that targeting GA RAN proteins with a human antibody, α-GA1, improved disease in a BAC transgenic mouse model of *C9orf72* ALS/FTD (C9-BAC). Surprisingly, the α-GA1 antibody not only reduced GA aggregates, but also lowered GP and GR RAN proteins through improved proteasome and autophagy function. While passive immunotherapy is promising, high manufacturing costs, the need for frequent dosing, and limited blood-brain-barrier (BBB) penetration (~0.1%) highlight the need to develop improved immunotherapy strategies. **Methods:** Here, we report a second-generation immunotherapy strategy that targets GA-RAN proteins using an AAV-based approach. We engineered IgG and single-chain antibody variants with high affinity to GA-RAN proteins for AAV delivery. Cell overexpression, mouse, and organoid models were used to test target engagement and therapeutic efficacy of these AAV-IgG-GA variants. C9-BAC and non-transgenic (NT) littermates were injected intracerebroventricularly with AAV-IgG1-GA or AAV-IgG-GFP (isotype-control). Hanging-wire and Open-Field behavioral analyses were performed on 16 and 23-week-old animals. Immunohistochemistry (IHC) and IF were used to evaluate the effects of AAV-IgG1-GA in the brain and spinal cord. **Results:** Our data show these novel a-GA antibody variants (IgG1, IgG2, or single-chain scFv) reduce GA-RAN proteins ($n \geq 3$, $p<0.0001$) and their toxicity ($n \geq 3$, $p<0.0001$) in cells. A pilot study identified AAV-IgG1-GA as the most effective AAV-antibody for reducing GA-RAN proteins in C9-BAC mice ($n>5$/group, $p=0.0499$). In a larger study (n=30 mice/group), we found that animals injected with AAV-IgG1-GA improved performance in open-field (e.g., ambulatory distance, $n \geq 5$/group, $p<0.0001$), hanging-wire ($n \geq 5$/group, $p=0.0301$) and importantly increase survival ($n \geq 5$/group, $p=0.0044$). Histopathological studies show that the AAV-delivered IgG1-GA antibody is broadly distributed throughout the hippocampus and motor cortex and that GA aggregates in the brains of IgG1-GA-treated mice are reduced. **Conclusion and Discussion:** These data show that AAV-anti-RAN immunotherapy reduces RAN protein load, improves behavior, and increases survival of C9-BAC mice. We are continuing to analyze the histopathological and molecular phenotypes of the mice to fully understand the molecular effects of AAV-anti-RAN immunotherapy. AAV delivery of high-

affinity anti-GA antibodies provides a novel strategy to achieve broad and sustained CNS expression and biodistribution of therapeutic antibodies. These data open new possibilities for developing AAV-antibody therapies as a novel approach for C9orf72 ALS/FTD and for a broader group of disorders characterized by RAN protein pathology.

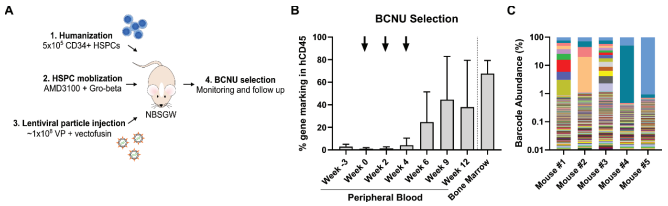
274. Systemic AAV Gene Therapy with CNS-Targeted Engineered Capsids Achieves Significant GCase Activity Increases in the Primate Brain to Support the Potential Treatment of GBA-PD

Kimberly McDowell, Reed Ressler, Brandon Wheeler, Shelby Thomas, Lubov S. Grigoryeva, Alexander Armendariz, Maeve Flynn, Hari Acharya, Paul Denis, Pasha Tchourilov, Swati Tole, Nick Goeden, Nicholas C. Flytzanis, Susan Catalano

Capsida Biotherapeutics, Inc., Thousand Oaks, CA

Parkinson's disease (PD) is the second most common neurodegenerative disorder with a prevalence of over 1.2 million people in the United States by 2030 and no approved disease-modifying treatments today. Current understanding of risk factors suggests approximately up to 15% of PD patients have mutations in the GBA1 gene, making this the most significant genetic risk factor for developing the disease. GBA1 encodes a lysosomal hydrolase enzyme, glucocerebrosidase (GCase), the reduced levels or aberrant function of which is associated with accumulation of alpha synuclein, loss of nigrostriatal dopaminergic neurons and development and spread of aggregated protein inclusions known as Lewy bodies, the pathological hallmarks of PD. GBA-PD is associated with the same motor and non-motor symptoms as idiopathic PD - bradykinesia, rigidity and resting tremor, cognitive decline, sleep disturbances, hyposmia, psychiatric symptoms, and autonomic dysfunction - but tends to present at an earlier age and with greater cognitive dysfunction. Growing clinical and preclinical data suggest that an effective treatment that restores GCase levels in the brain could slow or stop the progression of GBA-PD. A novel gene therapy candidate, CAP-003, may offer the potential to stably supplement wild-type GCase protein throughout the CNS with a single intravenous administration, enabling long-term disease modification and substantially slowing disease progression of GBA-PD with limited treatment burden. CAP-003, which consists of an engineered AAV capsid that is a product of our high-throughput, non-human primate (NHP)-based AAV engineering platform, packaging the human GBA1 gene, achieves breakthrough levels of neuronal transduction throughout the brain while de-targeting the liver 16-fold compared to AAV9. The CAP-003 candidate delivered at low to moderate doses successfully transduces up to 60% of dopaminergic neurons in the substantia nigra and up to 70% in other brain regions, raising bulk GCase enzyme activity levels up to 45% over wild-type in healthy NHPs. Estimated average levels of GCase activity increase within transduced neurons surpass 100% of wild-type levels and are expected to more than normalize the enzymatic activity deficit in human patients with PD. Importantly, these levels of GCase supplementation throughout the brain can be achieved at doses that are well tolerated, without any of the clinical pathology, immunogenicity or histopathological findings associated with higher dose systemic gene therapies. With the above profile, CAP-003 is being developed with the aim of achieving meaningful, disease-modifying clinical benefit for patients with GBA-PD through a convenient, single-dose, intravenous administration.

Advancements in Technologies for *In Vivo* Gene Therapies



275. *In Vivo* Application of BaEVRLess-Pseudotyped Lentiviral Vectors for Hematopoietic Stem Cell Gene Therapy

Denise Klatt[1], Boya Liu[1], Adele Mucci[1], Marie Peschers[1], Giulia Schiroli[2], Axel Schambach[1,3], Chad Harris[1], Danilo Pellin[1], John P. Manis[4], Myriam Armant[5], David Scadden[6], Els Verhoeyen[7,8], David A. Williams[1], Christian Brendel[1]

[1]Hematology/Oncology, Boston Children's Hospital, Harvard Medical School, Boston, MA,[2]Tessera Therapeutics, Cambridge, MA,[3]Hannover Medical School, Hannover, Germany,[4]Transfusion Medicine, Boston Children's Hospital, Boston, MA,[5]Trans Lab, Boston Children's Hospital, Harvard Medical School, Boston, MA,[6]Regenerative Medicine, Massachusetts General Hospital, Boston, MA,[7]INSERM/CIRI/EVIR, Lyon, France,[8]Université Côte d'Azur, Nice, France

Traditional *ex vivo* hematopoietic stem cell (HSC) gene therapy has effectively cured severe inherited blood disorders, such as sickle cell disease (SCD), but more widespread implementation is limited by high costs, scalability issues, and significant risks associated with myeloablative chemotherapy. *In vivo* HSC gene therapy, which aims to directly modify the cells *in situ*, has the potential to overcome these limitations. Here, we explore the use of retroviral vectors pseudotyped with the baboon endogenous retrovirus (BaEV) glycoprotein, and its derivative BaEVRLess, for stable gene transfer into HSCs *in vivo* (Figure A). Although BaEVRLess-pseudotyped retroviral vectors very efficiently transduce quiescent HSCs, their titers are often low due to toxicity associated with the high fusogenic activity of BaEVRLess during virus production. To overcome this problem, we generated a stable BaEVRLess-packaging cell line carrying knock-out of the viral entry receptor ASCT2. This resulted in a 2-fold increase in titers (10^8-10^9 infectious particles/mL) and a 3-fold reduction in cytotoxicity of virus preparations. Additional modifications to the packaging cells include the overexpression of CD47 and knock-out of B2M, which aims to reduce phagocytosis and immune responses *in vivo*, respectively. To increase *in vivo* HSC gene transfer, we mobilized humanized NBSGW mice with AMD3100 and Gro-beta, which achieved on average 20 hCD34+ cells/µL of blood. Upon mobilization, ~$1x10^8$ viral particles were injected intravenously into animals reaching up to 2.9±2.1% gene marking in peripheral blood hCD45+ cells within one week. To enrich gene-marked cells, we overexpressed MGMT-P140K in transduced cells, which mediates resistance to the alkylating agent BCNU. After three cycles of BCNU treatment, we observed a 38-fold enrichment of gene marked cells in the peripheral blood (Figure B). In bone marrow, gene marking reached 67.7% in hCD45+ cells and averaged 42.2% in hCD34+ cells. Barcode analysis showed the presence of 300-1000 unique barcodes and a polyclonal distribution in transplanted

mice (Figure C). Transduction and selection of *bona fide* HSCs was confirmed in secondary transplantations, where gene marking and clonality remained stable with 39.3-48.1% transduced hCD45+ cells. In proof-of-concept experiments, we targeted the transcription factors BCL11A and ZNF410 using miRNA-embedded shRNAs containing vectors. Downregulation of BCL11A and ZNF410 in erythroid cells led to sustained reactivation of gamma-globin and induction of fetal hemoglobin, which largely attenuates the hematologic effects of SCD. Following *in vivo* gene transfer and BCNU selection in humanized mice, we observed a significant upregulation of gamma-globin (35.6%) and fetal hemoglobin (25.1%) in transduced erythroid cells. In summary, we demonstrate that BaEVRLess-pseudotyped lentiviral particles can be applied for *in vivo* gene therapy to treat sickle cell disease.

276. LNP-Based Delivery of CRISPR/Cas12a for the Potential Treatment of Myocilin-Associated Glaucoma

Mariacarmela Allocca, Chi-Hsiu Liu, Chrysa Latrick, Xiaoqi (Kevin) Sun, Andrea Pinilla, Steve Bottega, Shrutokirti De, Khushboo Undavia, Alison Miller, Ruhong Dong, Eleanor Quenzer, He (Harry) Wang, Mark Jones, Steve Pietrasiewicz, Meng Wu, Stephen Sherman, Eugenio Marco, Kayla Delano, Jim Bochicchio, Georgia Giannoukos, John A. Zuris, Judith Newmark, Paul J. Wrighton, KaiHsin Chang, Heather MacLeod

Editas Medicine, Cambridge, MA

Glaucoma is one of the leading causes of blindness in the developing world. Mutations in the myocilin (*MYOC*) gene are the most common genetic cause of primary open angle glaucoma (POAG), accounting for 2-5% of the POAG cases. The mutations in the *MYOC* gene result in intracellular protein aggregates in the trabecular meshwork (TM) cells leading to endoplasmic reticulum (ER) stress, malfunction of the TM tissue, and elevated intraocular pressure (IOP). Medications to lower IOP are often not sufficient and surgery is required. Even then, the long-term prognosis is reduced vision and eventual vision loss. We hypothesize that editing of the *MYOC* gene to knock-out its expression would reduce ER stress and restore TM function, thus lowering IOP. We aim to develop an in vivo therapy for myocilin-associated POAG using lipid nanoparticles (LNPs) to deliver our engineered AsCas12a mRNA with a chemically modified guide RNA (gRNA) to edit the *MYOC* gene and reduce IOP. To this end, we developed in vitro and in vivo phenotypic models to evaluate the impact of editing on ER stress and IOP. The in vitro model was generated using HEK293T cells that stably express the Y437H mutant myocilin, which is one of the more aggressive mutations and is associated with early-onset of POAG. These cells exhibit intracellular buildup of the mutant myocilin protein and elevated levels of GRP78, a marker of ER stress. The in vivo mouse model was developed by replacing the mouse *Myoc* gene with the human Y437H mutant *MYOC* gene ($hMYOC^{Y437H}$) and presents with elevated IOP compared to wild-type control mice. We identified an ionizable lipid and LNP formulation that robustly targets the TM tissue in vivo by using GFP mRNA as cargo. The small AsCas12a gRNAs are subject to rapid degradation once released inside the cell resulting in lower editing efficiency. Therefore, we evaluated different chemical modifications to the gRNA in primary TM cells in vitro and selected those with improved editing efficiency for further testing in vivo in our humanized mouse model. LNPs encapsulating our engineered AsCas12a mRNA and gRNA with the top three modifications from in vitro testing were intracamerally injected into $hMYOC^{Y437H}$ mice and human *MYOC* mRNA levels were evaluated by RT-ddPCR. Finally, the modified gRNA leading to the greatest reduction in human *MYOC* mRNA in vivo was selected for the assessment of the reversal of the disease phenotype in vitro and in vivo. In our in vitro phenotypic assay, treatment of cells with increasing concentrations of LNPs encapsulating our engineered AsCas12a mRNA and the optimized gRNA resulted in concentration-dependent editing of the *MYOC* gene, reduction of *MYOC* mRNA and protein, as well as reduced GRP78 protein. The data demonstrate in vitro reversal of the ER stress phenotype that accompanies myocilin-associated glaucoma. We next tested our engineered AsCas12a mRNA with the optimized gRNA encapsulated in LNPs for in vivo efficacy in the $hMYOC^{Y437H}$ mice. Editing of the *MYOC* gene in $hMYOCY^{437H}$ mice resulted in a reduction of IOP at all doses tested. In summary, we demonstrate that editing of the *MYOC* gene, by LNP-mediated delivery of an optimized gRNA and engineered AsCas12a mRNA, reduces ER stress in TM cells in vitro and rescues IOP in $hMYOC^{Y437H}$ mice in vivo. These results suggest that *MYOC* gene knockout by LNP-based delivery of CRISPR/AsCas12a is a potential therapeutic approach for treating myocilin-associated glaucoma.

277. G-CSF-Free HSC Mobilization with WU-106/AMD3100 Allows for Safe and Efficient *In Vivo* HSC Prime Editing of the Sickle Cell Disease Mutation in a Mouse Model

Chang Li[1], Anna K. Anderson[1], Peter Ruminski[2], Michael Rettig[3], Darja Karpova[3], Hans-Peter Kiem[4], John F. DiPersio[3], Andre Lieber[1]

[1]University of Washington, Seattle, WA,[2]Washington University School of Medicine,, Saint Louis, MO,[3]Washington University School of Medicine, Saint Louis, MO,[4]Fred Hutch, Seattle, WA

We have reported direct repair of the sickle cell mutation *in vivo* in a disease model using vectorized prime editors after hematopoietic stem cell (HSC) mobilization with G-CSF/AMD3100. Despite its robustness in HSC mobilization, G-CSF is contra-indicated in patients with Sickle Cell disease (SCD), presenting a hurdle for the clinical translation of the approach. Additionally, G-CSF results in unselective bone marrow cell mobilization, which leads to leukocytosis and higher numbers of cytokine-producing cells in the periphery. This increases the number of cytokine-producing cells in the periphery that come in contact with intravenously injected viral particles, which in turn, contributes to higher cytokine levels in mobilized versus non-mobilized animals. Committed bone marrow cells mobilized to the periphery also sequester vectors thus reducing the effective dose

for primitive HSCs. Further, the five-day treatment regimen and high costs associated with G-CSF/AMD3100 justify the development of an alternative mobilization regimen. Here, we tested a G-CSF-free mobilization regimen using WU-106, a PEG-conjugated inhibitor of integrin VLA-4 (α4β1), plus AMD3100 for *in vivo* HSC prime editing in SCD mice (CD46/Townes). The all-in-one PE5max system expressed by a helper-dependent adenoviral vector (HDAd) was used to repair the sickle mutation (GTG>GAA conversion). Mobilization with WU-106+AMD3100 in CD46/Townes mice was rapid (with a peak at 2 hours) and efficient. In contrast to the G-CSF/AMD3100 approach, leukocytosis was minimal and serum cytokines (IL-6, TNF, IFN-γ) were not detectable after HDAd vector injection. Target site editing (T>A correction) of the SCD mutation was on average 23% in peripheral blood cells and bone marrow lineage-negative cells at week 16 after *in vivo* transduction and selection. The treated mice demonstrated phenotypic correction, reflected by normalized blood parameters and spleen size. Editing rates were significantly increased (29%) in secondary recipients indicating preferential mobilization/transduction of long-term repopulating HSCs. Using this approach, we found <1% of undesired indels and no detectable off-target editing at top-scored potential sites. Our study shows that *in vivo* transduction to treat SCD (including HSC mobilization and HDAd injection) can now be done within 2 hours involving only simple intravenous injections with an excellent safety profile. The same-day mobilization regimen makes *in vivo* HSC gene therapy more attractive for the resource-poor settings where SCD does the most damage.

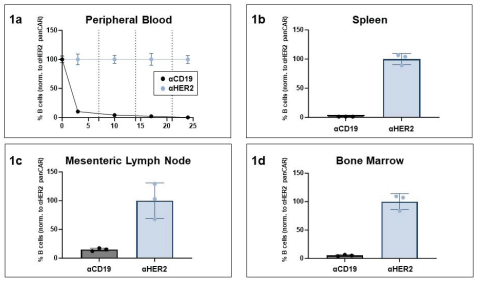
278. Cas12a CRISPR Hybrid RNA-DNA (chRDNA)-Mediated *In Vivo* Genome-Editing Technology for Efficient and Functional Hepatic Gene Disruption

Marta Losa-Llabata, Prachi Rajmane, Liz Stanaway, Mary Coons, Antonio Munoz, Vaibhavi Garish, Paul Donohoue, Scott Gradia, Steven Kanner, Meghdad Rahdar

Caribou Biosciences, Berkeley, CA

Familial hypercholesterolemia (FH) is an autosomal dominant inherited disease characterized by high circulating low-density lipoprotein (LDL) cholesterol. Affected patients quickly develop atherosclerosis, leading to peripheral and coronary artery disease and often followed by heart attack, stroke, or other cardiovascular complications. Transthyretin amyloidosis (ATTR) is a progressive life-threatening disease characterized by accumulation of misfolded transthyretin (TTR) protein in the nerves and heart leading to neurodegeneration and cardiomyopathy. While significant progress has been made to demonstrate the utility of Class 2 Type II Cas9 for *in vivo* genetic intervention, the *in vivo* potential of Class 2 Type V Cas12a has not fully been realized. In these proof-of-concept studies, we targeted proprotein convertase subtilisin/kexin type *9* (*Pcsk9*), angiopoietin-like 3 (*Angptl3*), and transthyretin (*Ttr*) - three clinically validated gene targets for FH and ATTR, using a Cas12a CRISPR hybrid RNA-DNA (chRDNA) genome-editing technology. We have previously shown that CRISPR guides designed with a combination of RNA and DNA nucleotides, called chRDNAs, can be leveraged with Cas9 and Cas12a to enhance nuclease specificity and significantly reduce off-target genome editing. Upon identification of high-activity gene targeting Cas12a guides, optimization of the Cas12a mRNA sequence, and refinement of our lipid nanoparticle (LNP) formulation, we sought to demonstrate functional gene disruptions in wild-type Balb/c mice. A single intravenous dose of Cas12a chRDNA optimized to target *Pcsk9* resulted in nearly 60% hepatic editing, followed by a 50% reduction in circulating PCSK9 protein and a 30% reduction of plasma cholesterol in wild-type mice. Similarly, targeting *Angptl3*, we demonstrated a >70% hepatic editing efficiency followed by a >70% reduction of plasma ANGPTL3 protein, accompanied by a 30% reduction of plasma cholesterol. Surprisingly, a dual knockout of *Pcsk9* and *Angptl3* did not demonstrate increased reduction of circulating LDL cholesterol compared to single disruptions. Lastly, targeting *Ttr*, we observed 70% gene disruption with a single administration, leading to a 98% reduction in circulating TTR protein levels. With all the targets, we did not detect significant liver toxicity or chronic cytokine release. Furthermore, analysis of *in silico* predicted off-target sites by next-generation sequencing (NGS) did not identify off-target genome editing. In addition, no significant peripheral organ on-target genome editing was detected following tissue isolation and NGS analysis. Our studies demonstrate that LNP delivery of Class 2 Type V Cas12a mRNA in conjunction with an optimized chRDNA guide is a powerful tool for efficient and functional genome editing in hepatocytes and a tractable alternative platform to first-generation CRISPR-Cas9 genome-editing.

279. *In Vivo* panCAR™ Therapy Using Circular RNA for the Treatment of B cell Malignancies in Oncology and Autoimmune Disease



Amy Becker, Isin Dalkilic, Allen Horhota, Robert A. Wesselhoeft, Akinola Emmanuel, Thomas Lee, Blake Cohen, Ramya Elangovan, Akshi Thakkar, Magnolia Chinn, David Soto, Sharmistha Kundu, Kevin Kauffman, Meghan Richardson, Chris Wright, Kristen Ott, Jui Dutta-Simmons, Rena Schindler, Yessica Wiryawan, Trent Stevens, Ashley Wong, Ian Langer, Rahul Vungutur, Corey Ciullo, Zifiso Nyoni, Junghoon Yang, Emily Fitzgerald, Nelson Chau, Tom Barnes, Robert Mabry

Orna Therapeutics, Watertown, MA

Orna Therapeutics is developing off-the-shelf *in vivo* panCAR™ therapies for the treatment of cancers and other immunologic diseases. ORN-101, our first clinical candidate, is an αCD19 panCAR for the treatment of leukemia and lymphoma. While traditional *ex vivo* generated CAR-T cell therapies have had tremendous success in the clinic, the manufacturing, safety, and efficacy remains a challenge. Circular RNA (oRNA™)-enabled panCAR therapies promise a transient, re-dosable and scalable immune cell therapy, without requiring immunodepletion. panCAR combines a novel, synthetic, circular coding RNA platform (oRNA) and immunotropic lipid nanoparticles (LNP) to drive CAR expression on the surface of immune effector cells after i.v. administration, eliminating the need for external manufacturing. LNPs deliver oRNA payloads to multiple immune effector subsets, including T cells, NK cells, and macrophages in vivo, potentially increasing efficacy and broadening application beyond hematologic malignancies. Immunotropism is

preserved across multiple species, including mouse, rat, humanized mouse, and non-human primate models. oRNA technology uses a sequence based IRES element to initiate protein translation in target cells. To identify IRES sequences that drive high reporter payload expression in primary human T cells, we screened over 3000 oRNAs containing IRES sequences extracted from viral genomes using our proprietary FoRCE platform. Of hundreds of sequences identified, a subset was selected to generate CAR expressing oRNAs for functional testing in vitro and in vivo. In a PBMC-engrafted NALM6 CD19+ tumor-bearing model, we observed tumor regression in a dose- and antigen-dependent manner in mice treated with the αCD19 panCAR but not αHER2 panCAR. Importantly, tumor regression was observed at doses as low as 0.1 mg/kg using a bi-weekly dosing schedule. While T cells are the primary cell type in PBMC-engrafted immunodeficient mice, CAR-expressing NK cells can augment tumor clearance as well. To understand this, we developed a humanized NK panCAR mouse model, where Raji cells were engrafted with primary human NK cells. The NK model showed improved tumor control in i.v treated mice with αCD19 panCAR compared to control treated animals. Taken together, these data suggest that panCAR can target and engage multiple potent anti-tumor effector cells. Analogous to an immune competent host, we evaluated endogenous B cell depletion by treating human CD34+ hematopoietic stem cell engrafted mice with αCD19 panCAR vs negative control panCAR. With weekly dosing, the panCAR-treated mice exhibited significant depletion of CD19+ cells in the peripheral blood, spleen, mesenteric lymph node, and bone marrow (Figure 1). Extensive B cell depletion in these compartments reinforces the effectiveness of αCD19 panCAR for diseases like hematological cancers or B cell-mediated autoimmunity. Collectively, Orna Therapeutics' panCAR therapy shows promise as an efficacious, scalable therapy that eliminates manufacturing time, thus providing patients access to immediate immune modulating treatments.

Figure 1: Evaluation of endogenous B cell depletion by treating human CD34⁺ hematopoietic stem cell engrafted mice with αCD19 panCAR. Mice were dosed weekly at 2 mg/kg. B cell counts were analyzed in the peripheral blood (1a, days 1-24) and spleen (1b), mesenteric lymph node (1c), and bone marrow (1d) at study termination, and percentages were normalized to αHER2 panCAR (negative control).

280. *In Vivo* HSC Gene Editing for Correction of Sickle Cell Mutation Using RNA Gene Writers

Giulia Schiroli[1], Yaser Heshmati[1], Yu Cao[1], Lorenzo Tozzi[1], Micheal Monte[1], Apiwat Wangweerawong[1], James Rottman[1], Rahul Palchaudhuri[1], Jane Wang[2], Jean-Antoine Ribeil[3], John Manis[4], Bill Querbes[2], Anne Bothmer[1], Cecilia Cotta-Ramusino[1], Micheal C. Holmes[1]

[1]Tessera Therapeutics, Cambridge, MA,[2]Tessera Therapeutics, Somerville, MA,[3]Boston University Medical Center, Cambridge, MA,[4]Boston Children's Hospital, Boston, MA

Tessera Therapeutics is pioneering a new approach to genome engineering through the development of our Gene Writing and delivery platforms. RNA Gene Writers are inspired by the biology of naturally occurring non-LTR retrotransposons, a class of mobile genetic elements that can edit the genome through target-primed reverse transcription, or TPRT. We have engineered non-LTR retrotransposon proteins that are designed to introduce a broad range of edits to the genome, from writing in a transgene, inserting an exon, or introducing single nucleotide changes. We believe RNA Gene Writers could potentially be applied to sickle cell disease (SCD) to correct the SCD causing mutation, *HBB* E6V, in primary hematopoietic stem cells (HSCs). We first modeled the efficiency of *HBB* editing by introducing *HBB* Makassar variant (E6A) in wild-type (WT) CD34+ human HSCs from healthy donors. We observed an average of 74% correction *in vitro* after optimization of the RNA template, delivery and expression of multiple RNA Gene Writers. Phenotypic or functional impairment was not observed in edited HSCs as measured by colony forming assays, differentiation, or *in vivo* reconstitution studies in immunodeficient mice. We observed high engraftment levels and *HBB* correction was maintained in long-term repopulating HSCs and their multi-lineage progeny isolated from mice 16 weeks post bone marrow transplant. Comparable editing levels were also maintained after secondary transplant of the edited cells. As compared to treatment with nucleases, *HBB* editing with RNA Gene Writers did not induce a detectable p53-related response in HSCs as measured by RNAseq. We then demonstrated efficient editing of CD34+ cells from multiple SCD patients. We observed ~70% correction of sickle alleles to WT. Erythroid differentiation further demonstrated edited cells exhibited improved enucleation and, importantly, restoration of normal adult hemoglobin levels by liquid chromatography-mass spectrometry (LC-MS) and high performance liquid chromatography (HPLC). Phenotypic correction of SCD donor CD34+ cells were further confirmed by culturing differentiated erythrocytes under hypoxic conditions and demonstrating abrogation of cell sickling compared to untreated donor cells. RNA Gene Writers are designed to be delivered as an all-RNA composition, which enables *in vivo* non-viral delivery by lipid nanoparticles (LNP). Delivery of a reporter gene to a substantial fraction of HSCs *in vivo* was observed, including >90% of long-term HSCs in both humanized mice and non-human primates. *In vivo* studies performed using a surrogate reagent, *B2M,* demonstrated an average of ~15% rewriting of long-term HSCs in humanized mice with a single LNP dose. By combining our LNP delivery platform and RNA Gene Writers, we believe we may be able to correct the SCD mutation by targeting HSCs *in vivo*.

281. The Development of a *Staphylococcus epidermidis* Strain Expressing LEKTI-D6 (ATR12-351) for Netherton Syndrome

Sara Mootien, Roger Leger, Dorival Martins, Francisco Salva, Travis M. Whitfill, Mary Spellman

Azitra Inc., Branford, CT

Netherton syndrome (NS) is a rare autosomal recessive disorder caused by mutations in the serine protease inhibitor of Kazal type 5 (*SPINK5*) gene, which encodes the serine protease inhibitor lympho-epithelial Kazal-type-related inhibitor (LEKTI). Loss-of-function mutations in the *SPINK5* gene lead to unregulated kallikrein (KLK) proteolysis and activation of the KLK cascade, resulting in skin desquamation and increased transepidermal water loss. Harmful microbial and allergen penetration trigger the release of antimicrobial peptides and activation of inflammatory pathways, including by IL-36γ. There are no approved therapies for NS. ATR12-351 is a live biotherapeutic topical ointment comprised of an auxotrophic strain of *Staphylococcus epidermidis* (SE351) engineered to express domain 6 (D6) of the human LEKTI protein. Delivery of recombinant human LEKTI-D6 (rhLEKTI-D6) in the lower layers of the stratum corneum restores normal KLK activity levels, while the *S. epidermidis* strain reduces IL-36γ. ATR12-351 is expected to inhibit skin serine protease activity, improve skin barrier function, and reduce underlying cutaneous inflammation, reducing the signs and symptoms (skin appearance, pain, and pruritus) of NS. Early developmental studies were conducted to measure the potency of protease inhibition of SE351 in a skin matrix with added KLK5, which showed an IC_{50} of trypsin-like activity of 4-16 mol/mol of LEKTI/KLK5. In an *in vitro* assay using human keratinocytes monolayer, SE351 culture supernatant significantly reduced Poly I:C induced IL-36γ levels. SE351 culture supernatant reduced IL-36γ levels by 93% compared to Poly I:C alone (908 pg/mL vs. 70 pg/mL) and were similar to untreated cells (~50 pg/mL). Formulation studies were conducted to optimize rhLEKTI-D6 expression by SE351. In *in vitro* studies, growth of SE351 in the presence of various excipients as nutrient sources in the formulation was assessed, and the addition of colloidal oatmeal to the formulation of ATR12-351 increased rhLETKI-D6 expression by 5-fold compared to formulation without colloidal oatmeal ($p<0.001$). The efficacy of ATR12-351 was evaluated on an NS model consisting of human skin extracts supplemented with recombinant KLK5 (7-fold excess over normal human skin to model protease activity in NS) focusing on trypsin-like activity. The results demonstrate that trypsin-like activity was reduced to levels like those of normal skin ($p<0.01$). Toxicology and rhLEKTI-D6 expression were evaluated on minipigs with abraded skin treated with either topical ATR12-351 or vehicle for 14 days. There were no adverse safety findings when ATR12-351 was applied to skin abraded minipigs, and ATR12-351 was not detected in blood. rhLEKTI-D6 was also significantly increased at day 14 in ATR12-351 vs. vehicle on the surface of the pig skin (12 vs. 2.6 ng/cm^2, respectively, $p<0.01$). An ongoing proof-of-concept, randomized, double-blind, multicenter, vehicle-controlled clinical study (NCT06137157) assesses the safety, tolerability, and pharmacokinetics of topical ATR12-351 in approximately 12 adult patients with NS. ATR12-351 ointment is applied twice daily to a defined area of affected skin on one side of the body, and its vehicle is applied to similarly affected skin contralaterally during a 14-day treatment period. Throughout the study, including a 70-day follow-up period, clinical assessments include safety and local tolerability, the severity of the signs and symptoms of NS, local biomarkers (including KLK activity), and the presence of rhLEKTI-D6 in skin. The results of this clinical study will establish an initial safety and efficacy profile of ATR12-351 in NS patients to potentially support further clinical development.

Novel Production Platforms

282. Healthy Donor vs Patient Manufactured Autologous Deltex DRI Product; Immunophenotyping Gene Expression

Mariska A. Ter Haak[1], Branimir Popovic[1], Caitlyn C. Lucas[1], Becca B. Weekley[1], Wenjing Pan[2], Daniel Weber[2], Miranda Byrne-Steele[2], Lawrence S. Lamb[1], Kate Rochlin[1]

[1]IN8bio, New York, NY,[2]iRepertoire, Hunstville, AL

Gamma-delta T cell based therapies have been advancing clinically and have shown therapeutic promise but their molecular profiles have not been well characterized. Gene expression changes that occur throughout the manufacturing process which can be >10 days, could provide insight into the potency, effector and trafficking capabilities of these products along with the reproducibility and robustness of particular manufacturing processes. Deeper analysis of the gene expression changes through manufacturing has not previously been demonstrated but may identify predictors of γδ T cell expansion and/or correlate to potency or clinical outcomes. Further, such data may elucidate which profiles or cellular characteristics are imparted by donor selection versus those from the manufacturing process. We evaluated TCR repertoire and gene expression from both (a) the apheresis starting material and (b) final manufactured γδ T cell product from healthy donors and glioblastoma (GBM) patients (NCT 04165941). Gamma-delta T cell clinical products were manufactured from apheresis using proprietary expansion protocols. The cells were transduced with a Methylguanine-DNA methyltransferase (MGMT) construct, which conveys resistance to temozolomide chemotherapy. TCR libraries were prepared with VDJ-specific primers for α, β, δ and γ chains by dimer-avoided multiplex PCR (dam-PCR) using iRepertoire's RepSeq+. In parallel, bulk RNA phenotyping libraries were prepared by dam-PCR encoding +150 immune profiling genes and sequenced using Illumina's platform. Multigroup comparisons were performed by nonparametric statistical test while controlling for false discovery rate. At manufacturing initiation, the TCR repertoire consisted primarily of αβTCR clones. Gene expression levels from healthy donors seem to have increased BCL6, naïve cells, CD8, CD63, but overall gene expression was similar between healthy donors and GBM patients. The corresponding shift to γδ TCR expression was confirmed in the final products, where preferential expansion of Vγ9 and Vδ2 clones was observed from both healthy donors and GBM patients. Interestingly, gene expression analysis showed a significant increase in markers of cellular activation and cytotoxicity in both final products. These markers, indicating that the cells are active and primed to kill, include IFNγ, Perforin, Granzyme B, TNF, CD25, CD40L, CD71, 41BB, CD226, Eomes, CXCR3, ICOS, and IL-4, as well as LAG3, TIM3, and CTLA-

4, which are suggested to be γδ T cell activation markers p <0.01. Interestingly, the expression of immune trafficking and stimulation markers were significantly increased in the final product, including STAT-1, STAT-4, CCR6, Runx1, Tbet, GATA3, CD103, CD193, S1PR1, Il-5, Il-13, IL7-R, IL-12Rb2, and Il-23R, p <0.05, suggesting the cells are capable of tissue trafficking and immune cell recruitment. Products manufactured from healthy volunteers and GBM patients exhibited highly similar gene expression profiles, suggesting that the process is both robust and reproducible across different donor populations. Our studies show activated, cytotoxic γδ T cell products were successfully manufactured from different starting materials and exhibited similar gene expression profiles. In addition, immunophenotyping gene expression of DeltEx DRI product elucidated additional attributes such as cytotoxic and/or trafficking potential along with the ability to stimulate immune cell recruitment.

283. Enhancing Cell Transfection Efficiency via Modulation of Extracellular Fluid Viscosity

Jingyao Ma, Yining Zhu, Jiayuan Kong, Di Yu, Wu Han Toh, Milun Jain, Junkai Yang, Qin Ni, Zhuoxu Ge, Jinghan Lin, Joseph Choy, Konstantinos Konstantopoulos, Maximilian F. Konig, Sean X. Sun, Hai-Quan Mao

Johns Hopkins University, Baltimore, MD

Statement of Purpose: Gene therapy and cellular programming rely on effective cell transfection in vitro and in vivo. While numerous viral and non-viral vectors and transfection techniques have been developed to improve transfection efficiency, the extracellular fluid viscosity as a biophysical parameter has long been overlooked[1]. Here we report a generic effect of culture media viscosity on transfection efficiency of several gene delivery vehicles. In this study, we examined the effect of extracellular fluid viscosity ranging from 0.77 to 15 cP (at 37°C) on transfection efficiency across various cell types, using plasmid DNA (pDNA) or mRNA-based lipid nanoparticles, polyplex nanoparticles, and viral vectors. **Methods:** The LNP formulation developed by Moderna was utilized as a standard benchmark formulation. We synthesized LNPs and administered them to a diverse array of over 20 cell types, and the cells were cultured in media with varying viscosities, ranging from 0.77 to 15 cP (Fig. 1a). To verify whether the media viscosity-dependent enhancement effect applies to other transfection vectors or carriers, we substituted the LNP cargo with polyplex nanoparticles and viral vectors, and employed pDNA instead of mRNA as the genetic payload. In addition, we conducted pathway inhibition studies using chemical inhibitors for specific cell entry pathways. **Results and Discussion:** The transfection efficiency of mRNA LNPs was increased by 2 to 60-fold when subjected to a higher media viscosity, among cancer cell lines, immune cells, and other frequently used cell lines (Fig. 1a). The optimal media viscosity varied among different cell types, though within the range of 1 to 4 cP. Additionally, LVV-mediated transduction of peripheral blood mononuclear cells (PBMCs) showed a media viscosity-dependence effect (Fig. 1b). We then examined the transfection of human primary B cells using mCherry mRNA LNPs and showed that the percent of transfected cells increased by about 2-fold and MFI increased by about 80% at 2 cP compared with 0.77 cP condition (Fig. 1c-d). The pathway inhibition study revealed that at 2 cP, in B16F10 cells, the predominant pathways for LNP uptake shifted from an evenly distributed mold of uptake to clathrin-dependent endocytosis and micropinocytosis (Fig. 1e). **Conclusion:** We present a novel approach to enhance transfection or transduction efficiency in a wide range of cell types by adjusting media viscosity in in vitro or ex vivo processes and report a protocol to better mimic the in vivo cellular conditions in the current gene delivery research. **References:** 1. Bera, K. et al. Nature 611, 365-373 (2022).

284. A Short, Simple, and Cost-Effective CAR-T Cell Manufacturing Process

Ying Xiong, Yanping Xie, Yang Liu, Matthew Addington-Hall, Beatrix Ferencz, Tony Luo, Maggie Yates, Oxana Slessareva, Ibeawuchi Oparaocha, Zhongyu Zhu, Boro Dropulic, Rimas J. Orentas

Caring Cross, Inc., Gaithersburg, MD

Chimeric antigen receptor modified (CAR-T) cell therapy has shown tremendous clinical efficacy for hematological malignancies, and limited efficacy in solid tumor therapy. However, bottlenecks in the ability to manufacture and deliver these engineered cell products, combined with their high cost, have limited patient accessibility of CAR T therapy, especially to those in underserved areas or who are uninsured. Therefore, we are developing a flexible, cost-effective CAR T manufacturing process that generates sufficient CAR T cells numbers with excellent functionality.It is possible to achieve a high degree of T cell purity and recovery after a rosetting-based negative T cell selection protocol from either 450ml fresh whole blood or a 45ml (quarter size) leukapheresis product. We are in the process of developing an in-house reagent composed of bi-specific antibodies that rosette by means of binding to CD235 on red cells and to target antigens on B cells and cells of monocytic lineage, termed (T-Pure). Using the T-pure reagent and a Sepax™ C-Pro instrument (Cytiva) large-scale CAR-T manufacturing was attained. When T cells were enriched either by our negative selection method by T-pure or by positive selection using CD4/CD8 magnetic beads (Miltenyi Biotec), higher γδ T cell recovery was observed with T-pure reagent, which might indicate an advantage of the negative enrichment method.For large-scale T cell transduction with a CAR-encoding LVV, 1x 10^8 T cells were suspended in TexMACS GMP medium (Miltenyi Biotec) with 200 IU/ml IL-2 and transferred to

a G-Rex cell culture device (Wilson-Wolf), followed by the addition of T cell activation reagent (TransAct from Miltenyi Biotec, or Enceed from GenScript) and HIV gp120 DuoCAR lentiviral vector (MOI 40). On Day 3, a complete medium exchange or direct fresh medium addition (1:10 dilution) was carried out in the same G-Rex culture vessel. CAR-T were then cultured and expanded to Day 8, when the final cell product was harvested. On days 6 and 8, cultures were sampled to monitor T cell growth, phenotype, CAR expression, and function. Evaluating 3 healthy donors, similar cell growth was observed with either complete medium exchange (the "wash" condition) or medium addition alone (the "no wash" condition) on Day 3. In addition, comparable transduction efficiency, memory phenotypes (T_{scm}% and T_{cm}%) and target gp120 cell cytolysis were observed on both Day 6 and Day 8, indicating the feasibility of simpler manufacturing protocol integrated with medium dilution. Furthermore, equivalent transduction efficiency, similar memory phenotypes and comparable target gp120 positive cell cytolysis were demonstrated when alternative activation reagents were tested, confirming the robustness of the simplified CAR-T generation process. In conclusion, this simplified large-scale CAR T production process can provide the flexibility of an earlier culture harvest, as well as the use of alternate GMP reagents for manufacturing. Implementing this approach in a point-of-care manufacturing setting creates an economical process for CAR T production that can be administered to all who would benefit, especially in low- and middle-income countries. Future work will include evaluation of this process with patient-derived material.

285. An Efficient Way to Generate Virus- and Factor-Free Human iPSCs Using S/MAR DNA Vectors

Anna Hartley[1], Cornelia Wincek[1], Manuela Urban[1], Alicia Roig-Merino[1], Luisa Burger[1], Zhaoyu Du[2], Tracy Li[3], Lieke Dons[3], Martin J. Hoogduijn[2], Mehrnaz Ghazvini[3], Richard P. Harbottle[1]

[1]DNA Vector Lab, German Cancer Research Centre, Heidelberg, Germany,[2]The Rotterdam Transplantation Lab, University Medical Center Rotterdam, Rotterdam, Netherlands,[3]Erasmus MC iPS Core, University Medical Center Rotterdam, Rotterdam, Netherlands

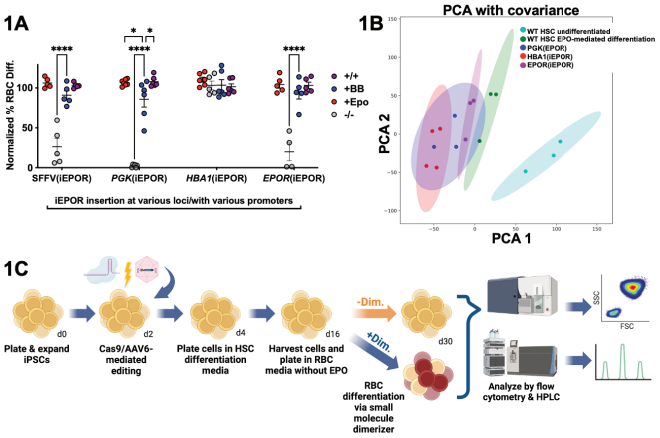
Generating isogenic or autologous cells for modelling diseases or cell- and organoid-based therapies depends on efficiently reprogramming cells derived from patients. This was originally accomplished using integrating viral vectors, which pose risks of insertional mutagenesis and oncogenesis. Alternatively, non-integrative reprogramming commonly uses viral components (EBNA1/oriP, Sendai) or involves multiple transfection steps (RNA). However, these methods raise concerns; cells reprogrammed with viral components exhibit increased markers of cellular damage and immune activation, and repeated transfections escalate both costs and the risks of non-compliance with clinical quality standards. To mitigate these risks and enhance the clinical potential of cells, we have devised a user-friendly approach to reprogramming primary human fibroblasts using entirely non-viral DNA vectors, requiring only a single transfection. Our vectors are based on Scaffold Matrix Attachment Regions (S/MARs), sequences of human origin that enable autonomous episomal replication of the vector within the host cell nucleus. This facilitates sustained expression of the necessary reprogramming factors without integration, paving the way for virus-free, vector-free human induced pluripotent stem cells (hiPSCs). hiPSCs made using our S/MAR vectors are morphologically and phenotypically indistinct from EBNA/oriP-derived hiPSCs, and express markers of pluripotency as measured by immunofluorescence and qRT-PCR. On a transcriptional level, S/MAR iPSCs show close similarity with human embryonic stem cell lines. S/MAR iPSCs are also capable of directed tri-lineage differentiation *in vitro*. Copy number variations (CNVs) assessed by microarray in comparison with input somatic cells show minimal perturbation of iPSC genomes in most clones assessed. An additional advantage is that S/MAR vectors can be lost passively after reprogramming, generating vector-free hiPSCs without the need for selection. Our S/MAR DNA vectors can also be employed for the stable and heritable genetic modification of hiPSCs. Importantly, these vectors are maintained episomally at a low copy number, preserving the cells' pluripotent capacity without causing damage. The stability of the vector transgene expression in hiPSCs persists over an extended period (>150 days) even in the absence of selection and remains unaffected by cryogenic cell storage. Furthermore, transgene expression is stable across all stages of differentiation into target cell types. We have demonstrated the persistence of transgene expression *in vitro* in the trilineage differentiation of S/MAR-modified hiPSCs into germ layers, as well as in directed differentiation into lymphoid effector cells and kidney organoids. Modification of mouse embryonic stem cells using S/MAR vectors led to the generation of chimeric pups which retained transgene expression. S/MAR DNA vectors present a safe and stable alternative for efficient reprogramming of primary human fibroblasts into hiPSCs, as well as a heritable means of genetic modification of stem cells for clinical application. Future work will focus on guaranteeing the passive loss of reprogramming vectors after iPSC generation, further improving the safety profile of the vectors, and progressing towards virus-free, vector-free, factor-free iPSCs which are feasible to generate at clinical scale and grade.

286. Establishment of Automated Point-of-Care Manufacturing of ΔNPM1 TCR-Engineered T Cells for AML Therapy

Isabella Elias Yonezawa Ogusuku[1], Eva Agiro[2], Vera Herbel[1], Caroline Brandes[1], Sabrina Veld[2], Lois Hageman[2], Marieke Griffioen[2], Thomas Schaser[1], Rosa de Groot[2], Dominik Lock[1], Ian C. D. Johnston[1]

[1]Miltenyi Biotec B.V. & Co. KG, Bergisch Gladbach, Germany,[2]Department of Hematology, Leiden University Medical Center, Leiden, Netherlands

Acute myeloid leukemia (AML) is a heterogeneous malignancy that requires the expansion of available therapeutic options, especially for the elderly and patient subgroups with poor prognosis. A recently discovered T cell receptor (TCR) targeting a common mutant nucleophosmin 1 (ΔNPM1) neoepitope presents an attractive opportunity to design such a novel cancer antigen targeted cellular therapy. We have recently developed a rapid (8-day), closed and GMP-compliant, automated TCR-T cell manufacturing process using the CliniMACS Prodigy®. Starting from cryopreserved leukapheresis, 2E8 CD8-positive T cells from healthy donors were magnetically enriched, activated, transduced with lentiviral vector expressing an HLA-A*02:01 restricted recombinant ΔNPM1-specific TCR, expanded and finally formulated. In downscaled experiments, we also verified that the planned approach yielded functional and potent



ΔNPM1-specific TCR-T cells when starting with frozen material from AML patients. After optimization of the manufacturing process, the protocols and associated quality control assays were transferred to the clinical manufacturing site at Leiden University Medical Center. As expected, the robust manufacturing process demonstrated comparable performance in all relevant IPC and QC assays yielding >5E9 CD8+ ΔNPM1+ T cells with >98% viability. We show that across independent donors, devices, manufacturing sites and operators, this process consistently yielded therapeutic doses of potent TCR-engineered CD8 T cells while maintaining the product's high viability, purity and favorable early memory phenotype, which is known to support in vivo persistence and efficacy. This novel state-of-the-art manufacturing process will now be used to manufacture autologous TCR-modified T cells for assessment in a phase I/II clinical trial to treat patients with relapsed or refractory NPM1-mutated AML.

287. Engineering Inducible Signaling Receptors for Erythropoietin-Free Erythropoiesis

Aadit P. Shah[1], Kiran R. Majeti[2], Matthew H. Porteus[2], Kyle Cromer[3]

[1]Stanford University School of Medicine, Stanford, CA,[2]Stanford University Department of Pediatrics, Stanford, CA,[3]University of California San Francisco Department of Bioengineering & Therapeutic Sciences, San Francisco, CA

Introduction: Blood cell transfusion is vital to medicine. In the US, more than 12 million red blood cell (RBC) units are used annually. Yet, availability relies on donor material, resulting in supply constraints and safety concerns. Shortages are expected to worsen with aging populations and diminishing donor numbers. To address this need, *ex vivo* manufacture of RBCs from induced pluripotent stem cell (iPSC) producer lines emerges as a potential solution that offers benefits compared to donor blood, including lower infectious disease transmission, streamlined production, product uniformity, and ability to source or genetically engineer antigen-negative cells. However, this approach remains extremely costly, largely due to purified, clinical-grade cytokines required to stimulate producer cells for expansion and differentiation into erythroid cells. Because erythropoietin (EPO) signaling through the EPO receptor (EPOR) is indispensable to RBC development, of all components in erythroid-promoting media, EPO is by far the costliest (currently $300,000/unit). **Methods:** We used synthetic biology tools and genome engineering to devise a series of FKBP-EPOR chimeras, termed inducible EPORs (iEPORs), that exchanged the requirement for native EPO ligand with an exogenous, orthogonal small molecule (SM). These were site-specifically inserted *in vitro* into primary human hematopoietic cells (HSCs) via CRISPR/AAV-mediated genome editing. Using flow cytometry, ddPCR, and RNA sequencing-based assays, we determined the fidelity (responsivity to SM) and potency (ability to drive differentiation towards the erythroid lineage) of iEPOR constructs with different signal peptides, extracellular and intracellular domain modifications, and insertion at different HSC and RBC-relevant loci. **Results:** We optimized iEPOR constructs with a highly efficient IL6 signal peptide and naturally occurring intracellular domain truncation enhancing erythropoiesis. When integrated at the *CCR5* locus and driven by the SFFV promoter, we drove 100% differentiation into RBCs from engineered HSCs using SM without Epo. However, we observed 26.2% differentiation without any erythroid-biasing ligand. To increase iEPOR fidelity, driving expression via the PGK promoter ablated ligand-independent differentiation (Fig 1A). Identical HSC response to iEPOR in the presence of SM versus native HSC in the presence of EPO was confirmed by flow cytometry and measurement of hemoglobin production by HPLC. By RNA sequencing, iEPOR-integrated HSCs differentiated into RBCs clustered with natively differentiated HSCs compared to undifferentiated HSCs by PCA covariance plots (Fig 1B). We observed effectively identical counts of hemoglobin RNA by EPO or SM-mediated differentiation supporting the HPLC findings. Finally, we integrated iEPOR into an iPSC line and devised a consolidated differentiation strategy from iPSCs to HSCs and, ultimately, RBCs (Fig 1C). This proves our approach serves as an *ex vivo*, EPO-independent RBC production strategy that closely mimics native EPOR signaling by surface biomarkers, relevant protein output, and transcriptional profile. Our iEPORs provide a starting point to address one of the greatest cost barriers to meeting the global demand for blood by transforming *ex vivo*-manufactured RBCs into a scalable and renewable source for transfusion medicine.

288. Non-Viral Engineering of Primary Human Macrophages Using a cGMP-Compliant Electroporation Platform

Ashley B. Strickland, Cornell Allen, Camille Ciesliga, Jason Papademetriou, Lauren E. Unsworth, James Brady

MaxCyte Inc., Rockville, MD

Macrophages are highly plastic innate immune cells that can exhibit pro- or anti-inflammatory effector functions depending on their activation state. For this reason, macrophages can be used for various therapeutic applications ranging from cancer treatment to regenerative medicine. To engineer macrophages for these purposes, biomolecules or other genome editing tools must be delivered into these cells. Electroporation, also known as electropermeabilization, is an effective non-viral transfection method that utilizes an electric field to facilitate the passage of molecules across biological membranes. Here, it is demonstrated that highly efficient delivery of mRNA, DNA and CRISPR ribonucleoproteins (RNPs) into primary human macrophages can be achieved using the MaxCyte® ExPERT GTx™ system - a cGMP-compliant electroporation platform. In fact, use of the ExPERT GTx™ to transfect macrophages with mRNA or SIRPα-targeting CRISPR RNPs

resulted in efficiencies greater than 90% with minimal impact on cell viability. This system also enabled delivery of DNA, ranging in size from 2.5-kb to 9.2-kb, into macrophages with transfection efficiencies between 60% and 90%. These efficiencies were inversely related to plasmid size and were accompanied by a dose-dependent decrease in cell viability. Despite this, electroporation was determined not to directly impair migration, activation/polarization, or phagocytosis in viable macrophages. For further proof-of-concept, the ExPERT GTx™ was also used to generate clinically relevant chimeric antigen receptor (CAR)-expressing macrophages targeting the tumor antigen CD19. These CAR macrophages were found to be functional and highly effective at eradicating $CD19^+$ target cells. Together, these demonstrate that the MaxCyte ExPERT GTx™ electroporation platform can be used to engineer macrophages for use in cell therapy applications.

AAV Manufacturing III

289. Optimizing for > 95 % rAAV Empty Capsid Removal at Process Scale with Anion Exchange Chromatography Using a Mechanistic Model

Vijesh Kumar, Ohnmar Khanal, Mi Jin
Spark Therapeutics, Philadelphia, PA

The current recombinant adeno-associated viral vector (AAV) system produces empty capsids in greater quantities than the genome-containing capsids, making the large-scale separation of empty and full capsids challenging. Anion exchange chromatography (AEX) is currently the industry standard for removing empty capsids. Despite the recent surge in published AEX methods for removing empty capsids, companies still struggle to find a robust and scalable AEX method that withstands load composition and quality variation, often seen over the product development lifecycle. Furthermore, an AEX process that requires peak fractionation is difficult to scale up and transfer, rendering the process less desirable. We present here a computational strategy, namely mechanistic chromatography modeling, which is based on the well-established and detailed fundamental understanding of chromatography, to achieve >95% removal of empty capsids. Our detailed model accurately describes the interaction between AAVs and the stationary phase. Given that AAVs are large and do not wholly penetrate the commercially available AEX resins designed for use with smaller proteins, we predicted the partial penetration of AAVs by modeling the resin particle as a core-shell bead using an advanced general rate model. This geometric representation was suitable for the widely used POROS XQ resin. Our mechanistic model describes the interaction between neighboring AAV capsids on the resin surface as well as the resin-AAV interaction using the comprehensive colloidal isotherm. These two interaction terms were the only two parameters calibrated using breakthrough curves at various experimental conditions, ensuring that our model was not over-fitted. The isotherms account for the capsid radius and were calibrated separately for empty and full capsids, allowing for the selective optimization of full capsid retention. The distinct isotherms for empty and full capsids showed that employing a higher ionic strength buffer during loading and a lower ionic strength buffer during washing leads to >95% removal of empty capsids with the optimal retention of full capsids. We will demonstrate the further utility of the model by providing model-derived solutions for empty capsid removal in flowthrough, step, and gradient-based operations.

290. A Proprietary HEK293 AAV Production System Can Achieve Greater Than 50% Full Capsids with Greater Than 1e15vg/L at Harvest Enabling Scalable Chromatography-Based Polishing with High Yield and Purity

Matt Edwards[1], Michael White[1], Paul Freeman[1], Esther Aribilola[1], Matt Bennett[1], Patrick Bresnahan[1], Rong Cong[1], Ramin Kamran-Sami[1], Ghazi Abuzarifah[2], Graham Lilley[2], Dan Linnehan[2], Shahrzad Parker[2], Jordan Shufro[2], Rob May[3]
[1]Process Science, Affinia Therapeutics, Waltham, MA,[2]Analytical Science, Affinia Therapeutics, Waltham, MA,[3]Technical Operations, Affinia Therapeutics, Waltham, MA

Manufacturing of AAV gene therapies has long been a challenge which has only increased with the discovery of novel AAV variants. Innovative solutions to vector production are needed to realize the potential of AAV gene therapy. The current barriers to AAV manufacturing are low vector yields, lack of scalability in downstream polishing and meeting the predefined CQA thresholds for percentage of full particles, detectable rcAAV, host cell DNA (hcDNA), host cell protein (HCP), and residual plasmid (rPlasmid) limits. These contribute to the high cost of goods and regulatory uncertainty. Varied efforts across the CGT field have attempted to address these challenges through novel cell culture additives, media and transfection optimization, plasmid engineering and cell line development. Here we discuss an Affinia Therapeutics developed HEK293 suspension manufacturing platform that meets these requirements more fully than any reported to date. Using this platform, we have achieved harvest titers equal to or greater than 1e15vg/L across numerous WT and engineered AAV capsids. In addition, we commonly see 40-60% full particles at harvest for WT and engineered capsids which enables chromatographic polishing that delivers high enrichment (>90% full) without the use of ultracentrifugation (UC). Analysis of vector quality shows an equal or increased reduction in hcDNA, HCP, rDNA, rcAAV and potency compared to other AAV production platforms. This platform is flexible and can be readily implemented into standard AAV manufacturing processes across serotypes, payloads, and scales.

291. Identification and Control of AAV Charge Heterogeneity through Optimized Bioreactor Operation

Thomas Thiers, Alex Meola, Eli Wiberg, Sarah Laughlin, Luke Mustich, Guang Yang, Qi Zhang, Iraj Ghazi, Lucas Govert, Alejo Zacarias, Danny Lassiter, Eugenia Fandunyan, Richa Jaiswal, Rob Horton
Oxford Biomedica (US) LLC, Bedford, MA

Small charge differences in recombinant adeno-associated virus (rAAV) capsids are often exploited with anion exchange (AEX) chromatography to separate empty and full capsids. During the development of this

step for rAAV9, we discovered that capsids are not uniform in charge and can be found in various AEX fractions eluted at variable salt concentrations. The observed broad distribution of capsids suggested a heterogenous charge profile. To therefore understand the root of this heterogeneity, we investigated the production time in the bioreactor and where in the system the heterogeneity is greatest (intracellular or extracellular). HEK293 cells were transfected using a transient transfection platform and incubated for a duration of either 3 or 6 days before harvest. In one arm, a detergent lysis was performed at day 3 post-transfection and the full lysate was collected. For the other arm, the cell and supernatant were separated by centrifugation at days 3 and 6 post-transfection. The cell pellets were resuspended and lysed to extract intracellular capsids. After harvest, all feed-streams were purified using affinity chromatography followed by an AEX purification step to enrich for full capsids and examine the observed charge distribution. We found that (i) empty capsids had more heterogeneous charge distributions than DNA-containing capsids and (ii) that surprisingly the intracellular capsids were more negatively charged than extracellular capsids. Further investigation revealed that extracellular capsids were composed of less empty capsids which helped to explain their more uniform charge distribution. LC-MS/MS of the various feed-streams unexpectedly showed that intracellular capsids had more asparagine N57 deamidation right out of the bioreactor than extracellular capsids and increased levels from day 3 to day 6 post-transfection. A linear correlation exists between N57 deamidation and capsids lost to the AEX strip, demonstrating the N57 deamidation was responsible for the increase in charge heterogeneity observed through AEX mass balance. Deamidation at N57 in the product was reduced by ~2x through AEX for all feed-streams tested, however, that step was not sufficient in completely removing deamidated species. Lastly, we found that potency, as measured by GFP expression and fluorescence, significantly dropped from day 3 to day 6 post-transfection for all feed-streams. We demonstrated that deamidation at N57 occurs within the bioreactor and is responsible for charge heterogeneity witnessed during the AEX step. While AEX is capable of removing some deamidated species generated through the bioreactor process, harvest time is a more significant parameter that can be controlled to decrease N57 deamidation and increase the potency of rAAV products. Finally, we show scale-up data demonstrating that it is possible to further reduce N57 deamidation and increase potency without significantly sacrificing titer by shortening the bioreactor duration to two days post-transfection.

292. Next Generation Adeno Helper Plasmids and Helper Stable Cell Lines for Efficient AAV Vector Production

Jiten Doshi[1,2,3], Emma Couto[1], Jillian Staiti[1], Luk H. Vandenberghe[1,2,3], Nerea Zabaleta[1,2,3]

[1]Mass Eye and Ear Infirmary, Boston, MA,[2]Harvard, Boston, MA,[3]Broad Institute of MIT and Harvard, Boston, MA

Recombinant adeno-associated viral vector (rAAV) has emerged as a preferred vector for therapeutic gene delivery due to advantageous features including non-pathogenicity, tunable tissue targeting, and durable transgene expression. The expanding number of AAV gene therapy products attaining regulatory approval and the substantial volume of ongoing investigational trials centered around AAV-mediated therapeutic approaches have led to a heightened demand for AAV vectors. Meeting this demand requires efficient, scalable production methods. The preferred method for AAV production involves transient transfection of three plasmids in HEK293 cells. These plasmids consist of packaging Rep and structural Cap genes, adenoviral helper genes, and an ITR-flanked transgene. Despite the method's advantages, there remains a notable unmet need for qualitative and quantitative improvements, especially in cost reduction. In this context, our investigation focused on the role of adenoviral helper genes in AAV production. Prior studies have recognized adenoviral E1A, E1B, E2A, E4orf6, and VA RNA I genes essential for production. Standard helper plasmids such as pDF6 and pALD-X80 harbor substantial additional adenoviral sequences, both coding and non-coding, which raise potential safety issues and inflate transfection costs. Here, we show that AAVs are produced with low efficiency as titers drop 7-fold when using only the essential genes in comparison to a standard helper, pDF6. Investigation of >15 adeno genes revealed that E2A, VA RNA I, and the previously overlooked 22k/33k genes are enough to restore viral vector titers equivalent to those obtained using the pDF6. Absence of E4orf6 gene did not impact production titers and hence proved dispensable. Armed with this knowledge, we engineered next generation helpers that were 5-7kb smaller yet achieved similar production titers across scales (up to 500mL), serotypes and transgenes to standard helpers. Moreover, stable cells were generated through random integration, incorporating both inducible E2A and 22k/33k genes, along with constitutive VA RNA I gene. The stable helper polyclonal cells exhibited similar viability and yielded titers 2-7 times lower than those achieved through the transient transfection method, pending the selection of monoclones with optimized production capabilities. In summary, we identified E1A/B, E2A, VA RNA I, previously unknown 22k/33k as the minimal adeno helper gene set for AAV production and generated shorter helper plasmids that improve safety and reduce cost yet match standard helpers in both qualitative and quantitative AAV production metrics. Additionally, our stable helper cell lines establish feasibility for streamlined AAV production requiring at least one less plasmid for transfection.

293. Development of a Powerful AAV Production Platform by Leveraging Comprehensive Design-of-Experiment & High-Throughput Automated Bioreactors

Érica A. Schulze[1], Christophe Chevé[2], Thomas Jeffery[3], Paul Giroud[4], Maina Kerbrat[5], Frederique Marmegalloo[5], Timo Schmidberger[1], Noushin Dianat[5], Emilie Audran[6], Veronique Blouin[2], Oumeya Adjali[2], Laurence Guianvarc'h[2]

[1]Sartorius Stedim Biotech GmbH, Göttingen, Germany,[2]Nantes Université, CHU de Nantes, INSERM, TaRGeT - Translational Research in Gene Therapy, Nantes, France,[3]Sartorius Stedim UK Ltd, London, United Kingdom,[4]Polyplus, IIIkirch, France,[5]Sartorius Stedim France SAS, Aubagne, France,[6]CAPACITES SAS, Nantes, France

Recombinant adeno-associated virus (rAAVs) vectors are a leading gene delivery platform. Seven rAAV-based gene therapies have been approved to date, and over 1000 clinical trials are underway worldwide. Despite advances in the clinic, rAAV vector manufacturing remains

challenging for therapeutic applications requiring high systemic doses due to the high productivity required and the high cost of goods (DNA as GMP starting material, affinity resin...). Efficient and scalable production of rAAV is critical to enable lower drug product cost and easier commercialization for gene therapy applications. Therefore, the aim of the project was to optimize a transient transfection platform of suspension HEK-293 for rAAV production using a Design-of-Experiment (DoE) approach to study the interaction of multiple factors (culture medium, pH, stirring,...) and its impact on CQAs. Experiments made use of DoE methodology in MODDE® to design, optimize, and predict process parameters. rAAVs were produced in Expi293F cells (Gibco®) with a three-plasmid system in a 24-way Ambr®15. At harvest, the encapsidated AAV genomes were quantified by qPCR and ddPCR and the total particles by ELISA. A Western Blot was performed to complete the analytical characterization, as well as cell culture media metabolite consumption was used for profile analysis. The impactful factors such as temperature, agitation, pH, culture medium, harvest time, and plasmid quantity were investigated using rAAV2-GFP as a representative vector to optimize virus production. The upstream process was developed in 3 phases: The first phase focused on cell culture media (HEK TF, ViP NB and NX) and initial process parameters, as pH and agitation. The second phase focused on the feeding strategy and different concentration ranges of recombinant Albumin (recombumin®) to boost AAV production. The third phase focused on optimizing the transfection step using FectoVIR®-AAV (Transfection cell density, DNA amount, FectoVIR-AAV:DNA ratio). Using this step wise approach supported by DoE to guide optimization of process parameters, we were able to significantly increase the productivity of the process in the Ambr®15. The optimized process was then scaled up into 2L bioreactors. The association of DoE with high throughput automated mini bioreactors should become a standard in the viral vector industry to speed up process optimization and to support process intensification needed to answer the ever-increasing necessity for higher productivity and quality of our production systems.

294. Short-Term and Large-Scale Production of High-Quality Recombinant Adeno-Associated Virus Using a Zonal Ultracentrifugation

Mikako Wada

Division of Molecular and Medical Genetics, Center for Gene and Cell Therapy, The Institute of Medical Science, The University of Tokyo, Tokyo, Japan

Background: High-yield purification of recombinant adeno-associated virus (rAAV) is required for the safe and efficient transduction in rAAV-based *in vivo* gene therapies because rAAV products contain full-genome (functional), intermediate, and empty rAAV particles as well as host-cell proteins. However, the conventional method for rAAV purification at the laboratory scale (up to 180 mL) is based on two-day ultracentrifugation with cesium chloride (CsCl) density-gradient protocol, limiting large-scale purification of functional rAAV for clinical usage. In addition, prolonged incubation in CsCl density-gradient ultracentrifugation reduces rAAV infectivity. In this presentation, we show a short-term purification method for large-scale rAAV production at high purity using a zonal ultracentrifuge. Methods: The rAAV-ZsGreen1 was harvested from culture supernatant without cell lysis 5 days after plasmid transfection. Large-volume rAAV-containing culture media (up to 1,000 mL) and escalating densities (2 or 4 steps) of CsCl solutions were separately placed in the zonal rotor, respectively. Following large-scale density-gradient ultracentrifugation of rAAV, the samples were fractionated automatically. These samples were evaluated for rAAV genome copies by quantitative PCR, rAAV capsid protein amounts by western blotting, and ZsGreen1 transduction efficiency by flow cytometry. The ratio of empty to full capsids was measured by mass photometry, analytical ultracentrifugation (AUC), and transmission electron microscopy (TEM) with phosphotungstic acid stain. The genomic DNA regions packaged in rAAV particles were detected by droplet digital PCR (ddPCR) using various primers and probes targeting the whole vector genome. Results: We performed 2-step CsCl density-gradient ultracentrifugation with a zonal rotor, allowing for a large volume (900-1000 mL) of rAAV purification as well as shorter ultracentrifugation for 4-5 hours with a steeper density-gradient in the area of rAAV fractions, as compared to the conventional method of 4-step density-gradient (300 mL) for 10 hours. rAAV capsid proteins were detected in 2 of the fractions, one of which also contained the peaks of rAAV capsid, genome copies, and ZsGreen1 transduction, demonstrating a separation between functional full-genome and non-functional empty rAAV particles. The intermediate particles would be included between these fractions. We determined full and empty ratios by mass photometry and a single AUC peak with separate sedimentation coefficients for fractions of full-genome (about 90S) and empty (about 60S) vectors, demonstrating a high-purity separation of rAAV. Interestingly, all genome regions were detected at similar levels in full-genome rAAV by ddPCR; however, ITR copies were 2.5-2.9 fold higher than the ZsGreen1 copies in the empty particles, suggesting that ITR fragments can be packaged in 'empty' particles. In addition, we purified large-volumes of rAAV (up to about $5x10^{14}$ v.g.) after removing small molecules and increasing concentration by simple pretreatment. Conclusion: We developed a 2-step density-gradient ultracentrifugation method with a zonal rotor in 4-5 hours, allowing for the large-scale purification of functional full-genome rAAV. We also improved the fractionation system for short-term purification. Our large-scale rAAV purification method would be applicable for considerable *in vivo* experimentation and clinical investigation. Furthermore, in respect to Good Manufacturing Practice (GMP) viral vector manufacturing, we improved the in-line system that should detect the rAAV during fractionation and shorten the time after zonal ultracentrifugation. We are also preparing for cleaning validation and regulatory compliance for GMP manufacturing of rAAV, to avoid cross-contamination.

295. Generation of a Stable High-Titer Production Cell Line for Therapeutic AAV Vectors

Stefan Seeber[1], Pedro A. Moura[2], Hendrik Knoetgen[3], Andreas Schaubmar[4], Nicole Schueler[1], Alina Schneider[1], Julia Hoelper[5], Nicole Faust[5], Ines Gil-Goncalves[5], Michael Muehle[5], Michelle Hussong[5], Sven Markert[4]

[1]Cell Technologies, Roche Diagnostics GmbH, Penzberg, Germany,[2]Spark Therapeutics, Philadelphia, PA,[3]Hoffmann La Roche, Basel, Switzerland,[4]Roche Diagnostics GmbH, Penzberg, Germany,[5]Cytiva, Cologne, Germany

AAV-vector based gene transfer is becoming routine in gene therapy. To meet the growing material demands, the use of stable cell lines for AAV-vector production is gaining attention in industry and science. Major advantages are scalability and high reproducibility paired with lower cost of goods compared to triple-transfection based processes. In this case study we describe the generation of a stable, high titer HEK293-based producer cell line for AAV-vectors using a therapeutically relevant transgene and an engineered capsid (both disclosed at the conference), which was performed in close collaboration between Roche, Spark and Cytiva (formerly Cevec Pharmaceuticals). This proof-of-concept study aimed to demonstrate the utility and effectiveness of stable ELEVECTA producer cell lines for manufacturing of therapeutic AAV-vectors. We will present the workflow for generating a pool and subsequently single cell clones, pool and clone characterization in ambr15 including the results of a 90-day stability study for selected clones.

AAV Vectors - Non-Human Primates and Large Animal Models

296. Neuron Regeneration Drives Functional Recovery from Severe Stroke Following Intracranial Administration of NXL-001 Gene Therapy in Non-Human Primates

Anna Kabanova[1], Lydia Wan[2], Gabriel Ramirez Garcia[2], Douglas J. Cook[2], Jie Xu[1], Andrew Grande[3], Chong Chen[1], Russ Addis[1]

[1]NeuExcell Therapeutics, Philadelphia, PA,[2]Queen's University, Kingston, ON, Canada,[3]University of Minnesota, Minneapolis, MN

Ischemic stroke is a leading cause of acquired adult disability with a high mortality rate worldwide. Stroke survivors often experience long-term disabilities due to neuronal cell loss caused by ischemic injury. Despite current advanced treatments that focus on the re-establishment of blood flow and neuroprotection, therapies that replenish the substantial neuronal loss and restore lost brain functions remain elusive. We developed a platform of neuro-regeneration in which direct in vivo overexpression of a single proneural transcription factor, NeuroD1, converts endogenous astrocytes into functional neurons. We now present an update on NXL-001, an AAV9 gene therapy delivering NeuroD1 to astrocytes via intracranial injection for the treatment of ischemic cortical stroke. To investigate NXL-001 treatment effect on neuronal regeneration and recovery of motor deficits in a clinically relevant NHP model of stroke, we induced transient cerebral ischemia in macaques by temporarily occluding the M2 branch of the middle cerebral artery. This model results in a large stroke with severe neurological and motor deficits as assessed by the Nonhuman Primate Stroke Score (NHPSS) and modified Rankin Score (mRS). Animals that received injections of NXL-001 in the peri-infarct area two weeks post-stroke showed significant functional improvement within 6-8 weeks post-treatment when compared to non-treated animals, with nearly complete recovery observed by 6 months post-treatment. Diffusion Tensor Imaging (DTI) of white matter projections demonstrated restoration of the cortico-spinal tract. Post-mortem histological analysis confirmed that newly formed neurons in the motor cortex sent axonal projections along the cortico-spinal tract, further validating the observed functional improvement. NXL-001 is on track to reach the clinic in 2024.

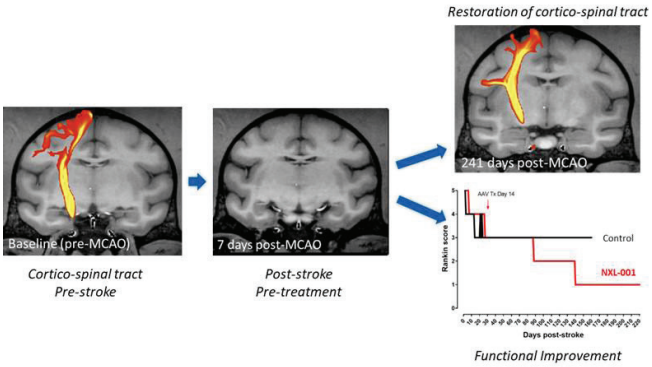


Figure: MRI Diffusion Tensor Imaging shows white matter tracts of the cortico-spinal tract (CST) at baseline and 7 days post middle cerebral artery occlusion (MCAO). NHPs treated at 2 weeks post-MCAO exhibited restoration of the CST and functional recovery (as measured by the modified Rankin score, with 5 = severely disabled and 0 = no disability).

297. AAV Intein Retinal Gene Therapy for Stargardt Disease is Effective and Safe in Large Animal Models

Ivana Trapani[1,2], Rita Ferla[3], Eugenio Pugni[1], Mariangela Lupo[1], Andrea Perota[4], Carlo Gesualdo[5], Settimio Rossi[5], Francesca Simonelli[5], Maria Laura Bacci[6], Cesare Galli[4], Ali Memon[3], Naveed Shams[3], Alberto Auricchio[1,2,3]

[1]Telethon Institute of Genetics and Medicine, Pozzuoli, Italy,[2]Dept. of Advanced Biomedical Sciences, University of Naples "Federico II", Naples, Italy,[3]AAVantgarde Bio, srl, Milan, Italy,[4]Laboratory of Reproductive Technologies, Avantea, Cremona, Italy,[5]Eye Clinic, Multidisciplinary Department of Medical, Surgical and Dental Sciences, University of Campania Luigi Vanvitelli, Naples, Italy,[6]Dept. of Veterinary Medical Sciences, University of Bologna, Ozzano dell'Emilia, Italy

Stargardt disease type 1 (STGD1) is the most common form of inherited macular degeneration, for which no therapeutic options are available. STGD1 is due to bi-allelic loss-of-function mutations in *ABCA4* which

has a large coding sequence that does not fit into adeno-associated viral (AAV) vectors, the most suitable vectors for retinal gene therapy. We have recently developed a gene therapy approach for STGD1 which relies on the use of two AAV vectors each encoding for one of the two halves of the ABCA4 protein flanked by split-inteins, that catalyze seamless joining of the two ABCA4 half proteins following AAV administration. Based on the finding that subretinal administration of AAV-*ABCA4*-intein vectors results in precise reconstitution of the full-length ABCA4 protein and in therapeutic efficacy in *Abca4*-/- mice, we set to evaluate both the efficiency and the safety of subretinal administration of AAV-*ABCA4*-intein vectors in relevant large animal models. Given the similarity between the swine and human retina, we have generated ABCA4 knock-out (KO) pigs, via *ABCA4* gene editing followed by somatic nuclear transfer. While KO pigs do not show obvious signs of photoreceptor degeneration up to 15 months of age, they accumulate lipofuscin in the retinal pigmented epithelium similarly to Abca4-deficient mice and STGD1 patients, and this was reduced upon subretinal delivery of AAV-*ABCA4* intein vectors. We then confirmed the safety of subretinal administrations of AAV intein ABCA4 vectors in a 13-week long toxicokinetic, ocular safety and expression study in non-human primates (NHP) which have the macula, similarly to humans. BaseScope analysis showed nearly total photoreceptor co-expression of mRNAs encoding both ABCA4-intein halves across an extended NHP retinal region. Overall, our data support both the efficacy and safety of AAV-*ABCA4*-intein vectors in relevant large animal models, providing important insights towards the clinical translation of this platform for gene therapy of STGD1.

298. Tissue De-Targeting Abrogates Hepatotoxicity and Complement-Related Thrombotic Complications Associated with High-Dose AAV Gene Therapies

Andrew D. Baik, Nicholas Giovannone, Nyanza Rothman, Chun Wai Yip, Poulami Samai, Leah Sabin, Laura Johnsen, Christos Kyratsous, Katherine Cygnar

Regeneron Pharmaceuticals, Tarrytown, NY

Many commonly used AAVs in gene therapies have extremely strong tropism to liver compared to other tissues. As a direct consequence, AAV gene therapies often require high doses (>1e14vg/kg) to achieve therapeutic efficacy in key peripheral tissues (*e.g.* muscle or brain). However, these doses have been associated with hepatotoxicity in humans and non-human primate models. In addition, excessive complement activation leading to thrombotic microangiopathy has also been observed in medium and high-dose systemic AAV clinical trials. Several factors have been suggested to be drivers of toxicity, such as activation of the alternative complement pathway by high capsid load in the bloodstream, activation of classical complement by anti-AAV antibodies, high capsid uptake, and transduction itself leading to cellular stress. However, the interactions of these factors remain poorly studied, especially in relevant toxicological models of AAVs. To parse the relative causes of AAV-induced liver and thrombotic complications, we conducted a three-week high-dose AAV toxicology research study in cynomolgus macaques comparing the impact of AAV capsid load, liver transduction, and mild pre-existing anti-AAV antibodies. To separate the contribution of AAV capsid load from transduction, we took advantage of an AAV9 capsid mutation, W503A. The W503A mutation disrupts capsid binding to galactose and profoundly de-targets many peripheral tissues and in particular, liver, which exhibits ~100 fold reduced transduction compared to wild-type (WT) AAV9. We dosed seronegative (nAb <1:5) and mild seropositive (1:10-1:20) macaques with 2e14vg/kg of either WT AAV9 or AAV9 W503A capsids containing CAG GFP genome (n=4 per group). As expected from previous reports, we found that macaques treated with WT AAV9 exhibited severe hepatotoxicity, with ALT elevations of ~50-100 fold 3 days post-AAV administration. Additionally, markers of complement activation (Bb, C3a, sC5b-9) peaked at Day 3, along with severe, but transient, thrombocytopenia (platelet counts <200,000/uL). Monkeys with the most severe thrombocytopenia displayed evidence of hemolysis and mild, transient impairment of kidney function. Notably, these findings were highly consistent between monkeys regardless of seropositivity, suggesting that either pre-existing immunity has a minor impact on overall toxicity at such high doses, or that these pre-existing titers were too low to have a meaningful effect. Conversely, animals that received AAV9 W503A exhibited almost complete absence of dose-related toxicities, with only mild ~2 fold ALT elevations, no changes in platelet counts, and significantly reduced markers of complement activation (Bb, C3a, sC5b-9). This data suggests that AAV exposure alone is insufficient to trigger excessive complement activation and transduction-related liver injury may be a more significant contributor to high-dose related AAV9 toxicities. We posit that improving AAV targeting, rather than viral load reduction alone, may significantly improve the safety profile of AAV gene therapies.

299. Toxicity Profile of Clade F Vectors Administered Intravenously in Nonhuman Primates

Juliette Hordeaux, Elizabeth L. Buza, George Buchlis, Sushobhana Bandyopadhyay, Alexandra L. Patterson, Amber Hamilton, Cecilia D. Dyer, Chelsea K. Wallace, James M. Wilson

Gene Therapy Program, University of Pennsylvania, Philadelphia, PA

Gene therapy vectors based on clade F recombinant adeno-associated viruses (AAVs), such as AAV9, are the current tools of choice for delivering therapeutic transgenes to the central nervous system, skeletal muscles, or heart. Many programs using high doses of AAV have faced test-article-related serious adverse events, which, in most cases, were not predicted by nonclinical safety studies. We and others have reported the utility of nonhuman primate (NHP) models that recapitulate many hallmarks of known serious toxicity events such as liver failure, acute thrombocytopenia, and sub-acute transgene-dependent immune myocarditis. The goal of this work was to investigate severe toxicity events in NHPs following systemic AAV administration. We conducted a meta-analysis including all NHPs that received intravenous AAV at our institution with available electronic records. The cohort represents 448 NHPs, with 280 males and 168 females. The majority of NHPs were macaques, with 248 rhesus and 175 cynomolgus macaques. Marmosets (n=12), African green monkeys (n=4), and Squirrel monkeys (n=9) were used infrequently. The doses administered ranged from 2E12 genome copies (GC)/kg to 2.5E14 GC/kg. Most animals received low to moderate doses (2E12 GC/kg to 4.5E13 GC/kg, n=363), whereas 85 animals received doses ≥5E13 GC/kg (high dose). Among the 448 NHPs that received intravenous AAV, we observed severe test-article-

related toxicity leading to emergency necropsy in 13 animals (3% of the total, 15% of the high-dose cohort). Toxicity was acute (within the first two weeks) in 10/13 animals. All the acutely affected animals and 2/3 of the non-acutely affected animals had received high AAV doses (≥5E13 GC/kg). Among all the toxicity cases, the vector was either clade F or engineered clade F, which were the only serotypes assessed at high doses in our facility. The promoters were mostly ubiquitous (n=12) or neuron-specific (n=1). The transgenes were enhanced green fluorescent protein (n=6), therapeutic human codon-optimized transgenes (n=6), or a capsid library (n=1). The vectors were produced via transient transfection of adherent human embryonic kidney (HEK293) cells, and most lots were purified via AAVX affinity resin. Severe acute toxicity was characterized by a rapid course of transaminitis with thrombocytopenia three days after administration, often followed by generalized edema (capillary leakage), hyberbilirubinemia, and/or coagulopathy that culminated in an unscheduled necropsy. The average time point for humane euthanasia was 5.3 days post-administration. The liver was the organ with the highest levels of vector GCs and was the main organ affected by toxicity, as assessed by bloodwork and histopathology. To elucidate the factors characterizing the most severe events, we examined study endpoint livers from NHPs that succumbed to toxicity via histopathological and single-nucleus RNA sequencing analyses. Liver enzyme elevations corresponded to hepatocellular necrosis. Thrombocytopenia corresponded to sinusoidal platelet microthrombi and sinusoidal endothelial injury identified via immunohistology, single-nucleus RNA sequencing, and a blood biomarker. In conclusion, our retrospective meta-analysis of systemic AAV administration in NHPs indicates that doses between 2E12 GC/kg and 4.5E13 GC/kg were well tolerated in 99.7% of the animals (n=362/363), with none of the NHPs developing severe acute toxicity in this dose range. This data set provides key translational insights for AAV gene therapy and establishes a potential threshold for severe acute liver and endothelial toxicity in NHPs receiving an AAV dose ≥5E13 GC/kg.

300. AAV-ARSA Mediated Gene Replacement for the Treatment of Metachromatic Leukodystrophy

Shyam Ramachandran[1], Jeffery Ardinger[1], Jie Bu[1], MiAngela Ramos[1], Lilu Guo[2], Dhiman Ghosh[2], Mahmud Hossain[2], Swathi Ayloo[1], Erik Wischhof[1], Johanna Adams[1], Yuxia Luo[1], Emily Crosier[1], William McCarty[2], SHelley Nass[1], Catherine O'Riordan[1], Martin Goulet[1], Christian Mueller[1]

[1]Sanofi, Waltham, MA,[2]Sanofi, Cambridge, MA

Metachromatic leukodystrophy (MLD) is an autosomal recessive neurodegenerative disorder caused by mutations in the arylsulfatase A (*ARSA*) gene, resulting in lower sulfatase activity and the toxic accumulation of sulfatide in the central and peripheral nervous system. Children account for 70% of cases and become progressively and severely disabled with death occurring within 10 years of disease onset. The standard of care is focused on symptomatic management and psychological support, with a high unmet need in the patient community. We present an AAV-mediated gene replacement strategy to treat MLD and report therapeutic benefit in MLD mice, and meaningful ARSA expression and biodistribution in the CNS of non-human primates (NHPs). First, we report the discovery of a novel capsid AAV.GMU1, demonstrating superior biodistribution and transgene expression in the CNS of NHPs, compared to a gold-standard CNS-tropic capsid. Second, we demonstrate that AAV-treated MLD mice show persistent, normal levels of sulfatase activity in the brain and spinal cord and a concomitant reduction in toxic sulfatides. Treated mice also show a near complete absence of MLD-associated pathology and reversal of abnormal hearing phenotype, indicating that a single administration of AAV.GMU1-h*ARSA* is well tolerated, long lasting and highly effective in MLD mice. Lastly, we present a dose-range finding pharmacology and safety study in juvenile cynomolgus monkeys, treated with AAV.GMU1-h*ARSA*. NHPs showed dose-dependent vector, mRNA and protein biodistribution in the CNS, with therapeutically meaningful h*ARSA* expression in >90% of the brain. NHPs presented no clinical signs (functional or behavioral) for the duration of the study, indicating that a single administration of AAV.GMU1-h*ARSA* by iCM was well tolerated and results in therapeutically meaningful ARSA protein levels in the CNS. In summary, we propose AAV.GMU1-h*ARSA* mediated gene replacement as a clinically viable approach to achieve broad and therapeutic levels of ARSA in the CNS and PNS.

301. Applying Artificial Intelligence to Multi-Property Optimization of AAV Capsids for Neuronal Gene Delivery

Mugdha Deshpande, Daniel Bloodgood, Barbara Diaz-Rohrer, Kailyn Looby, Sarah Hilton, Sam Chen, Sam Sinai, Kathy S. Lin, Jamie C. Kwasnieski, Adrian Veres, Eric Kelsic

Dyno Therapeutics, Watertown, MA

Previously we reported an engineered AAV capsid that enables highly efficient transduction of neurons upon IV administration in adult cynomolgus and African green monkeys, with a pan-brain delivery profile broadly applicable for neurological gene therapies. Here we use two approaches combining artificial intelligence and *in vivo* NHP experiments to modify its sequence, significantly advancing the state of the art by improving neuronal delivery and liver detargeting. For efficient IV administration of neurological gene therapies, AAV capsids can be engineered to direct delivery to the CNS and away from the liver. As such, our engineered starting capsid is well-suited for neurological gene delivery, transducing up to 29% of all cells in specific brain regions, 14% of upper motor neurons, 56% of lower motor neurons and 5-20% of neurons across most CNS regions in adult cynomolgus monkeys with a 1e13 vg/kg IV dose, while detargeting the liver 10x vs AAV9, and with productivity similar to AAV9. With machine-learning models trained on *in vivo* NHP data, we evaluated billions of capsid variants for improved CNS delivery and liver de-targeting, filtering out poor producers. In contrast to random substitution and insertion libraries, the design strategy was fully synthetic, allowing sequence edits to be introduced at any location on the capsid, both within and outside of the surface exposed variable regions. Capsid variants were more than 4 edits away from the starting capsid sequence on average. ~100k capsid variants were synthesized, with 88% of capsids capable of successfully packaging vector genomes. Measuring *in vivo* delivery properties in two adult cynomolgus monkeys, top variants exhibited above 5x higher CNS delivery combined with 3x liver detargeting relative to

the starting capsid. CNS transduction was significantly improved pan-brain for transgenes expressed from both constitutive (Cbh) and neuronal (hSyn) promoters, including in deeper brain regions such as basal ganglia and brainstem. In a parallel library tested in two adult cynomolgus monkeys, we designed capsids to enable highly improved CNS transduction using a design strategy that differed dramatically from the approach described above. While in both cases billions of capsid sequences were evaluated *in silico*, here we employed extensive computational cross-validation and human curation, narrowing our selections to only 10 designed capsids that were synthesized and tested, yet still yielding capsids with dramatic delivery improvement. Relative to the starting capsid, the best capsid was 8x enhanced for CNS delivery relative to the starting capsid, with a pan-brain delivery profile. Within the same pooled study this capsid outperformed the best external engineered capsids tested, especially in delivery to deeper brain regions. Single-nuclei RNA-seq of prefrontal cortex, motor cortex and putamen showed increased numbers of transduced neurons, astrocytes and oligodendrocytes, with rates similar to those from bulk NGS. This efficient design of next-generation capsids with highly optimized properties, surpassing those of all previously tested capsids, demonstrates the rapidly advancing combined power of *in vivo* data and artificial intelligence, while unlocking new potential to treat neurodegenerative and neurometabolic diseases.

302. Improving the Expression of AAV-Delivered Anti-HIV Broadly Neutralizing Antibodies in Nonhuman Primates

Michael Kuipa[1], Peter Koroma[1], Isai Leguizamo[1], Natalie Correa[1], Priya Dhole[1], Matthew R. Gardner[1,2]

[1]Division of Microbiology and Immunology, Emory National Primate Research Center, Atlanta, GA,[2]Department of Medicine, Division of Infectious Diseases, Emory University, Atlanta, GA

Background: Long-term expression of anti-HIV-1 broadly neutralizing antibodies (bNAbs) using adeno-associated virus (AAV) vectors may prevent and treat HIV-1 infection. However, AAV vectors expressing bNAbs induce immune responses that inhibit bNAb expression *in vivo*, limiting the study of their efficacy in nonhuman primates. Programmed cell death protein (PD)-1 is an immune checkpoint protein on T cell surfaces which inhibits T-cell activity upon binding to programmed cell death protein ligand (PD-L)1. We hypothesized that co-expression of PD-L1 on cells transduced with AAV.bNAb maintains bNAb expression by suppressing host anti-bNAb antibodies and T-cell responses. The long-term goal of this research is to develop a system that achieves sustained AAV-expressed bNAb concentrations in nonhuman primates. Methods: To evaluate our hypothesis, we conducted a nonhuman primate study consisting of five groups of six rhesus macaques each that received the following vectors: 1) AAV9.PD-L1; 2) AAV9.10-1074; 3) AAV9.PD-L1 and AAV9.10-1074; 4) AAV9.3BNC117; and 5) AAV9.PD-L1 and AAV9.3BNC117. Serum antibody concentrations were tracked for over 20 weeks for all animals and determined by gp120 ELISA. Host immune responses were assessed by anti-drug antibody ELISA and by ELISpot assay to determine B and T cell reactivity, respectively. Additionally, we evaluated the effect of AAV9.PD-L1 on immunomodulatory gene expression in PBMCs by RNAseq. Beginning at 20 or 30 weeks post AAV9 administration, all animals were challenged biweekly via low-dose, intrarectal challenge using SHIV-AD8 challenge virus stock. Protection from SHIV challenge was determined by monitoring plasma viremia by qPCR. Results: All six macaques that received AAV9.10-1074 and AAV9.PD-L1 had sustained concentrations of 10-1074 throughout the study compared to four of six macaques that only received AAV.10-1074. Similarly, all six macaques that received AAV9.3BNC117 and AAV9.PD-L1 had sustained concentrations of 3BNC117 compared to three of six macaques that only received AAV9.3BNC117 at the time of this reporting. Macaques that had sustained bNAb expression for the duration of the study had lower anti-10-1074 or anti-3BNC117 antibodies and lower T cell reactivity to bNAbs compared to macaques that had declining bNAb expression. There were no differences in immunomodulatory gene expression in PBMCs between the groups. Lastly, all macaques that achieved sustained expression of 10-1074 resulted in significant protection from SHIV challenges. Macaques that received AAV9.3BNC117 are currently undergoing the challenge arm of the study. Conclusions: Co-expression of PD-L1 on cells transduced with AAV9.bNAbs improves the consistency of bNAb expression by suppressing host anti-bNAb responses in rhesus macaques. Thereby, we have developed a strategy to evaluate new AAV vectors in nonhuman primates without the interference of the host immune response.

Neurologic Diseases IV

303. Optimized Artificial miRNAs Delivered by rAAV9 Dramatically Improve Survival, Respiratory and Motor Functions of SOD1^{G93A}-ALS Mice

Fang Wan[1], Jinchen He[1], Hong Ma[1], Veena Kumanan[1], Jisun Lee[1], Debora PiresFerreira[1], Sha Zhu[2], Gabriela Toro[2], Lingzhi Zhao[2], Alisha Gruntman[1], Zuoshang Xu[3], Joan Shen[2], Guangping Gao[1], Jun Xie[1]

[1]Horae Gene Therapy Center, University of Massachusetts Chan Medical School, Worcester, MA,[2]NeuShen Therapeutics US, Inc., Lexington, MA,[3]Biochemistry & Molecular Pharm, University of Massachusetts Chan Medical School, Worcester, MA

Autosomal dominant mutations in superoxide dismutase 1 (*SOD1*) gene cause motor neuron degeneration and are linked to 10-20% of familial and 2% of sporadic cases of Amyotrophic Lateral Sclerosis (ALS), a fatal disease for which an effective treatment is urgently needed. While current treatments such as gene silencing using ASO or siRNA have shown limited clinical benefits with the need for repeated dosing, our study explores the use of Adeno-Associated Virus serotype 9 (AAV9) for the delivery of optimized artificial microRNAs (amiRs) targeting SOD1 in a single-doses treatment for ALS-SOD1. Our choice of a miR-33-based amiR scaffold in the design of SOD1-amiR is based on our previous studies demonstrating its gene silencing efficacy, reduced off-target activity, and fewer truncated AAV9 genomes, compared to conventional shRNAs and other scaffolds. We generated an AAV9 vector (AAV9-hSMN1-dual-amiR) using a promoter derived from the endogenous human survival motor neuron 1 (hSMN1) to drive the expression of two amiR-Sod1 embedded in the mouse and human miR-33 scaffold. The SOD1^{G93A} mice were injected by tail vein

at the dose of 1.0xe14 vg/kg at three different time points: day 60-68 (the asymptomatic stage), day 90 (non-motor symptomatic stage when mice start to lose body weight), and day 105-125 (the motor symptomatic stage). PBS-treated transgenic animals were used as controls. In comparison to a median survival of 117 days observed in PBS-injected $SOD1^{G93A}$ mice (n = 17), the median survival of the AAV9-hSMN1-dual-amiR treated mice (n = 17) was extended by 98.5 days when animals were injected at day 60-68.More importantly $SOD1^{G93A}$ mice treated at day 90 (n = 24) and day 105-125 (n = 29), showed a median survival extension of 39 and 22 days, respectively. We further investigated the $SOD1^{G93A}$ mice treated on day 60. *SOD1* levels measured on day 105 by qRT-PCR showed a substantial reduction in the brain stem (down by 46 ± 12%; $p< 0.0001$), the spinal cord (down by 35-45%; $P< 0.0001$) in $SOD1^{G93A}$ mice treated with AAV9-hSMN1-dual-amiR, compared to PBS-treated controls. Reduction of SOD1 expression in motor neurons was confirmed by immunofluorescent staining. *SOD1* levels in peripheral tissues such as liver, heart, quadriceps, and diaphragm from same animals were also reduced. Notably, diaphragm, crucial for respiratory function, showed a by ~90% reduction in SOD1 levels in mice treated with the AAV9-hSMN1-dual-amiR vector. To gauge respiratory function, ventilation was quantified using whole-body plethysmography on day 105, 45 days post-injection. When compared to age-matched litter mates, PBS-treated $SOD1^{G93A}$ mice showed hypercapnia in minute ventilation, peak expiration and inspiratory flows. In contrast, hSMN1-dual-amiR vector-treated $SOD1^{G93A}$ mice performed at the same level as the age-matched litter mates. Remarkably, neither rotarod nor grip tests showed any significant difference between the hSMN1-dual-amiR-treated group and age-matched healthy litter mates until day 190. Thus, a single intravenous injection of AAV9-hSMN1-dual-amiR vector significantly reduces SOD1 expression within CNS and non-CNS tissues, effectively preserves respiratory and motor functions, and extends survival by 98.5 days, 39 days, and 22 days when administered at the asymptomatic, non-motor symptomatic and motor symptomatic stages in $SOD1^{G93A}$ mice, respectively. These therapeutic outcomes, unprecedented in $SOD1^{G93A}$ mice, suggested the need for a clinical evaluation of this promising treatment strategy. G.G. and J.X. are Corresponding Authors

304. Reduction of Atxn2, a Therapeutic Target for Sporadic ALS, in Non-Human Primates Using a Novel, Intravenously Delivered AAV Capsid

Giridhar Murlidharan, Emily Grandell, Stephen Janack, Amanda Berry, Isabelle Guelin, Charles Gualtieri, Tyler Ironside, Elizabeth Scott, Cynthia Pryce, Bryan Mastis, Ramin Kamran Sami, Matt Edwards, John Reece-Hoyes, Cara West, Roberto Calcedo, Dharmendra Goswami, Sherry Cao, Lisa M. The lack of safe and effective strategies for gene delivery across the blood-brain barrier hinders development of therapeutic modalities such as RNAi for neurological disorders. We report the discovery of a novel adeno-associated virus (AAV) capsid ATC-134 that achieves widespread central nervous system (CNS) exposure and durable RNAi function after intravenous (IV)-dosing in non-human primates (NHPs). Polyglutamine (CAG) expansions of intermediate length (27-33 repeats) within the RNA-binding protein Ataxin-2 (Atxn2) gene are an epidemiological risk factor for amyotrophic lateral sclerosis (ALS), making Atxn2 reduction a target for sporadic ALS. Additionally, a growing body of literature links reduction of Atxn2 transcript to improved survival in preclinical models of ALS. To further explore this hypothesis, we built a miRNA-based therapeutic cargo against Atxn2 to assess safety-pharmacology of ATC-134 in NHPs. First, we used bioinformatics to identify favorable siRNA sequences and then screened these molecules, in human- and mouse-cell cultures to quantify Atxn2 knockdown (KD) in vitro. Based on these data, we embedded the most potent siRNAs into natural miRNA scaffolds and packaged the cargo as AAV PHP.eB vectors to conduct IV-pharmacology studies in human-transgenic (Tg) mouse model of Atxn2 [BAC-hATXN2-Q22]. We observed dose-responsive reduction of both human [~40-70% KD] and mouse [~28-61% KD] Atxn2 transcripts in AAV-miRNA treated Tg mouse CNS at 60-days post dosing. In-situ hybridization showed cytosolic Atxn2 mRNA reduction within Tg mouse spinal motor neurons. We then vectorized the validated Atxn2-miRNA into ATC-134 capsid and dosed adult cynomolgus macaques at low (2e13 vg/kg) or moderate (6.7e13 vg/kg) dose-levels in a study of 28 or 60-day duration. No adverse safety events have been observed to date. In situ hybridization labeling the miRNA-cargo showed transduction of up to 60% of spinal cord motor neurons in the ventral horn at 28-days post dosing. Pharmacological assessments demonstrated dose-responsive increase in vector genome biodistribution and transgene-mRNA expression resulting in Atxn2-KD of >50% in multiple CNS regions in the NHP. In summary, we showed reduction of Atxn2, a therapeutic target for ALS, in non-human primates using a novel, intravenously delivered AAV capsid at safe and tolerable doses.

305. Development of Tau Isoform-Specific Reduction Therapy

Bonnie C. Lloyd[1], Irvin T. Garza[2], Karina Alvarado[2], Krishanna Knight[2], Rachel M. Bailey[2]

[1]Graduate School of Biomedical Sciences, UT Southwestern Medical Center, Dallas, TX,[2]Center for Alzheimer's and Neurodegenerative Diseases, UT Southwestern Medical Center, Dallas, TX

The microtubule associated protein tau (MAPT/tau) binds and stabilizes microtubules. Tau undergoes alternative splicing of exon ten to yield three-repeat (3R) or four-repeat (4R) tau. Under pathological conditions, tau dissociates from microtubules, adopts prion-like conformations leading to protein aggregation and neurotoxicity. The progressive accumulation of tau is the pathological hallmark of a group of neurodegenerative disorders called tauopathies. Some tauopathies, such as Alzheimer's disease, have aggregates that consist of both 3R and 4R-tau while others, such as progressive supranuclear palsy (PSP), consist mainly of 4R-tau. Reducing tau protein in an isoform specific manner is a potential therapeutic approach for tauopathies. This study aimed to develop tau-specific artificial micro-RNA (miRNA) shuttles delivered to the brain using adeno-associated virus (AAV) to selectively reduce tau as a therapeutic approach for different classes of tauopathies. We hypothesize that treatment with isoform specific tau miRNA candidates will selectively degrade tau mRNA, decreasing tau protein levels and reducing tau pathology and neurodegeneration.

We developed artificial miRNA shuttles that target either all isoforms of human tau mRNA (hTaui) or only 4R tau isoforms (hTau4Ri) for degradation. The antisense guide-strands of our miRNA contain perfect complementarity with tau mRNA across a 22 nt stretch of sequence, thereby directing the transcript toward an RNAi degradation pathway. To identify a lead miRNA shuttle, we did a primary screen using a dual-luciferase assay. Knockdown efficiency and isoform specificity were tested for each shuttle and a mismatched control shuttle (Scr) in HEK293T cells. The top candidates were then assessed in a secondary screen to directly measure the mRNA and proteins levels of 2N4R and 2N3R tau when overexpressed in HEK293T cells via qPCR and western blot analysis, respectively. We identified lead candidates for hTaui that reduced 3R and 4R tau mRNA and protein levels and a lead candidate for hTau4Ri that selectively reduced 4R tau as compared to Scr. These were then packaged into AAV9. To verify target engagement and benefit of our tau miRNA *in vivo*, 2 mouse models were used: hTau knock-in mice and PS19 mice. Adult hTau mice express all 6 human tau isoforms in place of mouse tau, which we confirmed via western blot analysis using isoform specific antibodies. hTau mice were injected with AAV/Scr, AAV/hTaui or AAV/hTau4Ri to confirm tau isoform-specific knockdown of mRNA via qPCR and protein via ELISA analysis. As hTau mice do not exhibit a pathological phenotype, we used PS19 mice to test potential, which overexpress human 1N4R tau with the disease-causing P301S mutation. PS19 mice develop pathological tau seeding early that progresses to severe neurological abnormalities including hindlimb clasping, progressive paralysis, and decreased survival by 9-12 months of age. PS19 mice were intra-cisterna magna injected with AAV/Scr or AAV/hTaui and followed for a minimum of 3 months and up to 12 months of age. qPCR, ELISA, tau seeding assays, and histopathological analysis showed treatment with hTaui significantly reduced tau mRNA, protein, seeding, and pathology when compared to mice injected with the scrambled control. In addition, hTaui treatment increased survival and decreased disease associated phenotypes even when treated at an advanced disease stage. Similar efficacy studies with our hTau4Ri miRNA shuttle are ongoing and will be reported. Together, in cells and mice, we verified that the artificial tau miRNA we developed can selectively and efficiently reduce tau in an isoform-specific manner, supporting these as potential therapeutic approaches for tauopathies.

306. Towards an AAV-Based Gene Therapy Strategy for Hereditary Spastic Paraplegia Type 52 (SPG52)

[1]Institute of Neuroscience, Universitat Autònoma de Barcelona (UAB), Cerdanyola Del Vallès, Spain,[2]Department of Biochemistry and Molecular Biology, Universitat Autònoma de Barcelona (UAB), Cerdanyola del Vallès, Spain,[3]Vall d'Hebron Institut de Recerca (VHIR), Barcelona, Spain,[4]Unitat Histologia Mèdica, Universitat Autònoma de Barcelona (UAB), Cerdanyola del Vallès, Spain,[5]Institute of Biomedicine (IBUB), Universitat de Barcelona, Barcelona, Spain,[6]Department of Pathology and Experimental Therapeutics, Hospital Universitari Bellvitge-IDIBELL, Hospitalet de Llobregat, Spain,[7]Department of Cell Biology, Physiology and Immunology, Universitat Autònoma de Barcelona (UAB), Cerdanyola del Vallès, Spain,[8]Centro de Investigación Biomédica en Red Enfermedades Neurodegenerativas (CiberNed), Instituto de Salud Carlos III, Madrid, Spain,[9]Department of Molecular and Translational Medicine, Università degli Studi di Brescia, Brescia, Italy,[10]Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain

Hereditary spastic paraplegia type 52 (SPG52) is an ultra-rare inherited neurological disorder caused by biallelic mutations in the AP4s1 gene, which encodes a subunit of the adaptor protein complex 4 (AP-4), whose function is believed to be key in the biogenesis of the autophagosome. The disease leads to lower-limb spasticity, weakness, global developmental delay, intellectual disability, and seizures and no effective treatment is available. Gene therapy aimed at restoring AP4s1 expression represents a rational therapeutic approach for SPG52. Fibroblasts and iPSC-derived cortical neurons from patient and control skin biopsies have been developed and characterized. These cortical neurons recapitulate an accumulation of the AP-4 complex main cargo ATG9A within the Trans-Golgi network. AP-4 complex-deficient cortical neurons also show abnormal neurite morphology and decreased activation of the neuronal network activity. We have overexpressed the AP4s1 subunit using AAV vectors and restored the formation of the complex, rescuing neuropathological phenotypes. Alongside our *in vitro* studies, we have successfully generated the first AP4s1 knock-out (KO) murine animal modeling SPG52. This animal model shows decreased body weight gain, impaired rotarod performance, a marked clasping phenotype, and a tendency towards diminished strength. Motor phenotypes were corroborated by neuromuscular deficits, reflected as decreased compound muscle action potential (CMAP) amplitudes of the hindlimb muscles. Nerve conduction tests also revealed a compromised sensory function. AP4s1 KO exhibited impaired short- and long-term memory during the Morris Water Maze test. Moreover, these animals manifested a more active exploratory behavior without signs of anxiety when performing Open Field tests. The thinning of the Corpus Callosum described in patients was also recapitulated, evidenced by magnetic resonance imaging, and subsequently validated through histological examination. Importantly, this model shows a significantly shortened lifespan

compared to healthy controls. To assess the phenotype rescue with our gene therapy approach, we systemically treated AP4s1 KO animals with neurotropic AAV vectors carrying a correct copy of the AP4s1 gene. Mice were injected postnatally or at 3 months of age and phenotype rescue was assessed through a range of motor and electrophysiological tests. The development of hiPSC-derived cortical neurons together with the AP4s1 KO model, both recapitulating SPG52 disease hallmarks, are crucial to elucidating the disease's pathogenesis. Our gene therapy approach paves the way for the treatment of SPG52 children.

307. Establishment of Gene Therapy Drug Development Assays Confirms Antiepileptic Activity of an AAV Encoding Neuropeptide Y (NPY) and Y2 Receptor (Y2R)

Pernilla Fagergren[1], Barbara Terzic[2], Esbjörn Melin[1], David Dobry[2], Juliet Eve Mengaziol[2], Benjamin Okyere[2], Lawrence Moon[2], Elizabeth Ramsburg[2], Karin Agerman[1]

[1]CombiGene AB, Stockholm, Sweden,[2]Spark Therapeutics, Philadelphia, PA

INTRODUCTION: Epilepsy affects approximately 50 million people worldwide; over 30% of patients are considered treatment resistant to currently available antiepileptic drugs. Neuropeptide Y (NPY) has been shown to inhibit excitatory synaptic transmission in human epileptic hippocampus, mediated via Y2 receptors. Hence, intrahippocampal gene-delivery of NPY and its receptor Y2 could provide a novel treatment for mesial temporal lobe epilepsy (TLE). **METHODS:** AAV consisted of a single stranded genome comprised of a CAG promoter, human NPY, IRES, human Y2R, WPRE and polyA. **RESULTS:** 1) Spontaneous neural activity was studied *in vitro*. Networks of primary rat cortical neurons were transduced *in vitro* using a lentiviral vector delivering a genetically encoded reporter of intracellular calcium ion concentrations (as a proxy for neural activity). Three days later, neurons were transduced with AAV.CAG.NPY-Y2R (5E5 or 5E6 vg per cell) or a negative control vector (AAV.CAG.FIX). Frequency and intensity of spontaneous neural activity was attenuated specifically by AAV.CAG.NPY-Y2R. 2) Acute epileptiform activity induced by 4-aminopyridine (4-AP) was studied in mouse hippocampal *ex vivo* slices. Slices of adult mouse hippocampus were recorded from *ex vivo* using multielectrode arrays in the absence or presence of 4-AP, a drug which induces epilepsy-like neural firing. Application of NPY peptide (1 μM) attenuated the 4-AP-induced increase in the number of spikes by ~80% and the number of bursts by ~95% (relative to vehicle) in the CA1 field of the hippocampus. 3) Next, mouse *ex vivo* slices were studied following bilateral intrahippocampal injections of AAV.CAG.NPY-Y2R (6E9, 1.9E10 or 6E10 vg/mouse) four weeks prior to recordings. 4-AP-induced neural activity in CA1 was attenuated by AAV.CAG.NPY-Y2R versus control. Subsequent bioanalysis of slices confirmed the overexpression of NPY protein in AAV.CAG.NPY-Y2R treated animals over control. 4) Effects of AAV.CAG.NPY-Y2R on epileptic activity *in vivo* were studied using a rapid kindling model. Anesthetized adult rats were injected bilaterally into the hippocampus with either vehicle or AAV.CAG.NPY-Y2R (1.2E10 or 1.2E11 vg/rat). Ten days after treatment, stimulating and recording electrodes were implanted for subsequent rapid kindling and electroencephalography (EEG) analysis. At 38 days, hippocampal and cortical EEG were recorded during electrical kindling of ventral hippocampus, and seizure intensity was quantified using the Racine Scale. This rapid kindling paradigm involved finding the amount of current (μA) needed to generate a hippocampal afterdischarge ('threshold') and then giving one 400 μA stimulus every five minutes (total of 40). Treatment with AAV.CAG.NPY-Y2R increased the threshold and reduced both seizure intensity and hippocampal EEG afterdischarge duration versus control. **CONCLUSIONS:** Anti-seizure activities of exogenous NPY peptide and AAV.CAG.NPY-Y2R were demonstrated using different models. Spontaneous neural activity was attenuated by AAV.CAG.NPY-Y2R in primary rat cortical cultures. Bath application of NPY peptide or AAV-mediated overexpression of NPY and Y2R both markedly attenuated activity evoked by 4-AP in *ex vivo* slices of mouse hippocampus. Seizure intensity and seizure duration measured by EEG were both reduced in the rat, *in vivo* rapid kindling model of epilepsy. These results validate the feasibility of NPY-Y2 receptor gene therapy as a therapeutic opportunity in focal epilepsies and the potential to use the in vitro and in vivo assays as a screening cascade. **P.F. and B.T. are joint first authors; E.R. and K.A. are joint senior authors.**

308. Long-Term Safety and Feasibility of a Cas13-Based RNA Editing Therapy for *MECP2* Duplication Syndrome in Humanized *MECP2* Transgenic Mice

Dong Yang, Mengsi Duan, Xiaoqing Wu, Meixian Wu, Shaoran Wang, Xuan Yao, Alvin Luk, Hui Yang, Linyu Shi

HuidaGene Therapeutics Co., Ltd., Shanghai, China

Background: Methyl-CpG binding protein 2 (*MECP2*) is a dosage-sensitive, X-linked gene critical for neurodevelopment whose gain of function causes *MECP2* duplication syndrome (MDS). This devastating disorder is characterized by intellectual disability, motor dysfunction, infantile hypotonia, epilepsy, respiratory tract infections, and premature death with no curative therapy. We developed a translational strategy using our novel, CRISPR high-fidelity Cas13Y (hfCas13Y) to reduce the MeCP2 protein levels and reverse disease phenotypes. **Methods**: We generated hfCas13Y and *MECP2*-targeting gRNAs (g*MECP2*) packaging in a single AAV vector (AAV-hfCas13Y-g*MECP2*) and then evaluated the editing efficacy in the brain of the *MECP2* transgenic (*MECP2*-TG) mouse model after neonatal intracerebroventricular (ICV) injection. The motor function, anxiety behavior, society impairment, and the restoration of fear learning deficits using the fear conditioning test of *MECP2*-TG mice were tested at 8 and 26 weeks following ICV injection. The long-term effects (48 weeks post-injection) and safety of AAV-hfCas13Y-g*MECP2* were further investigated in *MECP2*-TG mice via RNA-seq and RNA integrity analysis in cortex tissues 4 and 48 weeks after ICV injection of AAV-hfCas13Y-g*MECP2*, respectively. **Results**: We have demonstrated AAV-hfCas13Y-g*MECP2* editing efficacy in reducing MeCP2 protein levels in the humanized *MECP2*-TG mouse model at 8 and 26 weeks after ICV injection. The motor function, anxiety behavior, and society impairment of *MECP2*-TG mice were rescued by AAV-hfCas13Y-g*MECP2*. The fear conditioning tests revealed that 8-week-old *MECP2*-TG mice displayed an abnormal increase in fear learning in context paradigms, a hippocampal-dependent behavior, but not significant compared to wild-type (WT) mice (Fig. 1A). In contrast,

26-week-old *MECP2*-TG mice exhibited a significant elevation (Fig. 1B). Notably, the abnormal contextual learning was reduced by the AAV-hfCas13Y-g*MECP2* at both 8 weeks (Fig. 1A) and 26 weeks (Fig. 1B) post-treatment. In addition, *MECP2*-TG mice injected with the AAV-hfCas13Y-g*MECP2* had a significant increase in median lifespan (226 days) compared to that of PBS-injected littermates (156 days) (Fig. 1C, P<0.01). Among 90.9% (10 out of 11) of *MECP2*-TG mice treated with AAV-hfCas13Y-g*MECP2* surviving over 220 days, 45.5% (5 out of 11) of those *MECP2*-TG treated mice survived even over 300 days. Conversely, only 10% (1 out of 10) *MECP2*-TG mice treated with PBS lived past 220 days (Fig. 1C). Furthermore, RNA-seq analysis showed that abnormal gene expression in *MECP2*-TG male mice was largely restored (Fig. 1D). To comprehensively detect the potential collateral effects accompanying targeted RNA degradation by the AAV-hfCas13Y-g*MECP2* system, we analyzed total RNA integrity in cortex tissues of *MECP2*-TG mice after ICV injection. Cortical RNA integrity remained unaltered compared to PBS-injected controls at both time points, suggesting that the hfCas13Y-g*MECP2* system lacked detectable collateral activity *in vivo*. Furthermore, H&E staining showed no injury in the brain, spine cord, liver, and kidney of *MECP2*-TG mice 48 weeks after treatment. **Conclusions**: Our findings demonstrate the long-term efficacy and safety of AAV-hfCas13Y-g*MECP2* treatment in *MECP2*-TG mice, providing a promising CRISPR/RNA therapeutic strategy for MDS treatment. Recently, this program has granted orphan drug and rare pediatric disease designations by the U.S. FDA.

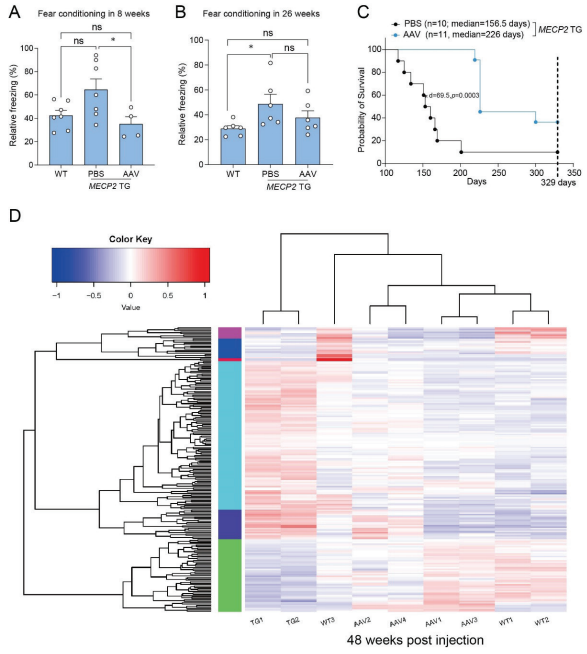

Figure 1. The long-term effect of AAV-hfCas13Y-gMECP2 in *MECP2* TG mice

309. AI Enabled ASO Design Can Lead to Rapid Initiation of Treatment for an Ultra-Rare Disorder Leading to Allele Selective Knockdown of a Toxic Protein and Consequent Clinical Improvement

David P. Dimmock[1], Lynne Bird[2], Amy Bouck[1], Allen Castro[1], Jason Ferrone[1], Jennifer Foley[3], Louis Gonzalez[1], Christopher Hart[1], Maureen Hart[1], Steven Kuntz[1], Mahati Krishna[4], Matthew Levy[5], Swagatam Mukhopadhyay[1], Timothy Nicholson-Shaw[1], Luke Ofria[1], Sankha Pattanayak[1], Amanda Reyes[1], George Samaan[1], Jeyaprakashnarayanan Seenisamy[4], Yiwei She[6], Megan Swim[1], Ruben Valas[1], Sara Yanke[1], Nicole G. Coufal[2]

[1]Creyon Bio, Carlsbad, CA,[2]UCSD, San Diego, CA,[3]Rady Children's Hospital, San Diego, San Diego, CA,[4]Creyon Bio, Bengaluru, India,[5]Creyon Bio, Durham, NC,[6]TNPO2 Foundation, New York, NY

Backgound: The subject suffers from a de novo heterozygous pathogenic variant causing a missense change in Transportin-2 (TNPO2) resulting in severe developmental delay and refractory epilepsy. TNPO2 is a nucleocytoplasmic transport receptor that facilitates transport of cellular cargo between the nucleus and cytoplasm (Kimura and Imamoto 2014). De novomissense variants in TNPO2 cause human developmental defects (Goodman et al. 2021). Data from Drosophila find that overexpression of this variant causes severe toxicity when compared to overexpression of the wild-type protein consistent with a dominant negative phenotype (Goodman et al. 2021). Human biobank data suggests that heterozygous loss of this gene is not associated with significant health or developmental problems. Further work by collaborators has demonstrated that knocking down this disease-causing variant leads to correction of a poor growth phenotype in patient derived brain organoids. However, TNPO2 is essential for cellular function and both loss of expression and overexpression are toxic. Consequently, therapy must selectively remove the toxic allele while maintaining function of the normal copy.The introduction of endogenous 'foreign' nucleic acids including both gene therapy vectors and antisense oligonucleotides (ASOs) are associated with immune and cytoplasmic DNA sensing mediated inflammatory reactions. Inflammatory reactions to ASOs have led to the failure of multiple drugs in early phase trials and interruption of dosing in individualized patient therapies.Creyon Bio implements a custom designed learning dataset paired with artificial intelligence (AI) to identify ASO sequence/chemistry collusions that are safe, thereby enabling the rapid design of allele selective ASOs. **Methods:** Proprietary tools were utilized to design 96 3-10-3 "Locked Nucleic acid gapmer" oligonucleotides against the disease causing variant. Eighty eight of these were demonstrated to be safe utilizing in vivo and in vitro model systems. Multiple candidates demonstrated allele selective knockdown in patient derived cell lines and the correction of an in-vitro phenotype. Based on selection criteria, the safest and most effective compounds were scaled up for GMP manufacturing, quality assessment and compounding. After the completion of GLP toxicology studies and after FDA permission, the index case was treated via intrathecal delivery with escalating doses of the allele selective ASO. **Results:** AI-informed design enabled initial approval to dose within 1 year of project initiation. Dose escalation up

to 40mg has been tolerated with no increase in inflammatory markers in the CSF or adverse changes on brain MRI. Subsequent to the second dose the child demonstrated a dramatic reduction in seizure frequency. Following the third dose he regained developmental milestones that were lost and developed new skills. This included previously regressed skills such as rolling and sustained attention and novel skills such as tripod sitting and responsive babbling. These clinical improvements were lost 6-8 weeks into the first (planned) extended (3 month) dose interval and were regained within 1 week of the subsequent 40mg dose. **Conclusion:** Allele selective knockdown of a toxic TNPO2 protein, using an AI-informed ASO design, leads to clinical improvement in a single case.

AAV Capsid Engineering: Multilevel Approaches for Enhanced AAV Delivery

310. Identification of AAV Capsid with Improved Tropism to Macular Retina Through Multi-Species Screening in Mice, Rabbits, Pigs, and Monkeys

Shengjiang Liu, Haifeng Chen, Xiaoming Gong, Sameera Peraramelli, Ningguang Luo, Alan Chen, Jinzhong Li, Eduardo Santillan, Derrick Huynh, Shuyi Li, Ying Li, Kevin Lin, Minghua Dai, Jianwu Chen, Zhe Yu, June Song, Son Thai Nguyen, John Zhang, Li Ou

Avirmax, Inc., Hayward, CA

Adeno-associated virus vector is the main *in vivo* gene delivery method. To improve tissue tropism, capsid engineering through rational design, directed evolution, and artificial intelligence has attracted much attention and has been performed, resulting in the usage of engineered capsids in clinical trials. However, the lack of cross-species translatability of novel capsids limits its broader application and creates significant challenges for clinical development. In this study, a novel capsid (AAV2.N54) with improved tropism to deep regions of retinas was identified through multi-species screening in mice, pigs, rabbits, and monkeys. In screening studies, fundus images, immunohistochemistry, and confocal scanning laser ophthalmoscopy were performed to assess the tropism of 18 candidate capsids and controls after intravitreal administration. Across all four species, AAV2.N54 showed improved tropism over wildtype AAV2 and a previously described engineered capsid AAV2.7m8, evidenced by efficient delivery to the macular retina and the ability to detarget from the ciliary body. AAV2.N54 also had a solid safety profile with minimal inflammation, similar to controls. The transgene expression cassette for treating wet AMD was optimized through in vitro screening and measurement of protein levels by ELISA. Then, AAV2.N54-Aflibercept was assessed in disease models of mice and rabbits. In the laser-induced choroidal neovascularization (LCNV) mouse model, fluorescein angiography and flatmount analysis showed that AAV2.N54-Aflibercept prophylactically reduced retina lesions, with improved efficacy than the commercial protein drug Eylea. In the DL-AAA rabbit disease model, AAV2.N54-Aflibercept demonstrated remarkable therapeutic efficacy in reducing retina leakage. In addition, a GLP toxicity study in NHPs was performed, demonstrating the safety profile of intravitreal dosing of AAV2.N54-Aflibercept at the dose up to $5.7x10^{11}$ vg/eye. Based on these results, GMP production has been finished, and an investigational new drug (IND) application will be submitted. In conclusion, an engineered capsid with improved delivery to the macular retina and cross-species translatability was identified, and a novel gene therapy for treating wet AMD was developed.

GFP expression was scored across all retinal and extra-retinal layers and across both antibody cocktails, for a survey of ocular GFP expression across all eyes enrolled in cryosection analysis. Dark green cells (+++) indicate where GFP expression was the highest; Medium green cells (++) indicate where there was moderate GFP expression; Light green cells (+) indicate where there was weak GFP expression; Red cells (-) indicate where GFP was absent. Abbreviations: GCL/ILM – ganglion cell layer/Inner limiting membrane; IPL – inner plexiform layer; INL – inner nuclear layer; OPL – outer plexiform layer; ONL – outer nuclear layer; IS – inner segment; OS – outer segment; RPE – retinal pigmented epithelium; C – choroid; S – sclera; M – muscle; ONH – optic nerve head.

311. AAV Capsid Selection at Spatial and Single-Cell Resolution in Non-Human Primate Retina

Ashley Robbins[1,2], Yonghong Chen[2], Brian Lewandowski[2], Dominika Houserova[2], Paul T. Ranum[2], Luis Tecedor[2], Beverly L. Davidson[2,3]

[1]Neuroscience Graduate Group, University of Pennsylvania, Philadelphia, PA,[2]Raymond G. Perelman Center for Cellular and Molecular Therapeutics, Children's Hospital of Philadelphia, Philadelphia, PA,[3]Department of Pathology & Laboratory Medicine, University of Pennsylvania, Philadelphia, PA

The development of novel adeno-associated viruses (AAVs) with tissue and cell-type-specific tropism is crucial to meet the need for efficient delivery of gene therapies. AAV selection methodologies have given rise to a new class of engineered AAV vectors capable of improved gene delivery at lower doses and with greater specificity than wild-type AAVs. However, a challenge remains in accurately resolving transduction status within heterogeneous cell populations and across multiple tissues. Existing approaches for identifying cell-type-specific tropism of engineered AAVs through single-cell RNA sequencing are acknowledged to be either low-throughput and/or cost-prohibitive. This limitation is, in part, due to their reliance on droplet-based single-cell or nuclei partitioning. Moreover, the use of fluorescent transgenes for detection raises concerns about potential toxicity, particularly in neuronal populations. Our lab has overcome these constraints by establishing an efficient approach for extensively multiplexed profiling of AAV tropism in specific cell types and regions. Our approach utilizes a modified version of the combinatorial indexing technique for sequencing single-cell transcriptomes (SPLiT-seq), first described by Rosenberg et al. in 2018, to simultaneously capture transcriptome and AAV transduction information at single-cell resolution. This

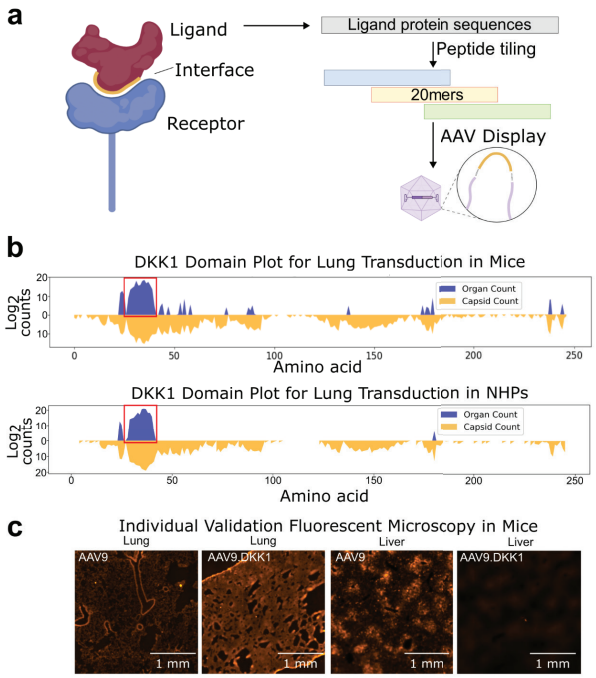
strategy offers numerous benefits in terms of scalability. A single experiment can profile ~150,000 cells or nuclei derived from hundreds of biological samples and enables the simultaneous assessment of tens to hundreds of AAV capsid variants. Importantly, our approach doesn't necessitate specialized equipment and is applicable across various tissues and species. To illustrate the utility of AAV SPLiTseq in defining the cell-type-specific tropism of clinically translatable capsids we performed a mixed pool capsid screen with 90 PM-AAVs from two parental serotypes delivered intravitreal to the retina of non-human primates (NHP). The cellular diversity of the NHP and human retina significantly varies spatially, and the degree of damage or sparing of the foveal cones differs across human retinal diseases. To ensure adequate coverage of therapeutically relevant retinal cell types, we isolated nuclei from both peripheral and foveal regions for single-cell sequencing. Capsid transduction was assessed at single-cell resolution using AAV SPLiTseq and more broadly using bulk RNA and DNA sequencing. This allowed for integrated analysis across these complementary screening modalities. Top-performing capsid variants were identified by comparative analysis of bulk and single-cell data and further evaluated for performance and cell-type tropism. In summary, we demonstrate the successful implementation of AAV SPLiT-seq for regional and cell-type-specific tropism to identify clinically relevant PM-AAVs for gene therapy delivery.

312. Identification of Novel AAV3B and AAV8 Variants with Superior Retina Transduction Profiles Following Suprachoroidal Delivery in Multiple Large Animal Models

April R. Giles, Elad Firnberg, Sigmund K. S. Tejada, Samantha A. Yost, Jessica D. Gumerson, Levi Winter, Ryan Kruse, Sungyeon Cho, Trang Nguyen, Christopher B. Tully, Bezawit Ejigu, Mi Shi, Samitha Venu, Ryan N. Clarke, Brendan N. Lilley, Ye Liu, Andrew C. Mercer, Olivier F. Danos

REGENXBIO Inc., Rockville, MD

Recent clinical advancements delivering adeno-associated viral (AAV) vectors into the suprachoroidal space (SCS) have established the feasibility and value of this in-office route of administration in ocular gene therapy. The identification of engineered capsids optimized for SCS delivery that both efficiently transduce ocular tissue in a targeted fashion and display favorable off-target transduction profiles would enable widespread use of this route of administration. We designed and produced three high diversity peptide insertion libraries (up to 10^8 variants per library), each encoding AAV *cap* under the control of the CMV promoter with randomized 7-mer insertions at VR-IV of AAV3B and VR-IV or VR-VIII of AAV8, and delivered them intraocularly to non-human primates (NHP, cynomolgus macaques). Leveraging our directed evolution platform NAVIGATE (Novel AAV Vector Intelligent Guided Adaptation Through Evolution), we identified 2-4k novel variants enriched in retina and RPE-choroid from each high diversity library, which we then re-packaged and administered to NHP via SCS delivery. We then selected 63 variants (41 AAV3B.VR-IV, 12 AAV8.VR-IV, and 10 AAV8.VR-VIII) for final library down-selection. Each variant (as well as parental controls AAV3B and AAV8) was produced individually with genomes encoding a barcoded CAG.tdTomato cassette, pooled, and delivered to NHP, again by SCS delivery at a dose of 3e12 GC/eye. All variants expressed transgene mRNA in retina more efficiently than parental serotypes as measured by average RNA relative abundance across multiple samples per eye. AAV3B.VR-IV insertions and AAV8.VR-IV/AAV8.VR-VIII insertion variants were up to >30-fold and up to >50-fold improved, respectively, when compared to the parental serotypes. Most AAV8-based insertion variants also expressed >20-fold more transgene mRNA in RPE-choroid compared to AAV8, with the top variant producing in excess of 200-fold more mRNA than AAV8. We also identified numerous variants with advantageous off-target transduction profiles. For example, the majority of AAV8.VR-IV and AAV8.VR-VIII variants that showed a greater than 10-fold increase in retinal transduction did not transduce liver, heart, or kidney to a greater degree than AAV8. We subsequently evaluated these variants in additional *in vivo* and *in vitro* model systems. We assessed the 63-member library and a subset of single vectors via SCS delivery in Yucatan minipigs. In a library setting, the improvement of AAV3B variants over AAV3B appeared to be species-limited. Findings from the AAV8 insertion variants, however, were largely translatable from NHP to minipigs, with top hits achieving improvement relative to AAV8 of >60-fold and >100-fold in RPE-choroid and retina, respectively. Variants evaluated as single vectors achieved up to 150-fold higher secreted transgene protein expression in the aqueous humor as compared to the AAV8 control. Transduction of iCell RPE cells and an ARPE-AAVR cell line with either the 63-member library or a subset of top hits as single vectors established that most variants exhibit superior transduction efficiency compared to AAV8 with top variants achieving >20-fold improvement in both the library and single vector settings. These results validate the utility of the NAVIGATE platform and its ability to identify AAV variants that significantly outperform parental serotypes and that have the potential to be developed as gene therapy treatments in ophthalmology.



313. Reprogramming Adeno-Associated Virus Tropism via Displayed Peptides Tiling Receptor-Ligands in Mice and Non-Human Primates

Andrew Portell[1], Kyle Ford[1], Duy An Le[1], Alice F. Tarantal[2], Prashant Mali[1]

[1]Bioengineering, University of California San Diego, La Jolla, CA,[2]University of California, Davis, Davis, CA

Adeno-associated viruses (AAVs) are common gene therapy vectors, however, their effectiveness is hindered by poor target tissue transduction and off-target delivery. Hypothesizing that naturally occurring receptor-ligand interactions could be repurposed to engineer AAV tropism, we fragmented all annotated protein ligands known to bind human receptors into tiling 20-mer peptides and displayed these onto the surface loops of AAV5 and AAV9 capsids at two surface-exposed sites (Figure a). The resulting four capsid libraries, comprising >1 million AAV variants, were screened across 9 tissues in C57BL/6 mice. Tracking variant abundance, we identified >15,000 variants that efficiently transduced at least one mouse organ. We individually validated 21 AAV variants with 74.3% of the organ tropism predictions accurately reproducing, confirming overall screen efficacy. We next performed mutagenesis on the top-performing displayed peptides and screened the resulting millions of AAV variants in C57BL/6 mice

and non-human primates. As our displayed peptides are systematically tiled from human ligands, we observed strong species concordance in transduction patterns with certain peptides also displaying consistent activity across mice strains, capsid insertion contexts, and capsid serotypes (Figure b-c). Comprehensive tiling and deep mutagenesis also enabled a thorough examination of homologous peptide activity with an ability to map functional domains across the entire amino acid sequence of the proteins from which the peptides were derived (Figure b). Interestingly, we observed functional peptides tended to be derived from specific domains on ligands which enabled the prediction of putative AAV-receptor interactions, which we successfully validated by targeted genetic perturbations. We anticipate this comprehensive ligand peptide tiling and display approach will enable the future engineering of tropism across diverse viral, viral-like, and non-viral delivery platforms, and shed light on basic receptor-ligand biology.

314. Improvement of Liver Tropic AAV Capsids: Neutralizing Antibody-Evading Variants of sL65 Which Demonstrate Cross-Species Transduction

Jing Liao[1], Shiliang Hu[1], Nannan Jia[1], Joy Wang[1], Krishna Chintaluri[1], Yinxing Chen[1], June Deng[1], Kirsten Lapoint[1], Megan Ericson[1], Isabel Alberta[1], Noel Walsh[1], William Lee[1], Delaney Dowdell[1], Nick DiGioia[1], Lauren M. Drouin[1], Gregory Preston[1], Ma Qicheng[1], Wei Ding[1], Marti Cabanes Creus[2], Leszek Lisowski[2], Matthias Hebben[1], Mariana Nacht[1]

[1]Alexion Genomic Medicine, Astra Zeneca Rare Disease, Lexington, MA,[2]Children's Medical Research Institute, Sydney, Australia

Antibodies against AAVs are a major cause of patient exclusion in gene therapy trials and prevent redosing of treated patients. We previously reported the generation of the novel human liver tropic capsid sL65, isolated in humanized mice and validated in non human primates (NHPs). The sL65 capsid shares a limited number of epitopes with capsids commonly used in clinical trials. However, its variable region I (VR I) is homologous to AAV2, AAV3B and AAV LK03, making sL65 vulnerable to certain antibodies directed against these serotypes. To enhance antibody evasion, we created around 15,000 variants of sL65 through VR I region mutations and screened them in humanized mice with and without neutralization by human immunoglobulins (IVIG). Remarkably, we identified candidates that evaded pre-existing neutralizing antibodies (NAb) while maintaining potency in human hepatocytes from FRG mice. These engineered capsids also exhibited enhanced transduction efficiency in various human cell lines, including HuH7 and RC32 Hela cells. Interestingly, several capsid variants showed increased transduction efficiency in mouse hepatocytes, indicating a potential improvement in cross-species translatability. Next, we barcoded key capsid variants and administered pooled capsids in NHPs following systemic administration. mRNA expression was quantified by next-generation sequencing (NGS) of the barcodes associated with each capsid variant. Confirmation was obtained that the transduction efficiency in NHP livers with NAb evading capsids was maintained, aligning with results observed in humanized mice studies. To explore the possibility of redosing by serotype switching, we performed an *in vitro* RC32 cell based NAb assay utilizing serum from NHPs previously dosed with different liver tropic capsids, including AAV8, AAV DJ, AAV LK03, and sL65. As hypothesized, we observed that, *in vitro*, the sL65 variants were less impacted by neutralizing antibodies from sera of NHPs dosed with AAV LK03 compared to the other capsids tested. In summary, the targeted engineering of sL65 VR I led to decreased capsid neutralization by pre existing anti AAV neutralizing antibodies while maintaining high transduction in human hepatocytes, mouse and NHP livers. This enhances cross species translatability, while offering the potential to treat a broader patient population and opening the possibility to re retreat patients who previously received gene therapy with an unrelated serotype.

315. Enhanced Precision for *In Vivo* Gene Delivery into Lymphocytes Through Mono- and Bispecific DART-AAVs

Luca J. Zinser, Samuel A. Theuerkauf, Fabian John, Muhammed Burak Demircan, Christian J. Buchholz

Gene Therapy and Molecular Biotechnology, Paul-Ehrlich-Institut, Langen, Germany

One of the major obstacles for *in vivo* gene therapy are vectors mediating highly selective gene transfer into a defined population of therapy-relevant cells. Currently, only a limited number of presently approved *in vivo* gene therapies tackle this challenge through the localized administration of non-targeted AAVs. However, numerous genetic and acquired diseases, including HIV, distinctly affect certain tissues or even a particular subset of cells. In this study, we present mono- and bispecific DARPin-targeted AAVs (DART-AAVs) addressing the lymphocyte markers CD8, CD4, CD56 or CD32a. By combining two DARPins in a specific manner, the bispecific DART-AAVs exhibit binding behavior that follows an AND-gate-like pattern for both surface markers. For CD56 a DARPin was selected *de novo* via ribosome display. Two DARPin candidates demonstrated

favorable binding characteristics to CD56 in a cellular binding assay conducted with primary human NK cells and NK92 cells. The most promising CD56 DARPin, along with previously established DARPins targeting CD8, CD4, and CD32a, was integrated into surface-exposed loops of the AAV2 capsid — either individually or in pairs. Both, the mono- and bispecific DART-AAVs preserved their structural integrity, as confirmed through high-resolution cryo-electron microscopy. Remarkably, bispecific vectors, in contrast to their monospecific counterparts, exhibited a clear preference e.g. for CD4/CD32a, CD4/CD8 and CD8/CD56 double-positive cells. This preference was consistently observed in cell mixtures as well as *in vivo* after systemic vector administration into a mouse model harboring double-positive cells in bone marrow. Even when double-positive cells constitute only a small fraction of the overall cell population such as the CD4/CD32a HIV reservoir cells, the CD4/CD8 T-cells and CD8/CD56 NKT-cells these vectors reliably targeted such cells in several settings, including healthy donor blood. The preference in transduction of double positive cells was up to 30-fold compared to single positive cells. Cell trafficking studies revealed an increased cell entry rate for bispecific over monospecific AAVs. Our results suggest a novel avenue for receptor targeting by enabling gene transfer into cell subtypes defined by two cell surface markers.

316. Engineered Adeno Associated Virus Capsids for Packaging Proteins

Ryan Sorensen[1], Mareike Daniela Hoffmann[2], Ajay Extross[2], Yungui He[2], Daniel Schmidt[2]

[1]Department of Biochemistry, Molecular Biology, & Biophysics, University of Minnesota, Minneapolis, MN,[2]Department of Genetics, Cell Biology, & Development, University of Minnesota, Minneapolis, MN

Adeno Associated Virus (AAV) is widely used in gene therapy as it is nonpathogenic and can efficiently deliver a therapeutic DNA payload to target tissue. Efficient nuclear delivery of DNA to a wide range of cell types is the consequence of evolved properties of the AAV capsid that overcome significant biological and cellular barriers (i.e., extravasation from the blood stream, escape from the endosome, and transport to the nucleus). While AAV is currently an excellent delivery vector for DNA, the possibility of packaging non-DNA payloads has not yet been explored. With the aim of expanding the payload options of AAV beyond DNA and to improve the utility of AAV as a delivery vector we engineered an AAV capsid capable of packaging protein. In prior work, we performed a domain insertion screen of AAV-DJ VP1 that, in addition to identifying new domain insertion positions on the outside of the capsid for cell-specific targeting, revealed positions on the inside of the capsid permissive to insertions. We utilize these permissive positions on the interior of the capsid to insert a nanobody, acting as a binding scaffold, which mediates packaging of a target protein. Production of engineered AAV packaging protein is performed by adapting widely used helper-free production in HEK293AAV cells wherein the plasmid normally encoding the transgene to be packaged into AAV is replaced by a plasmid encoding the target protein and lacking ITRs. The capsid protein containing the nanobody insertion is provided on a separate plasmid and is supplemented by the remaining wild-type capsid proteins required for capsid assembly. The expressed target protein binds to the nanobody inserted into the capsid protein and becomes packaged within AAV during the capsid assembly process. First, we demonstrate that our engineered AAV capsids containing either a GFP nanobody or an ALFA nanobody inserted into VP1, chosen based on our previous insertional data, are capable of packaging their cognate ligand (GFP or ALFA tagged GFP protein). Additionally, the low copy number of VP1 in assembled capsids was predicted to promote incorporation of the engineered VP1 into assembled capsids and packaging of the target protein. Western blot analysis of iodixanol purified AAV packaging protein demonstrated two permissive positions that package the target protein with differing efficacy. Next, we increased the efficiency of protein packaging by adding a nuclear localization signal to the target protein leading to its enrichment in the nucleus where capsid assembly occurs. Moreover, we demonstrate that through insertion of the nanobody into VP3, which has a higher rate of incorporation into the capsid than VP1, we can further enhance the efficiency of protein packaging. Finally, we determined the bulk ratio of target protein packaged per capsid using quantitative mass spectrometry. In conclusion, this work demonstrates the first instance of packaging protein inside of AAV and opens the possibility for the use of AAV to transiently deliver theragnostic agents and research tools in the form of proteins.

Physical Delivery and Novel Approaches

317. Single-Particle Spectroscopic Hydrodynamic Chromatography Reveals Heterogeneous RNA Loading and Size Correlations in Lipid Nanoparticles

Sixuan Li[1], Yizong Hu[2], Jinghan Lin[3], Kuangwen Hsieh[1], Fangchi Shao[4], Lai Wei[1], Tine Curk[3], Hai-Quan Mao[3], Tza-Huei Wang[1]

[1]Mechanical Engineering, Johns Hopkins University, Baltimore, MD,[2]Koch Institute for Integrative Cancer Research, Massachusetts Institute of Technology, Cambridge, MA,[3]Materials Science and Engineering, Johns Hopkins University, Baltimore, MD,[4]Biomedical Engineering, Johns Hopkins University, Baltimore, MD

Introduction: Lipid nanoparticles (LNP) have emerged as pivotal delivery vehicles for RNA therapeutics. Previous research and developments usually assume that LNPs are homogeneous in population, loading density, and composition. Such intuitive yet unverified perspectives remain due to the lack of suitable tools to characterize these physicochemical properties at the single-nanoparticle level. Here, we explore integrating spectroscopy and chromatography as a generalizable strategy to dissect the complexities of multi-component LNP assembly. We characterize a benchmark siRNA LNP formulation with a size distribution ranging from 30 to 200 nm and reveal the existence of seven distinct LNP species, variations in RNA packing densities spanning multiple orders of magnitude among similarly sized LNPs, and size-dependent loading-size correlations. **Methods:** We used Cylindrical Illumination Confocal Spectroscopy (CICS), a technique recently applied for LNP characterization[1] to examine the LNPs with fluorescently labeled siRNA, DSPC lipids, and PEG lipids. The LNPs were injected continuously or in a sample plug for Single Nanoparticle Free Solution Hydrodynamic Separation

(SN-FSHS)[2] in a microfluidic channel. A commonly referenced benchmark LNP formulation with DLin-MC3-DMA as the ionizable lipid was formulated by rapid mixing in a T-junction at pH 4.0 and dialyzed against PBS at pH 7.4. **Results:** The platform can report 4-dimensional LNP parameters (**Fig. 1a**), including the fluorescence of labeled siRNA, PEGylated lipid, and helper lipid detected by the single particle fluorescence (i.e., CICS), plus the size measured by the hydrodynamic chromatography (i.e., SN-FSHS). The 3-color fluorescence was used to distinguish 7 subpopulations within the LNP sample, based on the compositional features (**Fig. 1b**). We showed that SN-FSHS can measure LNP size in an unbiased manner and clearly differentiate two populations within a bimodal mixture of LNPs, while the DLS results are masked by the larger LNP population (**Fig. 1c**). By analyzing the LNP content and size at single particle level, we revealed the heterogenous loading-size correlation across LNP size ranges from 30 to 200 nm for 3 tested LNP formulations prepared with different mol% of PEGylated lipid (**Fig. 1d**), that would be otherwise masked by the bulk average method. **Conclusions:** The SN-FSHS-CICS platform provides the first integrated characterization tool for the simultaneous assessment of population distribution in composition and loading capacity of RNA in LNP formulations. This analysis can provide valuable insights into the heterogeneity of LNP preparations and permit systematic investigations in understanding critical physicochemical parameters in LNP engineering. The SN-FSHS-CICS platform can guide formulation optimization and manufacturing processes to achieve greater compositional homogeneity and further improve the performances of LNP delivery systems. **References:** (1) Nat. Comm. 2022, 13 (1): 5561. (2) J. Am. Chem. Soc. 2016, 138 (1): 319.

(a) Four-dimensional parameters reported by SN-FSHS-CICS platform that enables the following single-nanoparticle size and loading (including siRNA, helper lipid and PEG lipid) correlation analysis. (b) 3D scatter plot of the subpopulations within a benchmark siRNA LNP formulation classified based on the compositional features. Each dot represents one particle/molecule. (c) The hydrodynamic size of siRNA LNPs with bimodal mixture of 0.5 mol% and 4.5 mol% PEGylated lipid formulation, measured by DLS and SN-FSHS-CICS. (d) Correlation between siRNA loading and LNP size by SN-FSHS-CICS single particle measurement, overlaying all three formulations including 0.5%, 1.5% and 4.5% PEGylated lipid. n = 11,068, 15,191, and 8,637 LNPs analyzed for 0.5%, 1.5%, and 4.5% PEG formulations, respectively.

318. Engineered *Staphylococcus Epidermidis* as a Protein Delivery System for Treating Skin Diseases

Travis M. Whitfill[1], Roger Leger[1], Dorival Martins[1], Azim Munivar[2], Julia Oh[3], Sara Mootien[1]

[1]Azitra Inc., Branford, CT,[2]Atman Therapetuics, New York, NY,[3]The Jackson Laboratory, Farmington, CT

The topical delivery of large molecules through the skin surface has been a challenge for treating skin diseases, as human skin barrier function generally prevents large molecules from penetrating intact skin. Here, we present data for a novel platform using *S. epidermidis* (SE), a safe human skin commensal, as a chassis for delivering proteins throughout the epidermis. This system has important advantages over other methods of drug delivery, as it can establish residence on a patient's skin and continuously deliver therapeutic proteins *in situ*. We first developed genetic tools for using SE as a delivery system using GFP as a reporter, including plasmids for genetic manipulation, promoters to optimize protein expression, and secretion signals to export recombinant proteins from SE (**Fig 2B**). Engineered GFP-secreting SE secretes more GFP in culture with a secretion signal vs. no secretion signal (**Fig 2C**) and colonizes mouse skin after a single application **(Fig 2D)**. *In vivo* two-photon and light microscopy in mice showed engineered SE colonizes mouse skin down to ≥80μm and is found in hair follicles (**Fig 2E-I**).

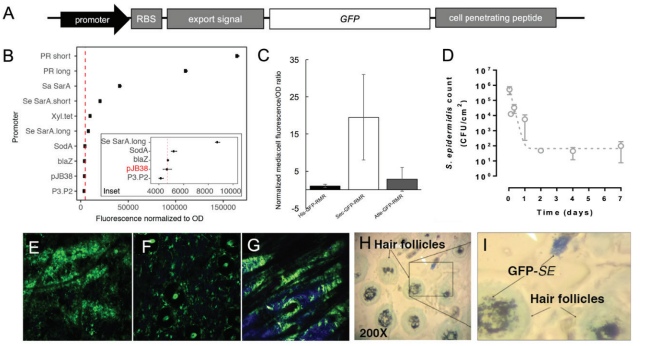


Figure 1. Features of a novel, SE-based protein delivery system using GFP. **(A)** Construct design comprised of a promoter, RBS, export signal. **(B)** Characterization of a selection of promoters for tunable control of protein expression (GFP used as reporter. **(C)** Characterization of export signals for protein export out of SE (GFP used as reporter) using fluorescence:OD measurements as a ratio of media to cells, normalized by the control (His-GFP-RMR). **(D)** Colonization of GFP-secreting *Staphylococcus epidermidis* onto mouse skin (tails) (n=3). 10^9 CFU were applied to 1 cm^2 of skin, and skin was recultured to determine CFU count over 7 days. **(E-G)** *In vivo* two-photon microscopy of mouse skin three days following treatment of GFP-expressing *S. epidermidis* (green). 25 μm **(E)** and 50 μm **(F)** depth of unshaved mouse ear skin, and **(G)** 80 mμ depth on shaved dorsal skin. **(H)** Light microscopy of dorsal skin of mice following SE-GFP application magnified in **(I).**

We focused on a disease case, Netherton syndrome (NS), a rare genetic disease caused by the loss of the lympho-epithelial Kazal-type-related inhibitor (LEKTI), which causes unregulated activity of kallikrein (KLK) proteases. ATR12-351 is a topical ointment containing an auxotrophic strain of SE, SE351, engineered to secrete domain 6 of human LEKTI protein (rhLEKTI-D6) to restore normal KLK activity levels in NS patients. A series of *in vitro* and *ex vivo* studies was performed to demonstrate proof-of-concept of SE351, an auxotrophic strain of SE, and its drug product, ATR12-351, as an rhLEKTI-D6 delivery chassis to treat NS (**Fig 3A**). *In vitro* studies of an NS model using human skin extracts (HSE) supplemented with recombinant KLK5 (7-fold protease activity excess over normal human skin) were used to measure the effect of SE351 on trypsin-like activity. SE351 supernatant rescued protease activity to normal skin baseline levels ($p<0.01$) (**Fig 3B**). We then used *ex vivo* tape stripped human skin to measure rhLEKTI-D6 penetration from ATR12-351 vs. vehicle

or topical rhLEKTI-D6 application. ATR12-351 delivered 6.1 µg of rhLEKTI-D6 throughout the epidermis in significantly higher amounts vs. topical protein alone (6.µg vs. 2.3 µg, p=0.008) (**Figs 3C-F**). Post application (t=24 hours) of ATR12-351 or vehicle, rhLEKTI-D6 activity was found in significantly elevated levels throughout all 30 tape-stripped skin layers (6.1 µg vs. 0.5 µg, p<0.01). The skin penetration of rhLEKTI-D6 to deeper layers in the skin was more prominent vs. topical application of rhLEKTI-D6.

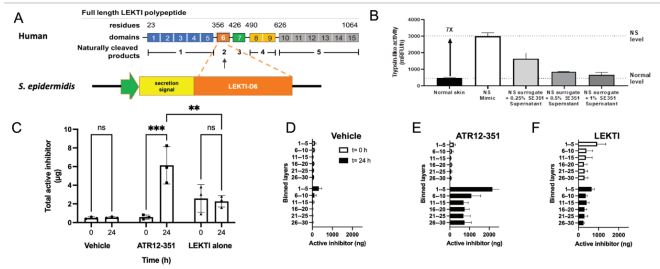

Figure 2. Design of a human recombinant LEKTI-secreting strain of SE (SE351). **(A)** Design of the gene sequence that was chromosomally integrated into *S. epidermidis*. **(B)** *In vitro* studies using tape stripped skin from healthy volunteers spiked with KLK5 to mimic Netherton syndrome. Samples were then added with ascending doses of culture supernatant of SE351. **(C)** Total active LEKTI-like inhibitor levels (µg) from *ex vivo* human skin treated with placebo, ATR12-351 or formulated LEKTI-D6 over 24 h. The total LEKTI-like activity was obtained by adding the µg amounts through layers 1-30 of human skin treated with (●) placebo, (■) ATR12-351 at 10^7 CFU/cm² or (▲) formulated LEKTI-D6 at 300-400 ng/cm² at t = 0 h and t = 24 h of exposure at 30°C. Data are means ± SD (N = 3). Statistical analysis in (**C**) was carried out using two-way ANOVA. NS: no statistical difference; ***: p < 0.001; **: p < 0.01. **(D-F)** Amounts of active LEKTI-like inhibitors in layers extracted from tape strips samples from *ex vivo* human skin treated with (**D**) placebo, (**E**) ATR12-351 at 10^7 CFU/cm² or (**F**) formulated LEKTI-D6. The sample collection proceeded immediately post skin application (t = 0 h, white bars) or after 24 h incubation at 30°C (t = 24 h, black bars). Data are means ± SD (N = 3).

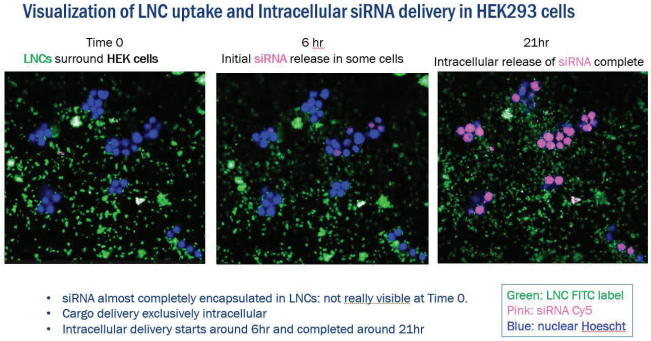

Here, we demonstrated proof-of-concept of a novel cutaneous protein delivery system using a live, engineered bacterial chassis composed of SE. We showed that engineered SE colonizes mouse skin, secretes functional rhLEKTI-D6 in an in vitro NS model, and delivers the desired LEKTI activity deep into the layers of the epidermis in ex vivo human skin. A clinical study of ATR12-351 in adult patients with NS has been initiated (NCT06137157).

319. Lipid Nanocrystal Delivery of siRNA: Dynamics of Uptake in Innate Immune Cells in Human Blood and Visualization of Small Oligonucleotide Delivery in Cell Culture

Hui Liu[1], Miriam Mikhael[1], Amra Tabakovic[1], Anne-Rika Holtzhausen[2], Caroline Beltran[2], Partha Samadder[1], Tzong-Jen Sheu[1], Thomas Hoover[1], Natalie Strickland[2], James J. Ferguson[1]

[1]Matinas BioPharma, Bedminster, NJ,[2]Synexa Life Sciences, Cape Town, South Africa

Background: Lipid nanocrystals (LNCs) are highly stable nanoparticles that self-assemble when phosphatidylserine and calcium are combined. Their unique multi-layer structure permits incorporation of cargo between layers, and they are able to deliver small molecules and small oligonucleotides to cells. Outside cells, normal high calcium levels maintain their crystalline structure, while in tissues they are avidly taken up by certain cells, where much lower calcium levels in the cytosol disrupt their structure and release cargo. We examined the dynamics of LNC uptake and cargo delivery ex vivo in human blood and in cell culture. **Methods:** Initial flow cytometry studies in human whole blood were performed with Cy5.5-labeled empty LNCs (20 and 80 ug/mL) incubated for 3 hours and 24 hours, and examined uptake in neutrophils, monocytes, dendritic cells, and T, B and NK cells, including stimulation with PHA and SEB. Subsequent studies in dual-labeled cargo-carrying LNCs (LNC-FITC, siRNA-Cy5) examined both the LNC uptake and cargo delivery in the same cells. Additional studies were performed to look in more detail at classical, non-classical and intermediate monocyte subsets. Dynamic live cell imaging studies were conducted in HEK293 cells with the same dual-labeled LNCs. 10^4 HEK293 cells were seeded into an imaging chamber system and allowed to attach and rest for 24 hours. Dual-labeled LNCs were added and cells imaged over 24 hours. For higher-resolution mechanistic imaging cells were stained overnight using LAMP1 in blocking buffer with AF555 secondary antibody used for detection; nuclei were stained with Hoescht 33342. Slides were imaged immediately using a LSM confocal microscope. **Results:** Empty LNCs were avidly taken up by innate immune cells (neutrophils, monocytes and mDCs) and B cells, with greater uptake at higher concentrations. Dual-labeled cargo-carrying LNCs showed similar uptake patterns; with siRNA cargo delivery distinct from LNC uptake. Stimulating cells did not noticeably affect uptake or delivery. Additional in vitro dynamic cell imaging corroborated LNC uptake and delivery of siRNA cargo into the cytosol and provided visual confirmation that LNCs encapsulate and protect cargo until intracellular release (**Figure 1**). The preparation protocols for higher-resolution simultaneous endosome/lysosome imaging proved to be incompatible with the current LNC/fluorophore formulation, and details of endosomal escape could not be ascertained. With LAMP1 imaging there was a prominent increase in endosome formation, peaking at 9 hrs; large structures were visible in all cells, strongly suggesting uptake via endocytosis. Both LNCs and cargo were present in the cytosol with cargo outside of endosomes; additional uptake by fusion of LNCs with cell membranes remains a possibility. **Conclusions:** LNCs, with and without cargo, are avidly taken up by innate immune cells in human blood, especially professional phagocytes. Delivery of fluorescently labeled siRNA can be dynamically visualized, with marked endocytotic uptake. LNCs hold considerable promise for intracellular delivery of therapeutics beyond the liver. Future work will examine relative uptake by endocytosis vs fusion, as well as exploring additional details of endosomal escape.

320. Improving Nonviral Gene Expression in T Cells via Inhibition of the Restrictosome

Eric Warga, Jacob Elmer

Chemical and Biological Engineering, Villanova University, Villanova, PA

Gene delivery to T cells has made it possible to successfully treat many serious blood cancers with CAR-T cell therapy. Gene delivery to other cell types enables effective treatment of other conditions, like hemophilia A (Roctavian) and B (Hemgenix), β-thalassemia (Zynteglo), and sickle cell disease (Casgevy). However, the viral vectors used to deliver these genes are associated with high treatment costs,

which could be alleviated by using nonviral vectors. The reason viral vectors are used is for their greater efficiency, which may be attributed to the expression of genes like ICP0 that specifically combat the host cell innate immune response. The goal of this study was to provide a similar inhibition of the innate immune response for plasmid DNA and determine if this inhibition improves nonviral gene expression, particularly in T cells. **Our research has identified ND10 bodies (also called restrictosomes) are problematic components of the innate immune response that repress nonviral gene expression. In this study we show that inhibiting the restrictosome improves nonviral gene expression in T cells.** Figure 1 is a simple diagram of the main proteins of the restrictosome and how they function.

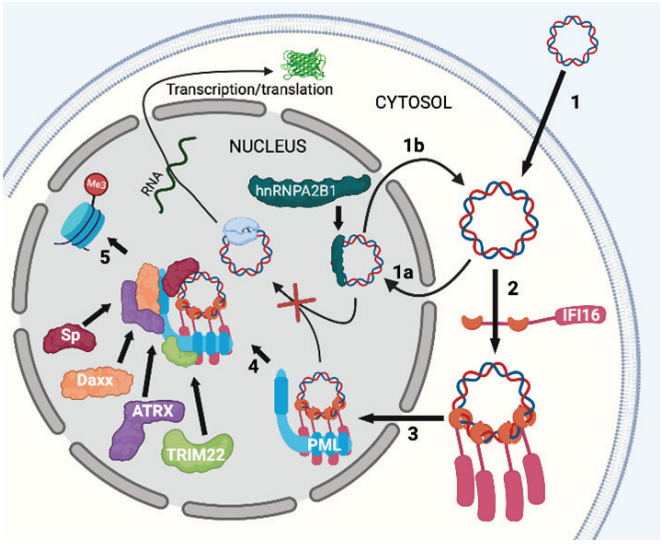

Figure 1. Overview of predicted restrictosome action on plasmid DNA. (1) Plasmid DNA enters cell. (1a) Plasmid DNA unbound by IFI16 enters nucleus. (1b) hnRNPA2B1 transports free plasmid back into cytosol. (2) At least 4 IFI16 monomers bind to plasmid. (3) Plasmid enters nucleus and PML is recruited. (4) PML recruits other complex members Sp100/110/140, Daxx, ATRX, and TRIM22. (5) pDNA is converted to heterochromatin, making transcription impossible. In the first part of this study, we compared the transcriptomes of T cells (e.g., Jurkat and Primary T cells) to HEK-293T cells to determine if the significant difference in transfection efficiency (with Lipofectamine LTX) between these cell types can be correlated to differences in the expression levels of host cell genes involved in the innate immune response. These experiments revealed that HEK-293T cells, which can be transfected to nearly 100% efficiency, lack several components of the restrictosome complex (e.g., IFI16, Sp100, Sp110, Sp140, and TRIM22), as shown in Table 1. Furthermore, an experiment where IFI16 was overexpressed in HEK-293T cells and followed by transfection with a GFP plasmid showed that the average transfection efficiency was reduced to 33.2% in the presence of IFI16 (n=18).

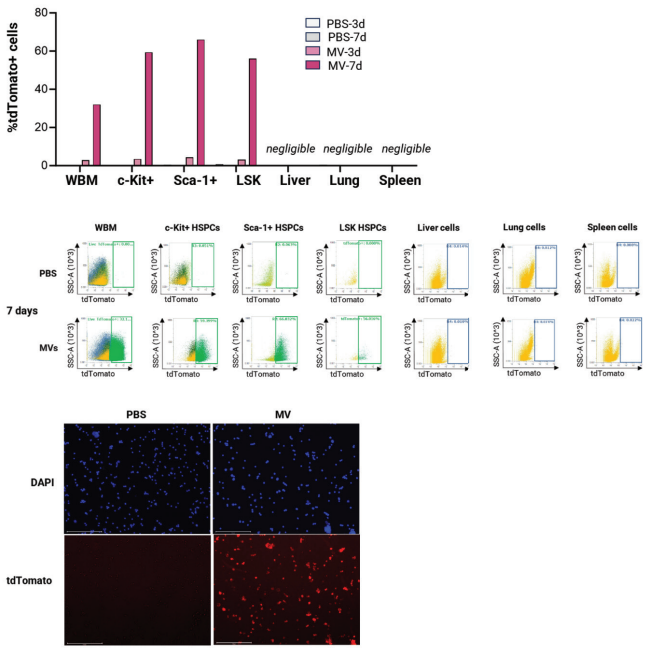
Table 1. Expression of selected genes in transcripts per million reads (TPM). n.d. = not detected.

Gene	Pan-T Cells	HEK-293T
IFI16	280	0.01
PML	65	20
Sp100	80	1.7
Sp110	62	0.23
Sp140	140	n.d.
ATRX	21	13
Daxx	87	110
hnRNPA2B1	730	800
TRIM22	48	0.02

Because the overexpression of IFI16 alone reduced transfection efficiency in HEK-293T cells, we knocked out IFI16 in Jurkat T cells and compared lipofection in the KO cells to lipofection in wild-type cells with GFP as the reporter. While knocking out IFI16 did not have any effect, we knocked out **every restrictosome component at once** and observed that the %GFP$^+$ cells increased by **2.5-fold on average**, measured by flow cytometry (n=12). This demonstrates that the inhibition of the restrictosome is a promising way of improving the efficiency of nonviral gene expression.

321. Megakaryocyte-Derived Extracellular Vesicles Deliver Gene Therapy Cargo That Targets Bone Marrow and Evades the Liver *In Vivo*



Iain R. Thompson, Navdeep Malik, Joe R. Inigo, Pragati Jain, Jenny T. Korunes-Miller, Diana Hernandez Hernandez, David M. Raiser, Sadettin S. Ozturk, Laura R. Goldberg, Jonathan N. Thon

STRM.BIO, Cambridge, MA

Limitations of current gene therapy tools are well documented, including toxicity, off-target effects, and inability to repeat dose. We are presenting a novel, non-viral based delivery platform, in which megakaryocyte-derived microvesicles (MVs) preferentially target bone marrow *in vivo* and are safe for repeat dosing. Here we demonstrate that MVs loaded with Cre recombinase mRNA, when IV injected into Ai14 Cre-LoxP reporter mice, completely bypass the liver and target bone marrow cells, preferentially editing the hematopoietic stem and progenitor cells (HSPCs). Similarly, when MVs loaded with luciferase mRNA were injected IV into NSG mice, luciferase expression was observed in bone marrow but not in the liver. Bone marrow targeted delivery of gene therapy drug substances that bypass the liver is a significant breakthrough, unachievable to-date by current delivery systems. Primary human CD34+ hHSPCs were differentiated into megakaryocytes *in vitro*. MVs were harvested and loaded with mRNA, encoding either Cre recombinase or luciferase, followed by removal of free cargo. For *in vivo* cargo-mediated protein expression studies, loaded MVs were IV-injected into mouse tail veins (Ai14 or NSG). For *in vitro* studies, HEK293 LoxP-GFP-LoxP-RFP cells were co-cultured with vehicle control or MVs loaded with Cre mRNA for 24-90 hr, followed by microscopy to determine relative fluorescence of GFP and RFP intensities. For Cre-LoxP reporter mice studies, tissues were

collected 3 and 7 days after IV injection, with MV payload delivery quantified by flow cytometry for % cells positive for tdTomato in bone marrow, liver, lung, and spleen, and by microscopy of bone marrow cells from mice injected with vehicle control or loaded MkEVs. For *in vivo* luciferase studies, luciferase expression was quantified by whole body IVIS 24hrs post IV injection. In order to define the cellular specificity and editing efficiency of MVs following IV administration, we employed the Cre-LoxP reporter system. First, we validated our MV loading and potency in HEK293 LoxP reporter cells *in vitro*. We consistently observed successful activation of RFP signal in cells treated with Cre mRNA loaded MVs. When MVs loaded with Cre recombinase mRNA or vehicle control were injected intravenously into Ai14 mice, we observed that tdTomato was specifically expressed in bone marrow cells, with preferential targeting of the HSPC compartment evident at day 7. tdTomato expression was elevated significantly in MV treated mice: 32%, 59%, 66%, 56% vs negligible in control mice, in live bone marrow cells; c-Kit$^+$; Sca-1$^+$; and LSKs, respectively (day 7). Strikingly, liver, lung, and spleen tdTomato levels were negligible and not significantly different between control and MV injected mice (day 3 and 7). NSG mice were injected with LNPs encapsulating HiExpress LUC (control) or MVs loaded with LUC2 mRNA. For LNP injected mice, whole body IVIS imaging revealed predominant signal in the liver. In stark contrast, luciferase expression was detected only in the bone marrow in MV injected animals, completely bypassing the liver. Taken together, these data establish an advanced gene therapy platform that can bypass the liver completely to target bone marrow cells, following IV administration, potentially eliminating the need for current *ex vivo* approaches to treat rare blood disorders.

Figure 1: MVs Deliver Cre recombinase mRNA Exclusively to Bone Marrow in Mice

Graphical representation of tdTomato positive cells identified by flow cytometry **(A)**. Representative flow cytometry plots of cells analyzed 7 days post injection of vehicle (PBS) or Cre-recombinase mRNA loaded MVs **(B)**. Microscopy of dispersed Ai14 mouse whole bone marrow cells after treatment with vehicle (PBS) or Cre-recombinase mRNA loaded MVs **(C)**. MVs, megakaryocyte-derived extracellular vesicles; WBM, whole bone marrow; HSPCs, hematopoietic stem and progenitor cells; LSK, lineage negative/Sca-1+/c-Kit+ hematopoietic stem and progenitor cells.

322. Ultrasound-Facilitated Brain Genome Editing

Yeh-Hsing Lao[1], Robin Ji[2], Naoto Yoshinaga[3], Kathy Snow[4], Chun-Wei Chi[1], Stephen Murray[4], Elisa Konofagou[2], Kam W. Leong[2]

CRISPR-mediated genome editing provides new opportunities to advance molecular medicine. Efficient delivery of CRISPR elements is critical to fully realizing the potential of this technology. CRISPR delivery to the brain is especially challenging because of the blood-brain barrier (BBB), which only permits the passage of certain small molecules. Despite significant efforts to develop new adeno-associated virus (AAV) serotypes with brain tropism and brain-targeting nanoparticles, brain genome editing through systemic administration remains inefficient or limited to certain animal models. Local intracranial administration is still the gold standard for CRISPR delivery to the brain. However, for diseases that may require multiple doses, this invasive administration route is not ideal. Here we present a focused ultrasound (FUS) delivery approach that enables somatic genome editing in the brain in a noninvasive manner. When co-administered with microbubbles, the confined acoustic field can elevate BBB permeability via microbubble cavitation-induced mechanical stress, thereby enhancing penetration of CRISPR element-encoding

AAV or nonviral vectors into the FUS-targeted region. In this study, we first optimized the FUS conditions for AAV delivery followed by screening of a library of DNA-barcoded nonviral polyplexes for brain genome editing. With our inhouse-optimized AAV vector, we demonstrated >25% gene editing efficiency in the target neurons in two different mouse models, while we also identified a potential polyplex composition for this application through our screening. Taken together, we confirm the feasibility of FUS for genome editing in the brain with both viral and nonviral vectors; our findings could potentially add to the armamentarium of somatic genome editing strategies for treating intractable genetic disorders in the brain.

323. Exploring mRNA Expression Dynamics in Mammalian Cells through Live Imaging of Single-Cells

Judith Anna Müller[1], Gerlinde Schwake[1], Sophia Rudorf[1], Joachim Rädler[2]

[1]Faculty of Physics, Ludwig-Maximilians-University, München, Germany,[2]Ludwig-Maximilians-Universität München, München, Germany

Introduction: A lot of effort has been directed towards improving lipid nanoparticle (LNP) mediated mRNA delivery and translation efficiency. However, there remains little control over expression level as dose dependent uptake dominates efficiency. As a consequence, heterogenous biodistribution can lead to local overdosing with possible detrimental effects. To address this issue, mechanisms of intrinsic expression control are required. Here, we investigate incoherent feed-forward loops (icFFLs) as well as variations of ribosome density as two approaches to control the kinetic time course and overall expression level of mRNA mediated gene expression. We use time resolved microscopy of reporter gene expression at the single-cell level to study the modulation of expression dynamics. Firstly, icFFLs are frequently occurring motives of transcriptional gene regulation when transcription factors are co-expressed with downregulating micro-RNAs. As a result, gene expression response is faster, less noisy and the steady state level better controlled. We incorporate this motif into transient LNP based gene expression by encapsulating eGFP-mRNA together with siRNA targeting the same eGFP-mRNA (Fig. 1a). The codelivery of these opposing components demonstrates characteristic features of icFFLs with an expression output determined by the ratio of mRNA and siRNA.

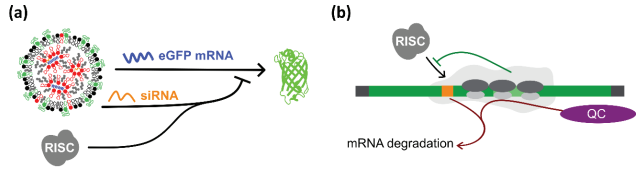

Figure 1: Approaches to control mRNA expression dynamics: (a) Schematic representation of the icFFL model; (b) Modulating mRNA stability via slow-codon windows on the ORF leads to quality control (QC) related degradation with simultaneous protection from RNAi.

Secondly, we employ the mRNA's codon bias within the coding region of mRNA to modulate ribosome movement by insertion of slow-translating codon windows. We then examine the effects of this synonymous recoding on the translation kinetics with a particular focus on the implications for mRNA lifetime. **Methods:** Live imaging on single cell arrays (LISCA) is used to follow many single-cell gene expression time courses in high throughput. Micropatterned substrates with cell adhesive squares (Fig. 2a) facilitate time resolved single-cell live-imaging (Fig. 2b). GFP serves as a fluorescence reporter, enabling quantitative time-resolved measurement of protein expression (Fig. 2c). We describe mRNA translation with biochemical rate equations (Fig. 2d) to assess expression rates, mRNA stabilities (Fig. 2e) and information about timing (Fig. 2f).

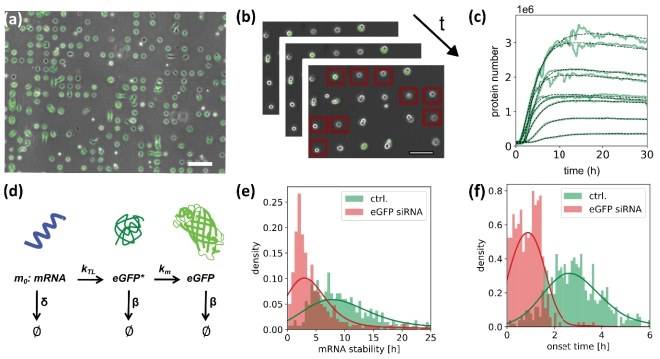

Figure 2: LISCA platform: (a) Exemplary overview of single cells transfected with eGFP mRNA, (b) Long-term imaging under physiological conditions and automated single cell tracking (scale bar corresponds to 400µm), (c) Exemplary fluorescence trajectories extracted with in-house software (green) fitted (dashed black) to (d) Three-stage maturation model for mRNA translation, (e) mRNA stability distribution in presence (red) and absence (green) of targeting siRNA, (f) corresponding onset time distribution.

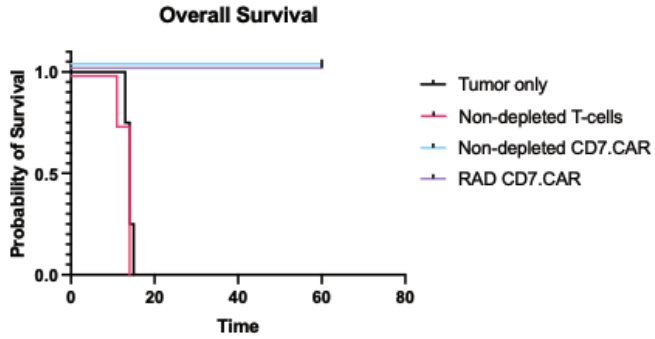
Results: Codelivery of eGFP-mRNA with siRNA in LNP transfection experiments demonstrates reduced noise in single-cell protein expression levels and control over timing, dependent of the ratio between mRNA and siRNA. Additionally, we find a power law decrease in the total protein expression levels dependent on siRNA/mRNA ratio. The data show typical features of icFFLs gene regulation and implement self-regulation in transient mRNA transfections. Furthermore, we found that insertion of slow codon windows in the open reading frame of GFP mRNA enables tuning of its stability. We report a position dependence of slow-codon windows on mRNA lifetime. This effect inverts dependent on the presence or absence of targeting siRNA. Both approaches represent potential toolboxes towards intrinsically regulated gene expression for future combinatorial LNP based mRNA therapies.

Targeted Gene and Cell Therapy I



324. Healthy Donor-Derived Unedited CD7. CAR T-Cells for Improved Therapy of T-Cell Malignancies

Daniil Shmidt[1], Chiou-Tsun Tsai[1], Norihiro Watanabe[1], Maksim Mamonkin[1,2,3]

[1]Center for Cell and Gene Therapy, Baylor College of Medicine, Houston, TX,[2]Texas Children's Hospital, Houston, TX,[3]Houston Methodist Hospital, Houston, TX

Patients with treatment-refractory or relapsed T-ALL and T-cell lymphoma have limited therapeutic options and poor prognosis. Development of CAR T-cell strategies targeting prominent surface antigens in T-cell neoplasms, such as CD7, requires mitigating unwanted targeting of normal T-cells that express the same antigens using gene editing or additional transgenes. Additional challenges include high levels of circulating leukemia in patients with treatment-resistant disease, which increases the risk of accidental CAR transduction, and low quantity and poor fitness of normal T-cells following multiple

rounds of lymphotoxic therapies. Treatment with allogenic CAR T cells manufactured from third-party donors overcome the latter challenges but produce short-term activity in HLA-mismatched patients and often induce fatal infectious complications due to the use of high-intensity lymphodepletion required to delay immune rejection. We have recently developed an alternative strategy to manufacture unedited CD7. CAR T cells where CAR T-cell fratricide is minimized by reversible pharmacologic inhibition. In the ongoing Phase I clinical trial at Baylor College of Medicine (NCT03690011), autologous unedited CD7.CAR T cells expand and select for fratricide-resistant CD7-negative CART cells with long-term functional persistence producing MRD-negative remissions in patients with recalcitrant T-cell malignancies. However, manufacturing of autologous CD7.CAR T-cell products for many patients with advanced disease has been difficult due to high levels of circulating disease and low quantity and quality of normal T cells. To overcome these limitations, we explored manufacturing unedited CD7. CAR T cells from haploidentical donors, such as parents or siblings. Potentially alloreactive T cells are removed using CD45RA depletion (RAD); importantly, this depletion preserves fratricide-resistant CD7-negative T cells, most of which are CD45RA-negative. Indeed, we show unedited CD7.CAR T cells generated from RAD T cells expand post-transduction in the presence of pharmacologic inhibitors dasatinib and ibrutinib and produce robust cytotoxicity in vitro against CD7+ malignant T cells (99.4% cytotoxicity over 3 days at 1:1 effector:target ratio), on par with control CD7.CAR T cells generated from non-depleted T cells. Critically, we observed strong anti-leukemic activity of RAD CD7.CAR T cells in a mouse xenograft model of human T-ALL resulting in complete and durable eradication of leukemia in most experimental animals and a significantly prolonged survival compared to control mice ($p<0.001$). Notably, despite an enrichment for effector/memory cells in the RAD CD7.CAR T-cell pre-infusion product, about half of long-persisting CD7.CAR T cells (60 days post-infusion) acquire a central memory phenotype. Anti-leukemic activity of RAD CD7. CAR T cells was similar to non-depleted control CD7.CAR T cells thus supporting feasibility and efficacy of donor-derived RAD CD7.CAR T cells for clinical translation. We surmise this method would expedite the treatment of patients with rapidly progressing disease while utilizing healthy donor T cells without the risk of malignant cell transduction. A clinical trial with donor-derived RAD CD7.CAR T cells for patients with refractory or relapsed T-ALL and T-cell lymphoma will open at Baylor College of Medicine in 2024.

325. Protection of CD33 Modified HSC Progeny from CD33-Directed CAR T Cells in Nonhuman Primates

Nicholas E. Petty[1,2], Stefan Radtke[1], Emily Fields[1], Olivier Humbert[1], George S. Laszlo[1], Sam Fiorenza[1], Mallory Llewellyn[1], Justin Thomas[1,2], Zach Burger[1], Seunga Choo[1], Greta Kanestrom[1], Haiying Zhu[3], Keith R. Jerome[3,4], Cameron J. Turtle[1], Roland B. Walter[1,3], Hans-Peter Kiem[1,3]

[1]Translational Science & Therapeutics, Fred Hutchinson Cancer Center, Seattle, WA,[2]Medical Scientist Training Program, University of Washington, Seattle, WA,[3]Laboratory Medicine & Pathology, University of Washington, Seattle, WA,[4]Vaccine & Infectious Disease Division, Fred Hutchinson Cancer Research Center, Seattle, WA

Acute myeloid leukemia (AML) is a devastating hematologic malignancy. Current work towards developing new anti-AML therapies is stymied by the shared antigen profile of leukemic cells with healthy myeloid cells. An example of this challenge is CD33, which is overexpressed on some AMLs but also widely expressed on mature and maturing myeloid cells. To overcome this challenge our group has investigated gene editing technologies to modify CD33 on hematopoietic stem cells (HSCs). This has been explored in conjunction with therapeutics such as CD33-directed chimeric antigen receptor T cells (CAR33), a combination that is now under investigation in the allogeneic cell transplant setting. However, the kinetics of CAR33 activity and protection conferred by CD33 editing have not yet been studied in an autologous large animal model. Here we report the development of a novel CAR33 construct and demonstrate its activity in vitro and in vivo. We further investigate the impact of CAR33 in two nonhuman primates (NHPs) that had previously received CD33-modified autologous HSC transplantations (HSCTs). We generated a second-generation CAR construct based on the antibody structure of a known CD33-binder. CAR functionality and specificity were validated in vitro using both chromium release and Xcelligence real-time cell analysis assays. CAR33 T cells were then infused into two animals previously transplanted with CD33-modified HSCs using CRISPR/Cas9 or base editor (BE). After CAR infusion, both animals were monitored for cytokine release syndrome (CRS), changes in immune composition in the peripheral blood (PB) and bone marrow (BM), and representation of edited cells within the PB and BM. The CAR33 construct showed specific, dose-dependent killing of $CD33^+$ cells in both in vitro assays. The two animals treated with CAR33 showed variable responses, with one animal displaying symptoms of CRS (lethargy, elevated temperature, elevated IL-6) and one animal remaining asymptomatic. CAR33 expanded in both animals as demonstrated by complete blood count and flow cytometric analysis of lymphocyte and T cell compartments in the PB, respectively. T cell expansion coincided with depletion of $CD33^+$ cells, primarily within the granulocyte compartment, as well as enrichment of CD33-modified peripheral blood mononuclear cells as assessed by digital droplet PCR and next generation sequencing. CAR expansion was transient, with T cell preponderance and CAR marking peaking at 7 days post-infusion and waning to pre-infusion levels after 14 days. Initial depletion of $CD33^+$ granulocytes reverted to baseline 1-2 months post-infusion, coinciding with a return to pre-treatment levels of editing. Here we report the first study of CAR33 in NHPs with CD33-edited HSCs.

We also demonstrate that BE rather than CRISPR/Cas9 editing CD33 confers similar protection from CAR33, a critical transition in mitigating the use of technology associated with double strand breaks in DNA and large-scale genomic recombination events. CD33-edited cells in the PB were selectively spared by our CAR33 T cells, leading to transient enrichment of edited cells within the PB compartment. Taken together, we demonstrate safety of CAR33, protection conferred to CD33-edited cells, and validated BE as an alternative, DSB-independent strategy to edit CD33. This work offers further support for the use of CAR33 in conjunction with CD33-modified HSCT for the treatment of AML.

326. Chimeric Antigen Receptor Discovery Through T Cell Display

Joseph J. Muldoon[1,2], Chang Liu[1,2], Charlotte H. Wang[1,2], Zhongmei Li[2], Akul Naik[3], Matthew A. Nix[3], Arun P. Wiita[3,4,5,6], Justin Eyquem[1,2,7,8,9]

[1]Department of Medicine, UCSF, San Francisco, CA,[2]Gladstone–UCSF Institute of Genomic Immunology, San Francisco, CA,[3]Department of Laboratory Medicine, UCSF, San Francisco, CA,[4]Department of Bioengineering and Therapeutic Sciences, UCSF, San Francisco, CA,[5]Helen Diller Family Comprehensive Cancer Center, UCSF, San Francisco, CA,[6]Chan Zuckerberg Biohub San Francisco, San Francisco, CA,[7]Parker Institute for Cancer Immunotherapy, UCSF, San Francisco, CA,[8]Department of Microbiology and Immunology, UCSF, San Francisco, CA,[9]Institute for Human Genetics, UCSF, San Francisco, CA

A standard approach for chimeric antigen receptor (CAR) discovery is to select for binders that are high affinity using phage or yeast display, characterize them on receptors in vitro, and assess a subset in vivo. However, this process is low-throughput and based on metrics that do not predict CAR efficacy. To accelerate discovery and select directly for anti-tumor potency, we developed T cell display, in which binders are functionally screened in primary cells. Specifically, CARs are integrated as a pooled knock-in library at the T cell receptor alpha constant (*TRAC*) locus, which confers monoallelic and homogeneous expression. To investigate this new approach, a pool of 25 nanobodies (VHHs) targeting the B cell leukemia antigen CD72 was cloned into a CAR backbone. Libraries were packaged as adeno-associated virus homology-directed repair templates and integrated via CRISPR/Cas editing (>75% knock-in). T cells were subjected to in vitro assays and to an in vivo challenge with or without NALM6 leukemia followed by bone marrow harvest. Binders were amplified from genomic DNA and sequenced to identify those that promote antigen-dependent expansion. Arrayed validation against NALM6 leukemia and JEKO1 lymphoma indicated that higher-ranked CARs indeed led to more expansion, better survival, and lower tumor burden. Notably, in vitro assays for cytokine production ($R^2 < 0.1$) and proliferation ($R^2 < 0.4$) did not correlate well with these outcomes. Therefore, in vivo T cell display accurately identified potent receptors. Affinity measurement is another low-throughput process. To address this, we took advantage of the scalability of T cell display to develop a method using recombinant antigen, flow-sorting, and sequencing for pooled measurement. A formula that weights the MFI of sorting bins by library member abundances was developed to calculate an affinity score. Comparison of these scores with other assays indicated that antigen escape occurred with a high-affinity binder, the best CAR was moderate affinity, and the highest cytokine production was from a moderate-affinity one. Furthermore, although CARs that did poorly in vivo were low affinity, those that did well were not necessary high affinity (overall $R^2 = 0.23$). These results support the utility of screening in the *TRAC* CAR-T cell context to map various receptor characteristics. We next examined whether a top VHH could be ported onto the HLA-independent TCR (HIT), which with an scFv improves antigen sensitivity over a conventional CAR. We modified the original HIT design and explored VHH placement on the alpha and beta chains. VHH on both chains compared to either alone synergistically increased antigen binding, which might be because CD72 is a homodimer. Importantly, VHH-HIT exhibited improved sensitivity vs. CAR against low-antigen-expressing cells in vitro; in vivo studies are ongoing. Thus, a VHH identified on a CAR can function on a HIT and retain its intended advantage. In all, T cell display identifies the best binders. We have also generated data showing this method is extensible to scFv binders and much larger libraries (~1,000). This novel method for binder discovery can streamline the development of immune cell therapies for cancer.

327. "Off-the-Shelf" Combination CAdVEC and CAR-NK Cell Immunotherapy for Pancreatic Ductal Adenocarcinoma

Greyson W. Biegert[1], Amanda Roswell Shaw[1], Caroline E. Porter[1], Daisuke Morita[2], Masataka Suzuki[1]

[1]Baylor College of Medicine, Houston, TX,[2]Shinshu University, Matsumoto, Nagano, Japan

To overcome the hostile, immunosuppressive tumor microenvironment (TME) and unreliable tumor-associated antigen expression in solid tumors, our laboratory exploits the distinct properties of local oncolytic adeno-immunotherapy (CAdVEC) and systemic CAR-modified immune effector cells. Currently in clinical testing, CAd*Trio* (expressing IL-12p70, anti-PD-L1 minibody, and HSV-tk safety switch) enhances both adoptively transferred CAR-T cells and endogenous NK cell anti-tumor activities in preclinical animal models, including pancreatic ductal adenocarcinoma (PDAC); a class of tumors that are difficult to treat and often characterized by limited immune cell activity within the TME. Our clinical data indicate that local CAd*Trio* treatment induces significant anti-tumor effects and is safe in combination with systemic autologous CAR-T cells (NCT03740256). In light of this success, quality autologous T-cell products are difficult to generate consistently and have high production costs. To circumvent these challenges, adoptive NK cell therapy is frequently investigated as a readily available "off-the-shelf" alternative. Since CAd*Trio* transgenes improve NK cell expansion and anti-tumor effects, we hypothesized that CAd*Trio* combined with adoptive CAR-NK cell therapy could provide sustained systemic tumor targeting as an "off-the-shelf" combination immunotherapy. CAR-NK cell treatment alone has minimal anti-tumor effects against PDAC in immunodeficient mouse models. However, the addition of CAd*Trio* treatment significantly improves CAR-NK cell persistence and anti-tumor effects, resulting in increased survival. To understand the underlying mechanism, we analyzed RNAseq data that indicates CAdTrio-derived transgenes activate memory-like NK cell developmental pathways. Since CAR-NK cells kill PDAC cells through natural ligand/receptor interactions in the absence of CAR target antigen, unlike CAR-T cells, we tested the efficacy of CAR-NK cells combined with CAd*Trio* in a heterogeneous

PDAC PDX tumor model. We observed that CAR-NK and CAd*Trio* combination treatment consistently controlled tumor growth superior to single-agent therapy. In humanized mouse models, this "off-the-shelf" combination immunotherapy is well tolerated and significantly controls PDAC tumor growth. Currently, we are investigating the contribution of the endogenous immune system in the context of this combination immunotherapy. Overall, our data indicates local CAd*Trio* and systemic CAR-NK cell combination immunotherapy may be an effective immunotherapy for treatment-resistant PDAC and potentially other immunologically "cold" solid tumors.

328. Selective Support of CAR-T Cell Therapies by Cis-Targeted IL2

Sara Sleiman[1], Tyler Hansen[1], Hannah Thomas[2], Jack Swain[2], Raimon Duran-Struuck[2], Nathan D. Mathewson[3], Feng Shen[1], Kelly D. Moynihan[3], Paul Bessette[3], Chris Kimberlin[3], Meghana Sukthankar[3], Terrence Park[3], Andy Yeung[3], Ivana Djuretic[3], Saar Gill[1,4,5]

[1]Center for Cellular Immunotherapies, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA,[2]Department of Pathobiology, University of Pennsylvania School of Veterinary Medicine, Philadelphia, PA,[3]Asher Biotherapeutics, South San Francisco, CA,[4]Division of Hematology-Oncology, Department of Medicine, Perelman School of Medicine at the University, Philadelphia, PA,[5]Abramson Cancer Center, University of Pennsylvania, Philadelphia, PA

INTRODUCTION In vivo behavior of CART cells has shown a strong correlation with improved outcomes, which has spurred an interest in developing approaches to enhance the expansion and persistence of infused CART cells. Although one proposed method combines CART cell therapy with exogenous cytokines such as the IL2 family, the pleiotropic nature of these cytokines can activate other immune cells, leading either to fatal toxicities or weakening of the immune response. Even engineered IL2 variants with attenuated binding to the IL2 receptor remain non-selective for CART cells. Other methods using orthogonal cytokine/cytokine receptors require further genetic modification of T cells. We have developed CAR-T-specific IL2 fusion molecules that selectively activate CART cells by recognizing an extracellular tag to address these challenges. METHODS Cis-targeted cytokine is comprised of a targeting antibody directed against an exogenous tag expressed on the CAR-T surface (truncated non-signaling epidermal growth factor receptor [EGFRt]) and an IL2 mutein with attenuated binding to IL2Rα and IL2Rβ subunits (EGFRt-IL2). The targeting arm of the fusion molecule enhances the functional avidity of the attenuated cytokines, resulting in potent yet selective activation of the targeted cells. RESULTS In vitro, the EGFRt-IL2 fusion molecule was able to rescue the proliferation of a small population of CART cells taken from the peripheral blood of a lymphoma patient 7 days after the patient received an infusion of a commercial CART19-targeting CAR-T cell that also expresses EGFRt. In vivo activity was demonstrated in NSG mice bearing an acute lymphoblastic leukemia (ALL) NALM-6 cell line treated with a suboptimal dose (0.1 x106) of healthy donor EGFRt-CART19 cells with or without the IL2 mutein. EGFRt-IL2 converted the suboptimal dose of CAR-T cells to a curative therapy (CR 5/5), compared to CAR-T cells alone (CR 0/5). The enhanced anti-tumor activity was subsequently confirmed in a model in which the CART cells were generated from a lymphoma patient. Response to treatment was accompanied by CART cell expansion resulting in superior survival in the mutein-treated mice ($p = 0.0015$). CONCLUSION In summary, EGFRt-IL2 enhances in vivo anti-tumor activity and survival in xenografted mice and enhances the activity of lymphoma patient CAR T cells. Given the unique ability to selectively expand EGFRt-expressing CAR-T cells, EGFRt-IL2 may have the potential to reduce the need for lymphodepletion prior to CART cell infusion. Temporal control of the cis-targeted cytokines directed by anti-tag antibodies represents a promising approach to enhance CART cell therapies.

329. ADI-270: An Armored Allogeneic Anti-CD70 CAR γδ T Cell Therapy Designed for Multiple Solid and Hematological Cancer Indications

Yvan Chanthery, Gauri Lamture, Nadine Jahchan, Melinda Au, Alexander G. Teague, Morgan Smith-Boeck, Michael Salum, Yogendra Verma, Ramandeep Kaur, Smitha Rao Yelaguli Gundurao, Jie Zhang, Amy Doan, Jyothi Sethuraman, Ngoc T. Hoang, Hayden Tessman, Philip Storm, Soojin Han, Swapna Panuganti, Christopher J. Rold, Marissa Herrman, Arun Bhat, Kevin P. Nishimoto, Shon Green, Blake T. Aftab

Adicet Bio, Redwood City, CA

Background: CD70 is a compelling target for CAR T cell therapy, given its elevated expression across multiple solid and hematologic malignancies, with expression in normal tissues limited to a subset of activated lymphocytes. γδ T cells combine innate and adaptive immunity and their capability to infiltrate solid tumors significantly correlates with clinical benefit. We have previously described ADI-270, an allogeneic CAR γδ T cell product engineered with a next-generation CAR to target CD70 using its natural receptor (CD27) as the binding moiety and armored with a dominant negative form of the TGFβ receptor (dnTGFβRII) that provides functional resilience to the immunosuppressive tumor microenvironment (TME) found in many solid tumors. We have shown that the design of ADI-270 provides enhanced functionality and potency in CD70+ expressing tumors such as clear cell renal cell carcinoma (ccRCC) models, where we observed robust infiltration and persistence, resulting in significant preclinical efficacy. Here we expand on previous data, evaluating the kinetics of ADI-270 activity in the ccRCC model and its efficacy against additional tumor indications, including models designed to mimic the low and/or heterogeneous antigen expression profile expected in most cancers. **Methods:** CD70 expression profiling by flow cytometry and immunohistochemistry (IHC) on tumor microarrays (TMAs) was used to identify tumor indications for which ADI-270 represents a potential therapeutic. Healthy donor PBMCs were used to activate, expand, and engineer Vδ1 T cells to express the armored anti-CD70 CAR construct. Functional characterization of ADI-270 against cancer cells with varying levels of CD70 expression was determined using cell-based cytotoxicity assays. Human tumor xenografts in NSG mice were used to evaluate the in vivo efficacy of ADI-270 against solid and hematological cancers including ccRCC, NSCLC, and T cell lymphoma. Tumors and blood were collected from A498 xenograft

models for pharmacodynamic analyses using IHC, multiplex IF, and Luminex. In addition, cytotoxicity assays against mixed CD70 +/- expressing cells were used to inform functional comparisons between ADI-270 and multiple clinically relevant benchmarks representing scFV-based anti-CD70 CAR approaches. **Results:** Elevated CD70 expression was confirmed in various solid and hematological tumor indications, with frequency being highest in ccRCC samples. ADI-270 exhibited potent in vitro cytotoxicity against a range of cancer cell lines expressing various levels of CD70. CAR-mediated killing of CD70(+) tumor cell lines by ADI-270 promoted enhanced γδ T cell activity, including innate and adaptive activity against CD70(-) tumor cells. ADI-270 significantly inhibited tumor growth in CD70+ ccRCC (A498), NSCLC (H1975) and T cell lymphoma (Hut78) human tumor xenograft models in NSG mice. In A498 tumor xenografts, robust ADI-270 tumor infiltration, proliferation, and effector function were observed at the earliest assessment time point (Day 3), leading to potent efficacy and eradication of CD70+ tumor cells. **Conclusion:** These results demonstrate the activity of ADI-270 in multiple cancers, which includes innate anti-tumor immunity, potent next-generation CAR targeting, and resilience to attenuation by TGFβ. Based on the functional characterization demonstrated to date, further clinical evaluation of ADI-270 is warranted in ccRCC and additional CD70+ cancers.

330. Discovery of Novel CARs for Solid Tumors Using Senti REVEAL™, a Massively Parallel Technology Platform Comprising Pooled Screening, Machine Learning, and Lab Automation

Tony Hua, Marcus Gainer, Brian Garrison, Kanya Rajangam, Timothy K. Lu, Nicholas W. Frankel
Senti Biosciences, South San Francisco, CA

Introduction. CAR-T and CAR-NK therapies have limited efficacy in solid tumors due to multiple factors including the immunosuppressive tumor microenvironment and the limited potency of the signaling domains of current approved CAR therapies. More potent CAR signaling domains may address this limitation by activating different pathways (or combinations) that increase robustness to the immunosuppressive tumor microenvironment. FDA-approved CAR therapies for liquid tumors tend to use a limited set of intracellular domains, highlighting a need for new signaling domains for solid tumors. Conventional approaches of screening and optimizing CAR designs are manual labor intensive, low throughput, and can suffer from operator and batch error. **Methods**. We developed a massively parallel technology platform, REVEAL™ (Research Engine for Validation of Engineered Asset Libraries), comprising (1) pooled screens of CAR libraries of 10,000s to 100,000s of signaling domains, (2) machine learning models to predict performance, and (3) parallel clonal validation of 100s to 1,000s of candidates using a purpose-built automated liquid handler. Here we used CAR-NK cells, but we anticipate that this framework can be used for other types of effector cells such as CAR-T. We designed libraries of CARs with a fixed extracellular domain targeting CEA, an antigen expressed on a range of solid tumors including colorectal cancer, and over 50,000 combinatorial signaling domains consisting of arrays of subdomains derived from native receptors. High-performing CARs in the libraries were discovered using a sort-seq approach: cells expressing CARs driving robust degranulation (CD107a+) were sorted, and CARs enriched in these cells were identified via NGS. We used these data to train machine learning models mapping CAR structure (i.e., the position and identity of constituent subdomains) to performance. In addition to reproducing experimental CAR performance, these models were used to predict CAR structures not present in the dataset due to cloning or coverage constraints. The highest performing library CARs and model-predicted CARs were then clonally validated in parallel using a liquid handler-based workflow that automated viral production, NK transduction, co-culture assay setup, and imaging-based readout of target killing. **Results**. Our library screens and modeling indicate, and our clonal validations confirm, that signaling domains enriched for TRAF-binding motifs have high performance in the context of anti-CEA CAR-NK cells. Among highest performing CARs, however, TRAF domains are typically accompanied by other functional motifs, constituting a more diverse signaling array than would be found in a single native immune receptor. Successful CARs often comprised multiple canonical immune signaling types, i.e., signal 1 (CD3z), signal 2 (one or more costimulatory motifs) and signal 3 (cytokine signaling), demonstrating that a variety of signaling features can be successfully packaged into a single compact CAR. Additionally, these CARs contained sequences from a wide variety of sources outside of canonical CAR domains such as CD3z, CD28, 4-1BB, indicating the untapped potential for designing new CARs for solid tumors. **Conclusion**. The REVEAL™ framework described here is capable of extensive optimization of CAR structures, and could potentially be applied to development of potent CAR cell therapies targeting solid tumors and hematologic malignancies beyond B cell cancers.

Oligonucleotide Therapeutics

331. Prenatal Intra-Amniotic Administration of an Antisense Oligonucleotide Achieves Widespread Biodistribution with Therapeutic Levels in Fetal Lambs

Beltran Borges[1], Maria T. Clarke[1], Akos Herzeg[1], Joshua Ross[2], Jae Hong Park[2], Daniel Ramos[2], Lingling Kong[2], Nalin Gupta[1], Stephanie Klein[3], John Matson[3], Frank Bennett[3], Charlotte Sumner[2], Tippi C. MacKenzie[1]
[1]University of California San Francisco, San Francisco, CA,[2]Johns Hopkins University, Baltimore, MD,[3]Ionis Pharmaceuticals, Carlsbad, CA

Introduction: The antisense oligonucleotide (ASO) nusinersen improves outcomes of patients with spinal muscular atrophy (SMA). Despite neonatal treatment, patients with severe genotypes still have suboptimal outcomes due to prenatal disease. We hypothesized that intra-amniotic (IA) injection of ASO may penetrate the CNS prior to formation of the blood-brain barrier. We tested the safety and efficacy of IA delivery of a therapeutic ASO in fetal SMA mice and fetal lambs. **Methods:** An SMN2-targeting ASO was injected IA in E13.5 fetal wild-type (WT) and Δ7-SMA mice and full-length SMN2 mRNA, survival, weights, motor behavior, and motor neuron number were assessed. We next injected the same ASO in fetal lambs (using both

IA and intra-cisterna magna (IC) injections [the latter as a positive control for CNS delivery]) and measured biodistribution using a dual-probe hybridization-electrochemiluminescent (ECL) assay and immunohistochemistry (IHC) and evaluated safety parameters including tissue histopathology, serum blood counts, coagulation panels and liver and kidney function tests. **Results:** *In mice,* SMA pups treated prenatally + postnatally showed improved weight gain, behavior, and survival compared to those treated postnatally alone. SMA mice treated prenatally also showed increased motor neuron numbers in lumbar spinal cord (SC) segments compared to postnatally treated SMA mice that were comparable to WT. *In sheep,* we injected 7 fetal lambs IA [137mg (n=2); 500mg (n=3); 1000mg (n=2)) and 3 fetal lambs intra-cranially (30 mg) at E75 (term=150 d). Survival to harvest at E96-E104 was 100% in all groups, with no growth restriction. We detected broad biodistribution of the ASO by hybridization-ECL in numerous fetal tissues after IA injection, with therapeutic levels (>1-10 μg ASO/g tissue) seen in the SC and skeletal muscle at 500-1000 mg doses. Supra-therapeutic levels were detected in liver and kidney after IA injection but there were no concerning histopathological changes in any fetal organ or derangements in serum chemistries. ASO was also detected by IHC, with more robust staining in liver, kidney, and lungs compared to SC. Maternal exposure to the ASO was only detected in the uterus of some dams, without spread to other organs or alterations in serum chemistries. **Conclusion:** Intra-amniotic ASO delivery ameliorates disease in SMA mice and appears safe for both fetus and mother in a large animal model. Levels of fetal CNS penetration are relevant for SMA while distribution to fetal lung and skeletal muscle suggest therapeutic utility in other disease settings. Biodistribution in the placenta and fetal respiratory and gastrointestinal tracts following IA administration suggest routes of entry into the fetal circulation. Accumulation in kidney and liver in lambs, likely due to recirculation after renal excretion, could potentially be mitigated through interval amniotic fluid exchange. Prenatal IA ASO therapy is a promising strategy to provide early, minimally invasive disease-modifying therapy without the risks of permanent genetic alterations associated with viral gene therapy or gene editing.

332. Targeting NLRP3 Splicing Variants with Antisense Oligonucleotides to Control Pathological Inflammation

Roni Klein[1], Janset Onyuru[2], Estela Viera[1], Lijo John[3], Rahul Vijay[3], Hal M. Hoffman[2], Michelle L. Hastings[4]

[1]Center for Genetic Diseases, School of Graduate and Postdoctoral Studies, Rosalind Franklin University of Medicine and Science, North Chicago, IL,[2]Department of Pediatrics, University of California, San Diego, CA,[3]Center for Cancer Cell Biology, Immunology and Infection, Department of Microbiology and Immunology, Rosalind Franklin University of Medicine and Science, North Chicago, IL,[4]Department of Pharmacology, University of Michigan, Ann Arbor, MI

Introduction: The innate immune system defends against pathogenic invaders and sterile insults. NLRP3 inflammasome activation, a key component of this defense mechanism, leads to IL-1β, IL-18 release and pyroptosis (inflammatory cell death). Aberrant NLRP3 activation is implicated in autoinflammatory, metabolic, and neurodegenerative diseases. To date, there are no approved NLRP3 inhibitors in the clinic. Alternative splicing of NLRP3 generates various mature RNA isoforms with distinct function. We hypothesize that manipulating alternative splicing using antisense oligonucleotides (ASOs) can be used to modulate NLRP3 activity and provide a means to treat NLRP3-driven inflammatory diseases. **Methods:** To identify NLRP3 spliced isoforms that lack the ability to activate inflammatory processes, we systematically evaluated the effects of NLRP3-targeted splice-switching ASOs on inflammasome activation in vitro in human THP-1 cells and mouse iBMDMs. We tested one promising ASO from our in vitro studies in a mouse model of acute inflammation following an intraperitoneal LPS injection and cryopyrin associated periodic syndrome (CAPS) myeloid-specific constitutive NLRP3 hyperactivation. **Results:** ASOs induced alternative splicing of NLRP3, knocked down NLRP3 protein expression, and inhibited IL-1β and IL-18 release in human THP-1 cells and mouse iBMDMs. Treatment with our most active ASO significantly reduced IL-1β and IL-6 levels in the plasma of LPS-injected mice. In $Nlrp3^{D301N+/LysMCre+}$ CAPS model, ASO treated mice exhibited improved survival and reduced IL-1β and IL-6 levels in the plasma compared to dPBS control littermates. **Conclusions:** This study demonstrates that altering NLRP3 splicing can modulate protein activity, revealing the importance of specific NLRP3 domains in inflammasome activation and identifying potential therapeutic targets for mitigating pathological activation of the inflammasome. To this end, splice-switching ASOs can specifically induce inactive spliced isoforms of NLRP3 to effectively inhibit the NLRP3 inflammasome. ASO treatment is efficacious in mouse models of acute inflammation and CAPS, providing evidence for a novel approach for treating NLRP3-mediated inflammation.

333. First in Class ASO Targeting *IGHMBP2* Cryptic Splice Variant: Efficacy and Safety

Sandra Paulina Smieszek, Bart Przychodzen, Christina Tyner, Caroline Johnson, Christos M. Polymeropoulos, Gunther Birznieks, Mihael H. Polymeropoulos

Vanda Pharmaceuticals Inc., Washington, DC

Charcot-Marie-Tooth disease Type 2S (CMT2S) is a rare autosomal recessive Charcot-Marie-Tooth disease subtype. Rare variants in immunoglobulin mu-binding protein 2 (*IGHMBP2*) have been shown to cause CMT2S by resulting in abnormal RNA processing leading to alpha-motor neuron degeneration. A patient was reported with pathogenic variants in *IGHMBP2*. Whole genome sequencing (WGS) revealed a paternally inherited cryptic splice site variant (non-coding variant (c.1235+894 C>A) deep in intron 8). The resulting transcript undergoes nonsense-mediated decay (NMD), resulting in IGHMBP2 haploinsufficiency. Our objective was to target this cryptic splice site, rescuing IGHMBP2 protein levels with a novel antisense oligonucleotide (ASO). We obtained the patient's fibroblast cell line and confirmed the variant with WGS and the existence of NMD. A 19mer ASO was designed to target deep in intron 8 (c.1235+894 C>A), around sequence CACTTCCAC(A)GGGGGAAGA. Fibroblast cells underwent ASO treatment (1μM) and 48-hour incubation. Induced pluripotent stem cells (iPSCs), iPSC-motor neurons (iPSC-MNs), and skeletal myofibers (SkM) stocks were generated through expansion and differentiation of the CMT2S patient's fibroblasts. We characterized the physiology of CMT2S-MNs through patch-clamp electrophysiology and examined subsequent neuromuscular junction (NMJ) defects. Derived MNs were then incubated with ASO, and treatment effects were quantified using Hesperos Inc.'s *in vitro* NMJ

system platform. Upon patient fibroblast treatment with ASO, we observed a significant IGHMBP2 protein level increase (~50-70%) in treated samples compared to control (untreated) samples (WB antibody Sigma SAB2106426). qPCR results confirmed an increased ratio of restored wild-type transcript to cryptic exon-containing transcript (~1.8-fold). RNA sequencing further confirmed an increase of *IGHMBP2* expression of 1.3$\log_2$-fold (adjusted p-value < 0.002) following treatment. Preclinical data support this ASO as a potential treatment for restoring IGHMBP2 protein levels, with limited off-target effects *in silico*. Electrophysiological studies revealed hyperexcitability and spontaneous firing of CMT2S-MNs, resembling an amyotrophic lateral sclerosis (ALS) phenotype, and a reduced resting membrane potential, capacitance, and cell body area, as compared to WT-MNs. Analysis of the CMT2S NMJ system revealed a higher fatigue index (FI) compared to the WT NMJ system. Following muscle contraction, the CMT2S NMJ system showed quick fatigue, revealing a tetanus followed by decay phenotype. We examined the effects of ASO treatment and demonstrate rescue of NMJ functioning, as captured by a decrease in fatigue index. NMJ tetanus characterization following treatment shows this rescue with an increase in classical tetanus and a decrease in decay and sporadic responses. To evaluate the potential toxicity of the ASO, a 3-month rat toxicity study was conducted. Transient clinical observations were noted following administration; however, findings were resolved within 24 hours. There were no neurobehavioral changes noted at the 24-hour post-dose evaluation. The no-adverse-event-level (NOAEL) was set at the highest dosage. An increased number of autosomal recessive CMT2S cases caused by *IGHMBP2* pathogenic variants are being reported. The N-of-1 precision medicine approach may prove instrumental to the design of treatments for this highly diverse genetic disorder. Patient-specific phenotypic analysis of MNs and subsequent NMJ systems further confirms the genetic diversity of this disorder. This N-of-1 case exemplifies the shifting boundary between rapid WGS-based clinical diagnoses and research capabilities allowing for the design of personalized ASO-based treatments, serving as a framework for others with ASO-amenable mutations in *IGHMBP2*.

334. Potent, Durable mRNA Knockdown in Extrahepatic Tissues Using siRNAs with Novel Phosphoryl Guanidine Backbone Variants

Wei Liu, Naoki Iwamoto, Subramanian Marappan, Himali Shah, Snehlata Tripathi, Erin Purcell-Estabrook, Khoa Luu, Anthony Lamattina, Qianli Pan, Fangjun Liu, Frank Favaloro, Arindom Chatterjee, Tomomi Kawamoto, Genliang Lu, Jake Metterville, Priyanka Prakasha, Hailin Yang, Yuan Yin, Lola Owen, Hui Yu, Michael Byrne, Pachamuthu Kandasamy, Chandra Vargeese

Wave Life Sciences, Cambridge, MA

Conjugation of *N*-Acetylgalactosamine (GalNAc) to small interfering RNA (siRNA), which enhances their receptor-driven uptake by hepatocytes, has driven the successful *in vivo* knockdown of liver mRNAs. By contrast, the development of siRNA chemical modifications that result in potent, durable knockdown in extrahepatic tissues remains a major challenge for the field. Previously, we showed that incorporating phosphoryl guanidine (PN) backbone linkages in GalNAc-siRNAs can improve the potency, tissue exposure, and durability of knockdown in mouse liver *in vivo*. We have recently developed a new stereopure siRNA design that, when incorporated with chemically modified PN linkages called "PN variants," results in potent, durable knockdown in extrahepatic tissues *in vivo*. To initially understand the impact of the new stereopure siRNA design, we developed GalNAc-siRNAs with PN linkages directed against the liver target transthyretin (*Ttr*) in mice. siRNAs with the new design enhanced knockdown durability, supporting >50% knockdown of serum Ttr protein levels up to 50-days post-dose, compared to the benchmark siRNA, which sustained >50% knockdown for only ~27-days post-dose. Using this more durable siRNA format, we decided to test the impact of introducing PN variants on knockdown by non-GalNAc-siRNAs in both hepatic and extrahepatic tissues, including the central nervous system (CNS), adipose tissue, kidney, and heart and skeletal muscle. In the CNS, we developed a stereopure siRNA format, incorporating the new design and PN variants, that targets mouse *Amyloid precursor protein* (*App*). These siRNAs delivered potent knockdown, resulting in 70-90% *App* mRNA reduction across 6 regions of the mouse CNS, including the cortex and striatum, for up to 16 weeks after a single intracerebroventricular (ICV) dose. Consistent with these data, marked reductions in App protein levels were observed by immunohistochemistry across the mouse brain at 16 weeks post-ICV injection. For systemically delivered siRNAs, incorporation of PN variants can support siRNA target engagement in multiple peripheral tissues of interest and can be used to tune relative potency among specific tissues, such as liver versus kidney. By incorporating select PN variants, we designed siRNAs that could knockdown *Superoxide dismutase 1* (*Sod1*) mRNA in desired combinations of metabolically important tissues, such as both liver and adipose tissue. PN variants can also improve the potency of non-GalNAc siRNAs in the liver, which may be useful when simultaneous RNA suppression of a gene in both hepatic and extrahepatic tissues is desired. Incorporating one type of PN variant in a non-GalNAc-siRNA resulted in >80% knockdown of liver *Sod1* mRNA up to 14-days post single dose, compared to ~25% knockdown in liver by non-GalNAc-siRNAs containing PN linkages. In sum, our novel siRNA designs that include PN variant backbone modifications support potent and durable knockdown of both hepatic and extrahepatic targets, including the brain cortex and striatum. In addition, these data support the potential to tune siRNA targeting toward tissues of interest through chemical modifications to backbone linkages.

335. miRNA Site-Blocking Oligonucleotides as a Novel Therapeutic Strategy for STXBP1 Encephalopathy

Alex J. Felix[1,2], Jennine M. Dawicki-McKenna[1,2], Elisa A. Waxman[2,3], Congsheng Cheng[3], Alexey Bogush[1,2], Lea V. Dungan[2,3], Deborah L. French[2,3], Beverly L. Davidson[2,3], Benjamin L. Prosser[1,2]

[1]University of Pennsylvania, Philadelphia, PA,[2]Center for Epilepsy and NeuroDevelopmental Disorders (ENDD), Philadelphia, PA,[3]Children's Hospital of Philadelphia, Philadelphia, PA

STXBP1 encephalopathy is a rare neurodevelopmental disorder caused by heterozygous mutations in the *STXBP1* gene. STXBP1 plays an essential role in neurotransmitter release by regulating pre-synaptic vesicle exocytosis. Loss of function mutations in *STXBP1* impair

neurotransmission, resulting in epilepsy, intellectual disability and motor and behavioral impairments. In this case, the upregulation of the remaining functional *STXBP1* allele may be therapeutic. Since most human mRNAs are at least partly repressed by miRNAs, disrupting the interaction between miRNAs and *STXBP1* mRNA could upregulate STXBP1 expression. Here, we performed comprehensive *in silico* analyses and *in cellulo* miRNA sequencing to identify multiple miRNAs that are both predicted to bind to STXBP1-3'UTR and highly expressed in STXBP1 patient iPSC-neurons. Further, our CLIP-seq data from human brain tissue showed prominent binding of AGO2 to the same region of the STXBP1-3'UTR in which multiple miRNA candidates are predicted to bind, suggesting miRNA-mediated regulation of *STXBP1* mRNA in human brain. In STXBP1 patient iPSC-neurons, blocking miRNA candidates using antagomirs led to STXBP1 mRNA upregulation, thus identifying miRNAs that are repressing STXBP1 in the disease context. As a therapeutic approach, we designed Steric Blocking Oligonucleotides (SBOs) targeting candidate miRNA binding sites in STXBP1-3'UTR and screened them in NGN2-inducible neurons, identifying SBOs that increased STXBP1 mRNA abundance. Also, we showed that several "lead" SBOs were capable of augmenting STXBP1 mRNA abundance in a dose-dependent manner in STXBP1 patient iPSC-neurons, and demonstrated that these compounds act by specifically disrupting the binding of the candidate miRNAs to STXBP1-3'UTR. Finally, we have engineered and characterized the first STXBP1 humanized mouse model in which we replaced the mouse *Stxbp1 locus* with the entire human *STXBP1* gene. We are currently generating a STXBP1 humanized haploinsufficient mouse model, which represents an ideal platform for therapeutic testing and functional rescue assessment *in vivo*. Overall, these studies reveal several miRNA site-blocking oligonucleotides as promising therapeutic candidates for the treatment of STXBP1-related disorders.

336. Modulation of Somatic Repeat Expansion with Small Interfering RNAs

Jillian Belgrad[1], Daniel O'Reilly[1], Ellen Sapp[2], Ashley Summers[1], Eric Luu[1], Nozomi Yamada[1], Hassan Fakih[1], Raymond Furgal[1], Nicholas Gaston[1], Sarah Allen[1], Allison Maebius[1], Katherine Gross[1], Dimas Echeverria[1], Neil Aronin[1], Marian DiFiglia[2], Anastasia Khvorova[1]

[1]UMass Chan Medical School, Worcester, MA,[2]Massachusetts General Hospital, Mass General Institute for Neurodegenerative Disease (MIND), Charleston, MA

Huntington's disease (HD) is a neurodegenerative disorder affecting 7/100,000 people with no treatment available. HD is caused by CAG trinucleotide repeats in exon 1 of the huntingtin gene. Symptoms including chorea, hemiballism, and depression present at >37 CAG repeats, with the age of disease onset decreasing as CAG repeat length increases. The somatic CAG expansion in striatal medium spiny neurons primarily contributes to age-driven HD neurodegeneration. Human GWAS have associated multiple mismatch repair (MMR) pathway components in HD progression. MMR mediates the expansion of trinucleotide repeats by facilitating strand cleavage of slipped loop intermediates during transcription. Blockage of somatic expansion slows HD progression in mice. Thus, MMR-driven somatic expansion is a therapeutically targetable driver of HD. Potent and selective CNS RNAi is now possible with di-valent siRNA. Here, we have screened, identified, and validated potent siRNA silencing key MMR proteins. Using these di-valent siRNA, we performed a systematic evaluation of the impact of RNAi-based silencing of single MMR components on somatic repeat expansion *in vivo* in the Q111 mouse model of HD. We have so far identified that RNAi-based interventional lowering of MSH3, PMS1, and MLH1 each blocks somatic expansion. This work allows a mechanistic understanding of the key players facilitating somatic expansion in HD and represents a therapeutic category of repeat-expansion blocking agents. These siRNAs can be used alone or in combination to manipulate somatic expansion as a potential HD intervention. Further, the work presented here informs novel, RNAi-based treatment options for HD and similar trinucleotide repeat disorders.

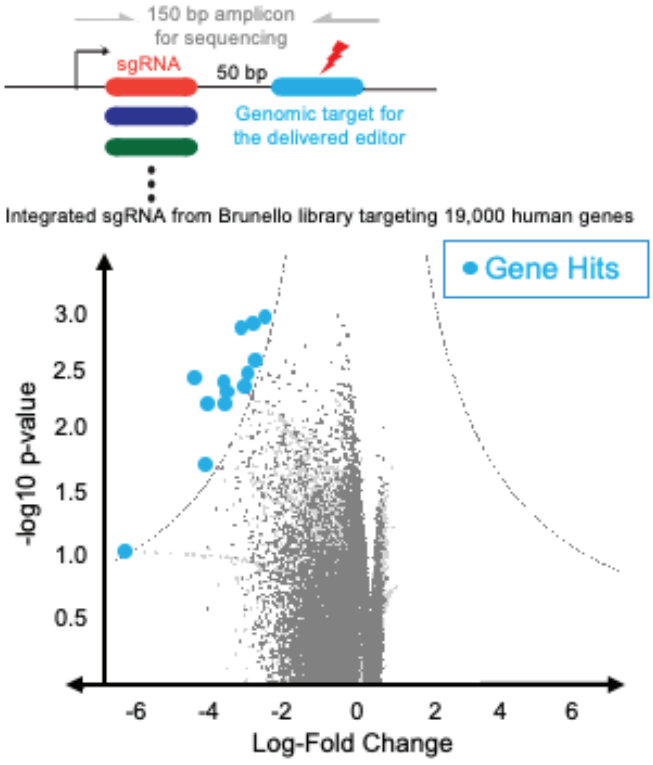
337. Therapeutic Oligonucleotides Induce Acute Toxicity in CNS, Preventable by the Addition of Divalent Cations to Formulation

Rachael Miller[1], Joseph Paquette[1], Dimas Echeverria-Moreno[1], Ken Yamada[1], Ellen Sapp[2], Nicholas McHugh[1], Brianna Bramato[1], Nazomi Yamada[1], Alexandra Barker[1], Julia Alterman[1], Christelle Anaclet[3], Marian DiFiglia[2], Anastasia Khvorova[1], Neil Aronin[1]

[1]UMass Chan Medical School, Worcester, MA,[2]Mass General Institute for Neurodegenerative Disease, Charlestown, MA,[3]University of California Davis, Davis, CA

Oligonucleotide therapeutics (ASOs and siRNAs) have become widely explored for the modulation of gene expression in the central nervous system (CNS). Huntington's Disease (HD), a neurodegenerative disorder caused by a dominant genetic mutation resulting in the production of toxic mRNA and protein, is an optimal target for oligonucleotide therapeutics. Previous studies show that intracerebroventricular (ICV) injections of siRNAs targeting huntingtin (HTT) protein effectively spread throughout small and large brains and reduce total HTT. Administration of highly concentrated compounds carrying a negative charge to the CNS can induce acute toxicity. We hypothesized that these negatively charged regions promote cation exchange, subsequently chelating divalent cations from the cerebral spinal fluid (CSF) and intracellular stores, which results in abnormal behavioral phenotypes. Electroencephalogram (EEG) and electromyography (EMG) electrophysiology studies in awake mice confirmed these behavioral observations were seizures. Additionally, *in vitro* ion chromatography studies revealed that each phosphodiester/phosphorothioate (PO/PS) in the oligonucleotide backbone has the capacity to bind divalent cations at molar equivalents. To alleviate this acute toxicity, we developed a method of buffering siRNAs with precise divalent cation concentrations in artificial CSF (aCSF) buffer prior to injection, to prevent this cation exchange and subsequent neurotoxic effects. Here, we demonstrate that adding divalent cations to the injected formulation can mitigate this type of toxicity in a dose-dependent fashion *in vivo*, without impacting distribution or efficacy. This new formulation enables the safe delivery of oligonucleotides at high doses directly into the CNS, which broadens the opportunities for treating patients with HD and other neurodegenerative diseases with these therapeutic modalities. The data presented here defines the

importance of evaluating the safety of therapeutic oligonucleotides for CNS administration and defines the path toward better clinical translation.



Nonviral Methods for Delivering Nucleic Acids

338. A Novel High-Throughput Screen to Identify Factors Controlling CRISPR-Mediated Non-Viral Genome Editing

Shivani Saxena[1], Min Zhu[2], Divya Sinha[2], Amr Abdeen[2], David Gamm[2], Shaoqin Gong[2], Marcela Martinez[2], Srikumar Sengupta[2], Krishanu Saha[2]

[1]University of Wisconsin-Madison, Middleton, WI,[2]University of Wisconsin-Madison, Madison, WI

Background: After administering a genome editor, the delivery of genome editors is limited by a multi-step process, involving cellular uptake, trafficking, and nuclear import of the vector and its payload. These processes vary widely across cell types and differ depending on the nature of the vector, whether it is a lipid nanoparticle or a different synthetic material. To better understand these delivery limitations within human cells, we developed a novel genome-wide CRISPR screening strategy to identify genes modulating cellular uptake and gene editing efficiency. **Methods:** Our assay interrogates the cellular processes controlling delivery and stimulating non-homologous end-joining (NHEJ) in human embryonic kidney (HEK293) cells. We transduced HEK293 with a pooled lentivirus sgRNA library comprising of 19,000 target genes (Brunello library), prior to delivering non-viral genome editors. Using a low multiplicity of infection, each of the 19,000 genes in the library was knocked out within a specific subset of cells, allowing us to test the influence of nearly every human gene in a single experiment. To facilitate screening, the lentiviral vector genomically integrated into HEK293 cells included the perturbation identifier (i.e., sgRNA sequences) and the target for NHEJ-based editing within a single PCR-based amplicon (*Figure*). We delivered Cas9 ribonucleoprotein (RNP) payloads using lipofectamine 2000, to generate double-stranded DNA break within the integrated screening vector (Figure A).Next, we performed next-generation sequencing to quantify indel frequency distribution and sgRNA identity within the same amplicon from genomic DNA collected from the perturbed cell population. The library was sequenced on Illumina NovaSeq 6000 system (paired-end 150 bp reads). Our coverage was >2000 reads per sgRNA in the library. **Results:** We used MAGeCK analysis to assign 'Phenotype,' defined as the enrichment of a particular sgRNA in an edited pool of reads. This enrichment phenotype is evidence that the activity of the corresponding gene suppresses NHEJ-mediated Cas9 editing. Based on this enrichment analysis (*Figure*), we identified 27 top genes involved in trafficking pathways that facilitate enhanced cellular uptake. Upon the knockout of these top genes, the NHEJ editing rate in HEK293 cells increased dramatically. Identified genes were further validated in separate arrayed screen experiments, successfully verifying the reproducibility of our novel screening technique. Knocking out the top hits uncovered in our screen led to a 10-fold increase) in the gene editing efficiency of Cas9 mRNA delivered via lipid-based nanoparticles (e.g., moving from 6% to 60% editing efficiency). Six of the genes also led to a 5-fold increase in Cas9 RNP editing efficiency using lipofectamine delivery. **Conclusion:** We report a novel genome-wide screen that examines the impact of 19,000 human genes on the delivery and outcomes of genome editors. Distinguished by its potential for large-scale screening, the screen allowed the genome-wide exploration of delivery mechanisms that can be further manipulated for efficient trafficking of CRISPR-Cas9 machinery. We anticipate this high-throughput technique could facilitate the systematic engineering of novel nonviral genome editing delivery strategies.

339. Development of Envelope NanoBodies for Guided *In Vivo* Cell Engineering

Jesus Beltran[1], Barbara S. Perez[1], Jonathan Gunn[1], Dan S. Kaufman[2]

[1]University of California, San Diego, San Diego, CA,[2]University of California - San Diego, La Jolla, CA

Cell and gene therapy technologies continue to rapidly advance. However, despite their exciting potential, most current therapies remain confined to *ex vivo* applications, grappling with challenges in achieving precise and efficient *in vivo* delivery. To address these challenges, we introduce Enveloped NanoBodies (ENaBs), an innovative genetic delivery platform designed for targeted and efficient *in vivo* cell engineering. ENaBs incorporate an engineered version of the GAG protein, complemented with an engineered version of baboon envelope fusogen and designed ankyrin repeat proteins (DARPins), to enable efficient and precisely targeted cellular delivery. We designed our ENaBs to carry cell-lineage specific mRNA-expressing chimeric

antigen receptors (CARs), tailored to each immune cell line, including T cells, NK cells and macrophages. When tested in human immune cells, ENaBs were able to specifically target each cell line of interest, reducing the number of bystander cells and reprograming the immune cells to target and kill ovarian cancer cells, increasing the killing capacity of T cells (from 15% to 80%) and NK cells (from 35% to 95%), as well as the phagocytic activity of macrophages (from 20% to 60%) *ex vivo*. When testing the ENaBs capacity to *in vivo* engineer human immune cells, a single injection of ENaBs generated high levels of *in vivo* engineered cells, ranging from 25% engineered T lymphocytes by anti-CD3 targeted ENaBs to 30% engineered NK cells using anti-NKp46 darpins and 40% engineered macrophages using anti-CD14 darpin-targeted ENaBs. Notably, naked ENaBs also engineered high levels of macrophages, achieving up to 45% cellular editing, likely due to the phagocytic activity of these cells. When analyzing the cellular specificity achieved by each class of ENaB *in vivo*, all of them showed enhanced levels of cellular specificity compared to naked ENaBs, reducing the cellular off-targets, and significantly increasing cellular engineering levels, particularly for NK cells. We then tested the ENaBs ability to *in vivo* reprogram endogenous immune cells to target and kill ovarian cancer tumors. Here, a single injection of each cell-specific targeted ENaB mediated improved anti-tumor activity compared to untreated (human PBMCs alone) mice. Interestingly, the mice treated with the macrophage-targeted ENaBs (CAR-Mac group) had the longest remissions, reducing the tumor mass by 97% at day 15 post-treatment (66% survival at day 60) compared to the untreated tumor group that had a median survival of 27 days. NK cell-targeted ENaB-treated mice also had improved anti-tumor activity with a median of survival of 56 days, reducing the tumor mass by 52% at day 15 post-treatment, and the T cell-targeted mice had a median of survival of 43 days, reducing the tumor mass 84% at day 15 post-treatment. These results demonstrate the ability of our novel ENaB system to mediate complex cell-engineering *in vivo*, reprograming different immune cells to specifically target and kill difficult to treat solid tumors. This new approach introduces an efficient and versatile modular platform that enables specific, targeted *in vivo* engineering of human cells for wide-ranging research and therapeutic applications.

340. An Optimized PBAE Nanoparticle Formulation Allows for Targeted Gene Delivery to the Lungs Following Systemic Injection

Erin Kavanagh[1], Stephany Tzeng[1], Anya Joynt[2], Gregory Newby[3], Neeraj Sharma[3], Garry Cutting[3], Jordan Green[1]

[1]Biomedical Engineering, Johns Hopkins School of Medicine, Baltimore, MD,[2]UMass Chan Medical School, Worcester, MA,[3]Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD

Current treatments for cystic fibrosis (CF) primarily focus on modulator drug therapies designed to correct malfunctioning CFTR protein. However, these modulators are ineffective for the 10% of CF individuals with variants that do not allow protein production. Gene editing of these variants would allow production of CFTR protein and restoration of function. Here, we demonstrate poly(β-amino ester) (PBAE) nanoparticle (NP) formulations allow for efficient delivery of GFP mRNA to primary human nasal epithelial (HNE) and bronchial epithelial (HBE) cells from healthy and CF individuals. Optimized PBAE endcap formulations systemically administered *in vivo* allow for high expression of fLuc mRNA within the lungs, with E63 demonstrating high levels of editing in an Ai9 reporter mouse model across bronchial, epithelial, and endothelial cell populations. Multiple administrations with and without a targeting ligand proved both efficacious and non-toxic. PBAEs were synthesized via Michael addition, fabricated into NPs by electrostatic self-assembly with mRNA, and evaluated for gene delivery by flow cytometry. mRNA-encoded GFP served as a reporter to evaluate transfection efficiency, cell viability and mean fluorescence intensity across 3 dosages (150, 75, 32.5 ng mRNA), 4 polymer-to-mRNA weight to weight ratios (60, 40, 30, 20) and 4 polymers. Primary HBE and HBE cells from CF and healthy donors were seeded in 96-well plates then transfected with NPs before undergoing microscopy and flow 24 hours post transfection. NPs carrying Cre mRNA were delivered intravenously to Ai9 mice at three intervals (1x, 3x, 9x). Lungs were dissociated and stained with antibodies before undergoing analysis. NPs achieved 80-90% GFP transfection in primary HNEs from a CF and healthy individual, with ~70% transfection of primary HBEs from a CF individual and ~50% transfection of those from a healthy donor (**Figure 1a**) at 32.5 and 72ng doses. Viability with these two doses was consistently between 70-85%. Systemic delivery to the Ai9 mouse model showed consistent increase in transfected cells across all lung cells as the number of injections increased, from 0.8 to 1.9 to 9% at 1x, 3x and 9x dosing respectively. Additionally, the number of epithelial cells transfected consistently increased across dosing, with the number of endothelial and epithelial transfected cells ranging from 15-40% and 15-30% respectively (**Figure 1b**). We hereby demonstrate systemic delivery of optimized PBAE NP formulation E63 allows for over 90% transfection rate in healthy primary HNEs *in vitro* while maintaining at least 75% viability. This same polymer achieves 20-30% transfection of epithelial and bronchial cells with systemic delivery in mice. *In vitro*, electroporation of modified CRISPR-Cas9 base editor mRNA to primary HNEs carrying 3120+1G>A/G480S achieves 81% correction of the 3120+1 G>A allele. This nonviral transfection results in CFTR function within or above the range of WT values observed in WT HNEs. This gene editing approach is promising for new, durable CF treatment. In ongoing work, we are investigating targeted cell types during *in vivo* delivery to a CF mouse model.

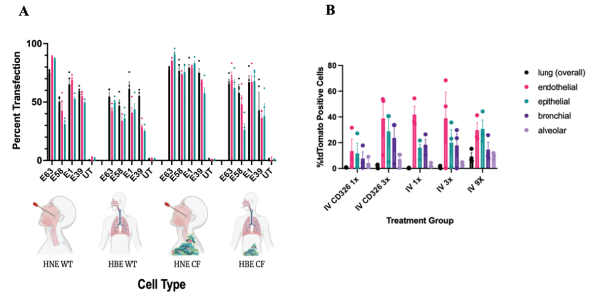


Figure 1: (A) Representative GFP transfection from PBAE NPs screens in primary HBE and HNEs from WT, CF individuals across 4 polymers and 3 dosages at a 30 weight-to-weight ratio. Data shown as mean ± SEM (N=4 biological replicates). **(B)** Flow cytometry in Ai9 mice after systemic delivery of 5 μg Cre mRNA with or without a targeting ligand (CD326) and number of injections (1x, 3x, 9x) displaying relevant tdTomato+ lung cell types.

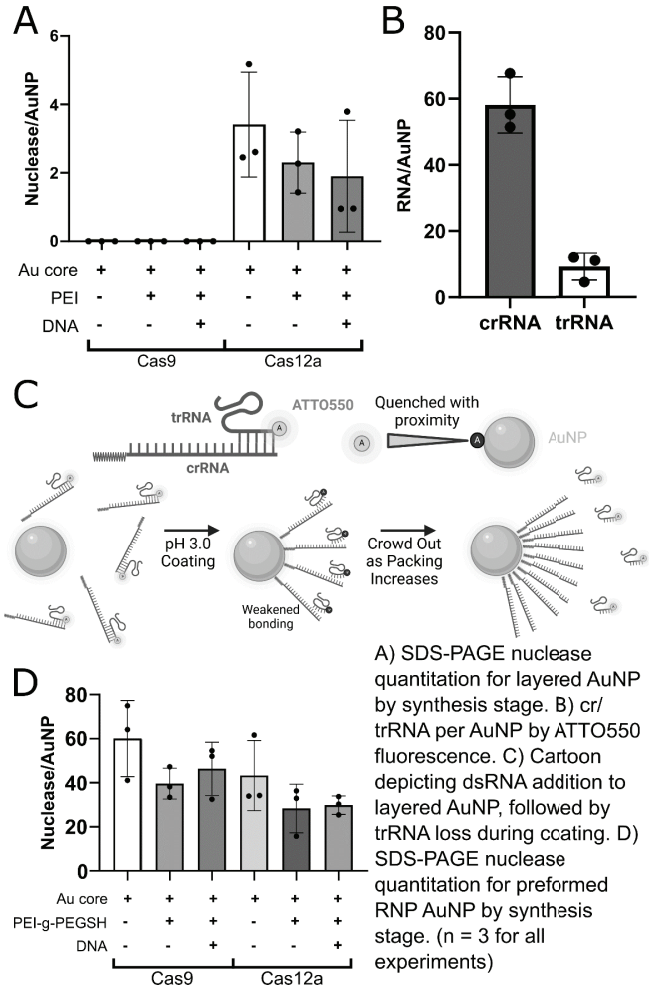
341. High-Throughput Screening Platform Identifies Nanoparticles Capable of Delivering 19.5 kbp Plasmid to Neuronal Cells *In Vitro* and *In Vivo*

Cherry Gupta[1], Ashlee Colbert[1], Caleb Hillrich[1], Emma Schmitz[1], Molly Kaufman[1], Allison Secard[1], Bradley William[2], Hui Liu[2], Deeann Wallis[2], Robert Kesterson[3], Andrea McCue[1], Michael Riedl[1], Danielle Huk[1], Smith Brian[1], Joanna Hoy[1], Miguel Pedrozo[1], Nick Andrioff[1]

[1]Battelle, Columbus, OH,[2]University of Alabama, Birmingham, AL,[3]Pennington Biomedical Research Center, Baton Rouge, LA

Reconstituting functional proteins via exogenous cDNA delivery to treat genetic diseases such as Neurofibromatosis 1 (NF-1) presents a promising treatment modality which, due to its wide applicability, has high potential for near-term clinical translation. This is currently blocked because of the lack of suitable delivery vectors that can encapsulate the large NF1 cDNA. To overcome these challenges, we used self-assembled cationic polymeric nanoparticles (PNP) to encapsulate and deliver a *hNF1* plasmid (19.5 kbp). *Polymer synthesis and characterization*: Diblock copolymers were synthesized using reversible addition-fragmentation chain-transfer (RAFT) polymerization process, self-assembled into cationic PNPs and functionalized with different targeting groups. The resultant library of ~500 PNPs was tagged with unique DNA barcodes to enable high-throughput *in vivo* screening and loaded with the *hNF1* plasmid (19.5 kbp). The loaded PNPs were tested *in vitro* in the hTERT NF1 -/-(null) ipNF97.4 SC line (derived from parental NF1 +/+ (wildtype) SC line ipNF97.4). Plasmid loading efficiency was characterized using a RiboGreen dye exclusion assay, transfection efficiency (TE) was quantified by flow cytometry, and cytotoxicity was quantified using a live-dead stain. Our results demonstrate that a subset of the PNP library demonstrated high DNA encapsulation and ability to transfect the SCs better than the rest. The cell viability was >80% for all tested PNPs. In parallel, >250 of these barcode tagged PNPs were pooled together and tested for bio-distribution in wild-type mice via intracerebroventricular injection (ICV) injections. DNA barcodes were extracted, sequenced, and analyzed to assess relative tissue specific PNP abundance. Multiple DNA barcodes corresponding to unique PNPs were found to be significantly enriched in the brain and one barcode was found to be significantly enriched in the sciatic nerve. This early parallel screening is unique to our approach and tailored to eliminate the risk of having delivery vectors that work *in vitro* but not *in vivo*. Further, the combinatorial high-throughput platform used here increased the probability of quickly finding potential candidates thereby reducing the risk of failure inherent in a rational design approach. *These results provide a basis for future optimization of these delivery vehicles that can transfect this challenging cell target. PNP mediated delivery and expression of NF1 protein***.** Based on the high-throughput screenings described above, 19 PNPs were down-selected and tested in hTERT NF1 SCs (97.4 NF1 -/-) and MCF7 NF1 -/- mammary epithelial breast cancer cells. Preliminary data indicates that PNP mediated delivery of the *hNF1* results in detectable NF1 protein expression in both cell lines. *PNP mediated delivery and expression in mouse and rat cortex***:** A single PNP, selected based on TE was loaded with the *hNF1* minigene plasmid and dosed in wild-type mice via ICV injection. No adverse toxicity related events were observed. Enhanced GFP fluorescence was observed in the mouse cortex. The same plasmid-loaded PNP was then administered to wild-type Sprague Dawley rats via ICV injection to assess repeatability and investigate cell-specific expression. Multiple GFP positive neural cells were seen in cortex, but no GFP positive astrocytes were detected. These results are the *first ever demonstration of delivering the large 19.5 kbp hNF1 minigene plasmid in vivo and point to an exciting discovery for non-viral gene delivery to neuronal cells.*



342. Mechanistic Investigation of Cas9 Affinity for CRISPR-AuNP Utilizing Direct RNA Surface Assembly

Daniel D. Lane, Karthikeya Gottimukkala, Rachel Cunningham, Youngseo Jwa, Molly Ellena Cassidy, Jennifer E. Adair

Fred Hutchinson Cancer Center, Seattle, WA

State of the art for hematopoietic stem cell (HSC) genetic editing (GE) occurs *ex vivo,* requiring advanced facilities with treatment costs in the millions (e.g. $2.2 million for Casgevy). A reduction in cost and equipment is essential to global dissemination of GE therapy. We previously described a layered nanoformulation to deliver CRISPR *in vitro* without electroporation (CRISPR-AuNP)[1] to reduce cost of therapy, among other advantages. Formulating CRISPR-AuNP with Cas12a and Cas9 ribonucleoproteins (RNP) resulted in *in vitro* HSC GE levels of 7.65% and 10.42%, respectively, by TIDE. While CRISPR-AuNP showed matching Cas12a/9 GE levels, RNP electroporation shows clear advantages for Cas9, with higher indel formation (47.6%) vs Cas12a (15.18%) at the B2M locus by Miseq (guides cut within 2 bp). This resulted in B2M surface expression knockdown of 10% (Cas 9) vs 0.24% (Cas12a) (5 guides, n = 3), by flow cytometry. Consensus comparing Cas12a/9 matches this conclusion, so we believed the lower Cas9 activity was structural to the AuNP. Investigation of protein binding by SDS-PAGE, after stripping all non-covalent nuclease-Au interactions, found that Cas9 binding was undetectable and Cas12a bound 4 RNP complexes per AuNP. Furthermore, DNA cutting activity of Cas9 CRISPR-AuNP was undetectable while Cas12a CRISPR-AuNP showed substantial activity after β-mercaptoethanol (BME) release from the Au surface. As CRISPR-AuNPs are stabilized through Au-thiolated gRNA interactions, we first tested whether gRNA differences between Cas12a/9 alters binding. Cas9 gRNA consists of two separate, complementary RNA components (crRNA/trRNA) that are duplexed (dsRNA) to become active, with only the crRNA containing the anchor thiol. Cas12a consists of a single thiolated gRNA. dsRNA of Cas9 relies on 10 complementary base pairs, resulting in low coordination energy (melting temperature = 27 °C). Using labeled trRNA, we found 10 trRNA molecules retained on the AuNP, vs 60 crRNA-thiol after dsRNA loading. Kinetic fluorescent recovery shows Cas9 dsRNA to be poorly stable, with buffer conditions alone driving 100% loss of bound trRNA within 12 hrs, compared to a <1% loss of Cas12a's gRNA. To increase active RNP attachment, we loaded preformed Cas9 RNP onto the Au surface, with the protein interaction stabilizing the dsRNA. We investigated RNP cutting activity at differing loading pHs, showing an IC50 of 3.01± 0.03 for Cas12a and 3.23 ± 0.10 for Cas9. At the pH without decrease in Cas9 cutting activity, the nuclease loading increased to 60 RNP/AuNP for Cas9 and 43 RNP for Cas12a, with confirmed cutting activity after stripping non-covalent interactions by dialysis. This AuNP formulation has reduced charge density and requires an

alteration of the polymer coating. The ideal endosomal escape polymer identified for nanoparticle stability includes a thiol anchor to covalently attach to the AuNP (PEI-g-PEG-SH), overcoming the reduced charge's decreased polymer affinity. However, confocal microscopy revealed endosomal entrapment of these 2nd generation CRISPR-AuNP in K562 endosomes, suggesting polymer optimization is required to achieve GE activity in living cells. Future studies in primary HSC and other cell types will permit fine tuning of nanoparticle characteristics to achieve the desired GE which the increased RNP loading will allow.

343. Peptide-Based Nanoplatform for Cas9 RNP Delivery and Gene Editing

Joseph V. Lavalla[1], Alyson Schwartz[1], Audrey Wessinger[1], Jessica Larsen[2], Angela Alexander-Bryant[1]
[1]Bioengineering, Clemson University, Clemson, SC,[2]Chemical Engineering, Clemson University, Clemson, SC

Introduction: Gene editing using CRISPR/Cas9 for the treatment of genetic diseases has rapidly advanced to become an integral part of the biotechnology field over the past decade. Delivering Cas9 via RNPs has demonstrated higher editing efficiencies and lower off-target effects than either plasmids or mRNA. However, due to their xenogeneic nature and charge properties, RNPs alone cannot be internalized into cells and require a delivery vehicle. Viruses, lipids, and polymers have been used as vehicles for Cas9 RNPs, though limitations of safety and efficiency in delivering the gene-editing cargo into cells have posed a large hurdle to overcome. Peptides have emerged as a promising alternative for transporting bioactive nucleic acids into cells due to their high tunability, stability, and biocompatibility. We have previously demonstrated that a novel fusogenic peptide, DIV3W, can electrostatically complex with and protect RNA, is cytocompatible, and mediates efficient endosomal escape of bioactive RNAs. This proof-of-concept study aims to evaluate the DIV3W peptide for delivery of RNPs to induce efficient gene knockout. **Methods:** RNP:DIV3W complexes were synthesized by combining gRNA and Cas9 at equimolar ratios, followed by complexation with various molar concentrations of DIV3W peptide. Complexation of the RNP with the DIV3W peptide was analyzed using agarose gel electrophoresis. To assess the cytocompatibility of the RNP:peptide complexes, RNP:DIV3W complexes were synthesized and incubated with HEK293 cells at increasing molar ratio complexes for 48 hours, followed by an MTS assay to determine RNP:peptide cytotoxicity. RNP:DIV3W complexes were additionally delivered to HEK293-GFP cells to knockout GFP expression. Changes in fluorescence after 96 hours were analyzed using flow cytometry. **Results and Discussion:** We previously observed that molar ratios greater than 1:1:20 (Cas9:gRNA:DIV3W) resulted in the complete complexation of RNPs and, therefore, a successful delivery vehicle capable of protecting the RNP from premature degradation. MTS results confirmed RNP:DIV3W complexes were not cytotoxic to HEK293 cells, with viability greater than 90% for molar ratios up to 1:1:80 (Figure 1). Preliminary knockout studies have demonstrated successful GFP editing, with up to 33% knockout after RNP:DIV3W treatment (Figure 2). **Conclusion:** The DIV3W peptide can self-assemble with and completely complex free RNPs and are cytocompatible with HEK293 cells. The RNP:DIV3W complexes can escape the endosome prior to lysosomal degradation and traverse the nuclear membrane, as shown through successful gene editions. These results demonstrate the early potential of peptide-based delivery systems for Cas9 RNPs and warrant further investigation. Future work of this project includes characterization of the size and charge of the RNP:DIV3W complexes, evaluation of cellular internalization, and quantification of indel mutations.

344. Novel Non-Viral Delivery Vehicles That Distribute to the Sciatic Nerve and Brain Identified via Iterative Design-Build-Test-Learn Polymer Nanoparticle Discovery Platform

Kenneth R. Sims[1], Emma Schmitz[1], Caleb Hillrich[1], Ashlee Colbert[1], Michael Riedl[2], Andrew Matas[2], Adele Guglielmi[3], Kyle D. Fink[4], David J. Segal[5], Danielle Huk[6]

[1]Advanced Materials and Energetics, Battelle Memorial Institute, Columbus, OH,[2]Health Analytics, Battelle Memorial Institute, Columbus, OH,[3]Biological Chemistry and Molecular Medicine, University of California, Davis, Davis, CA,[4]UC Davis, Sacramento, CA,[5]UC Davis Genome Center, Davis, CA,[6]Drug Development and Precision Diagnostics, Battelle Memorial Institute, Columbus, OH

Introduction & Methods: Nervous system delivery remains a key challenge for gene therapy. To overcome this challenge, a proprietary design-build-test-learn (DBTL) polymer nanoparticle (PNP) discovery platform was used to make and test novel PNP designs *in vitro* and *in vivo*. PNPs were synthesized via reversible addition-fragmentation chain transfer polymerization, purified, and characterized for size, polydispersity, loading efficiency, cytotoxicity, and transfection efficiency. In parallel, proprietary nucleic acid barcoding technology was used to evaluate PNP biodistribution in C57BL/6 wild type (WT) mice. After two DBTL cycle iterations, new, non-intuitive PNP designs capable of distributing to the brain and sciatic nerve following intrathecal administration were identified. *Results*: Previous biodistribution screening of >1,000 PNPs revealed a few PNPs that distributed well within mice. In parallel, *in vitro* results revealed that 5 of 10 top PNPs out of the >100 PNPs that showed high cell viability and transfection efficiency in HEK cells were from the same polymer compositional family as the well distributed PNPs found in the biodistribution study. Altogether, these top PNPs from early *in vitro* and *in vivo* testing came from a single polymer compositional family "design box." These initial results provided key insights to non-intuitive polymer composition designs that warranted further investigation as part of a second DBTL cycle. Thus, a second polymer library focused on these design box parameters associated were synthesized, characterized, and tested *in vitro* and *in vivo*. The second DBTL cycle produced >500 PNPs, and 96 of them were focused on further interrogating the previously identified design box while the others included slight polymer composition modifications. These PNPs were evaluated *in vitro* for size, loading efficiency, immunogenicity, cytotoxicity, and transfection efficiency. In parallel, these PNPs were DNA barcoded, pooled, and injected intrathecally into WT mice to evaluate PNP biodistribution performance *in vivo*. Biodistribution test results revealed several PNPs with elevated accumulation levels in sciatic nerve and brain tissue. The PNP design parameters were compared back to the initial library design using both human intuition and machine learning (ML) to determine if any useful patterns emerged. Indeed, a clear trend was found where lead PNP candidates that distributed to the sciatic nerve and brain were clustered together within an even smaller design box. Moreover, the PNP molecular weight and size data within this design box fell outside of typical, intuitive rational PNP design criteria, so it is unlikely they would have been discovered using traditional non-viral delivery field dogma. *Conclusions*: These iterative DBTL studies have leveraged key elements of a proprietary DBTL platform, namely rapid PNP production and testing followed

by ML guidance, to dial in on a PNP design space with potential to produce lead candidate non-viral delivery vehicles capable of delivering to sciatic nerve and/or brain tissue. Future DBTL cycles will further refine the polymer design parameters within the design box of interest to identify if any new designs may enhance delivery to the brain and/or sciatic nerve tissues in mice. Ultimately, this work informs future non-viral delivery vehicle designs to deliver to the central and peripheral nervous systems.

AAV Vector Integration

345. The Genomic Architecture of 24 Carcinogenic rAAV Integrations in Mice: Implications for Human Gene Therapy

Randy J. Chandler[1], Eli J. Kaufman[2], NIH Intramural Sequencing Center (NISC)[3], Paul N. Valdmanis[2], Charles P. Venditti[1]

[1]Metabolic Medicine Branch, National Human Genome Institute, NIH, Bethesda, MD,[2]Division of Medical Genetics, School of Medicine, University of Washington, Seattle, WA,[3]Comparative Sequencing Program, NIH, Bethesda, MD

Background: Hepatocellular carcinoma (HCC) in mice exposed to recombinant adeno-associated viral (rAAV) vectors was first reported over 20 years ago. More recent reports of an association between human HCCs and wildtype AAV infections, rAAV integrations with clonal expansion in hemophilic dogs, and the formation of an HCC in patient following rAAV treatment for hemophilia continues to raise concerns about the possibility of rAAV integrations causing insertional mutagenesis in humans. Elucidating the mechanisms by which rAAV causes HCC in mice after integration will provide critical insights that might help mitigate potential toxicity after AAV gene therapy in humans. However, the complete genomic characterization of AAV associated HCCs has been limited to the capture of a single ITR junction, with PCR based genomic walking across integrations attempted by several groups in the past without success. Using a combination of sequencing approaches, we have performed the first, and most comprehensive, analysis of toxic rAAV integrations associated with HCC formation in a large cohort of mice. **Methods:** We used LAM PCR, locus specific amplification, Sanger sequencing, and 2 distinct linked-reads platforms and a long-read sequencing platform (10x Genomics, TELL-Seq and Oxford Nanopore) to study HCCs from a historic cohort of 33 MMA mice and unaffected control littermates treated with a variety of single stranded therapeutic and reporter AAV vectors (R. Chandler JCI 2015, PMCID:4319425). A subset of integrations obtained by linked- and long-read sequencing platforms were validated by Sanger sequencing. **Results:** We detected rAAV sequence in 24 murine HCCs: 17 captured the entire integration and 7 captured partial rAAV integrations. All 24 rAAV integrations mapped to the Rian locus. The 17 rAAV integration events completely sequenced ranged in size from 255 to 4,535 base pairs; 15 contained truncated AAV genomes less than 1.3 kilobases in size. Only 3 of the integrations contained the transgene coding sequence with 2 of these events having a majority of the packaged rAAV genome intact. ITRs were recovered in all but 2 integrations and the ITRs were substantially rearranged. One rAAV integration contained the origin of replication (ori) from the plasmid used to package the AAV in cis with a truncated vector genome. Common elements to all 24 AAV integrations included AAV enhancers and/or transgene promoters. **Conclusions:** The genomic architecture of pathogenic events reveals that all contain transcriptional transactivating elements with some as small as ~ 250 base pairs. Concatemers that underwent intramolecular recombination and subsequent deletion are predicted as the in vivo precursor(s) of some integrations, and the identification of an event that contains a reverse packaged vector plasmid *ori* suggest that future studies should focus on longitudinal assessment of integration events in animal models, with an expansion to query all elements of plasmids used to produce AAV as possible candidates for unwanted integration. Lastly, our data support a model where vector mediated enhancer insertion, with subsequent dysregulated transcription mediated by transgene encoded regulatory elements, appears to be the mechanism underlying tumorigenesis after AAV integration. In aggregate, our study helps define the approaches needed to assess AAV integration, supports a mechanism(s) by which rAAV can contribute to tumorigenesis, and should help inform the design of safe vectors for human gene therapy.

346. Comprehensive Preclinical Integration Site Analyses of SPK-3006, a Liver-Mediated AAV Gene Therapy for Pompe Disease Reveals a Low Theoretical Risk for Insertional Mutagenesis

Ali Nowrouzi[1], Daniela Cesana[2], Matthew Jennis[3], Valeriya Posternak-Ball[3], Francis Pankowicz[3], Carlo Cipriani[2], Laura Rudilosso[2], John Everett[4], Aoife Roche[4], Chao Di[1], Pichai Raman[1], Zhenming Yu[1], Ype P de Jong[5], Frederic D. Bushman[4], Federico Mingozzi[6], Eugenio Montini[2], Meena Jain[7], Michael Olaopa[3], Kathila Alatsis[8], Mehdi Sarmady[1], Christopher R. Riling[3]

[1]Genomic and Data Sciences, Spark Therapeutics Inc, Philadelphia, PA,[2]San Raffaele Telethon Institute for GT (Sr-Tiget), IRCCS San Raffaele Scientific Institute, Milan, I, Milan, Italy,[3]Systemic Gene Therapy, Spark Therapeutics Inc, Philadelphia, PA,[4]Department of Microbiology, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA,[5]Division of Gastroenterology and Hepatology, Weill Cornell Medical College, New York, NY,[6]Former employee, Spark Therapeutics Inc, Paris, France,[7]Clinical Development, Spark Therapeutics Inc, Philadelphia, PA,[8]Toxicology and Pharmacology, Spark Therapeutics Inc, Philadelphia, PA

Adeno-associated virus (AAV) gene therapy for Pompe disease marks an innovative approach to treating this rare genetic disorder caused by a deficiency of acid alpha-glucosidase (GAA). In contrast to the current enzyme replacement therapy (ERT), with its patient burden for lifelong treatments and potential development of neutralizing antibodies, AAV presents a promising alternative. Recent preclinical studies with our clinical candidate SPK-3006 demonstrated the efficacy of AAV-mediated hepatic GAA expression in animal models. The therapy demonstrated enhanced pharmacokinetics and greater enzyme uptake in relevant tissues compared to ERT. To balance the therapeutic benefits of AAV-based gene therapy with long term safety, addressing concerns regarding AAV integration into hepatocyte genomes is essential.

Such integration poses potential risks, including the development of hepatocellular carcinomas (HCCs) through insertional mutagenesis. To assess the genotoxic safety of AAV-based gene therapy for Pompe disease, a comprehensive analysis of over 8000 integration sites was conducted in non-human primates (NHPs) and in primary human hepatocytes engrafted in a liver chimeric humanized mouse model treated with SPK-3006 at various doses. A low and dose-dependent integration frequency of SPK-3006, calculated as retrieved integration events per haploid genome, was observed ranging between 2.8 and 5.8 x 10^{-4} in NHPs and 3.3 x 10^{-4} and 1 x 10^{-3} in the liver chimeric humanized mouse model. These integrations exhibited typical intragenic preferences common for AAV vectors, with no observed enrichment in cancer genes or regulatory regions of cancer genes with increasing doses of hepatic AAV transduction. Long-term follow-up studies in NHPs showed no signs of integration-driven clonal expansions or pathological findings in the liver. Preliminary analyses of cell-free DNA from NHP plasma confirmed detectable SPK-3006 integration sites, warranting further development of this method as a potential minimally invasive approach for monitoring AAV integration sites *in vivo* AAV-mediated gene therapies. In conclusion, the SPK-3006 AAV candidate for Pompe disease treatment chromosomally integrates at a low frequency comparable to reported AAV vectors. Importantly, there are no abnormal preferences for integration near cancer genes, supporting a low theoretical risk of SPK-3006 for insertional mutagenesis mediated induction of HCCs in patients. This work further expands our understanding of AAV integration of a liver tropic capsid in primary NHPs and human hepatocytes, serving as a resource for future AAV integration related studies in preclinical models.

347. Predicting Truncation Events in AAV Vector Genome Designs Using Deep Learning

Sandhiya Ravi[1,2], Mitchell Yip[1], Ngoc Tam Tran[1,2], Suk Namkung[1], Guangping Gao[1,2], Phillip Wl Tai[1,2]

[1]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[2]Department of Microbiology and Physiological Systems, UMass Chan Medical School, Worcester, MA

The presence of truncated genomes found in recombinant adeno-associated virus (rAAV) vector preparations can have significant impact on the effectiveness of gene therapy treatments that are based on these biodrugs. The packaging of truncated genomes is known to be caused by template-switching events centered on inverted repeats and sequences with high GC content. Importantly, they may result in the production of non-functional vectors with unknown consequences. The propensity of some vector design elements to drive the formation of truncated genomes is not completely known and can vary from batch-to-batch. Therefore, the ability to predict truncation hotspots in AAV vector designs is crucial for developing future vectors. In this study, we aimed to use deep learning (DL) to identify truncation events in AAV vector genome designs, *de novo*. We have accumulated multiple datasets related to the detection of truncated genomes from previous and ongoing studies that profile vector genome heterogeneity in packaged rAAVs using single molecule, real-time (SMRT) and nanopore sequencing technologies. Additionally, recognizing the intricate variability in AAV vector design, our study encompasses an extensive diversity of design features including different promoters, transgenes, single-stranded (ss) versus self-complementary (sc) configurations, diverse capsid types, and various preparation methods. We hypothesized that using a large dataset of detected truncation events found among a diversity of rAAV designs to train a DL model, we can develop an accurate truncation hotspot prediction algorithm. We have defined as features across the training data, the relative positions of the truncation events and truncation abundances centered at 200-nt sliding windows. Using this metadata, we trained a combination of convolutional neural network (CNN) and bi-directional long short-term memory (LSTM) models to predict truncation events. The model is designed to classify whether a sequence will house a truncation hotspot and predict the "strength" of the truncation. The model incorporates both regression and classification components and achieved remarkable classification accuracy (98%). Crucially, the algorithm can accurately predict truncations in vector designs tested thus far. This study illustrates the potential for DL models to predict genome truncations in rAAVs. These advancements will not only aid in designing more effective gene therapy vectors, but also deepen our understanding of AAV's biophysical properties. G.G. and P.T. are corresponding authors.

348. Characterization of AAV Vectors in Tissues Transduced with Conventional and Novel ITRs Show Differences in ITR Recombination, Episome Structures, and Transgene Expression

Suk Namkung[1], Elisabet Mandon[1,2], Jialing Yang Liang[1], Fang Zhang[1], Mitchell Yip[1], Tapan Sharma[1], Jackson McGowan[1], Sophia Liu[1], Thomas Leland[1], Mengtian Cui[3], Dan Wang[1,2], Phillip Tai[1], Guangping Gao[1]

[1]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[2]RNA Therapeutics Institute, UMass Chan Medical School, Worcester, MA,[3]Horae Gene Therapy Center, Umass Medical School, Worcester, MA

The inverted terminal repeat (ITR) sequences that were originally isolated from the genomic termini of adeno-associated virus serotype 2 (AAV2) have been obligatory for producing recombinant (r)AAVs. The ITRs are also essential for driving intramolecular recombination to form stable circular episomes in the host cell. It has been reported that ITRs contribute to transgene expression via their promoter-like activities. However, the consequences of vector genome circularization on transgene expression have not been extensively explored. We serendipitously found a vector design that when transduced into mouse livers, showed a complete lack of transgene expression. Through Hirt DNA extractions and nanopore sequencing of episomal vector species in transduced tissues, we revealed that the episomes completely lacked the ITRs. Some species even included deletions of transgene segments. AAV-GPseq of the vector preparation showed that the vectors were intact and homogenous, suggesting that the lack of ITRs in episomes extracted from transduced tissues were not due to truncations found in vector preparations. We hypothesize that recombination to form episomes is error prone and stochastic. This premise offers another facet to poor transduction seen in certain vector designs. To understand how transgene expression is impacted by ITRs post-circularization, we are developing a novel platform that permits the examination of different episomal forms (*e.g.,* monomers, dimers/concatemers), and the characterization of ITR structures post-transduction. Using third-

generation, single molecule, real-time (SMRT) sequencing, this study aims to reveal, 1) the fate of ITRs post-transduction and circularization, and 2) outcomes of recombination between ITRs of different AAV serotypes that yield distinct transgene expression profiles. This work also uncovers concepts that contrasts with common knowledge regarding the retention and conformation of ITRs post-transduction *in vivo*. These results shed light on an unexplored property of vector genome processing and has paradigm-shifting impact for AAV vector biology and the field of gene therapy. In addition, our findings open the door to new avenues of research aimed at improving the transgene expression and stability of rAAV episomes in order to increase the efficacy of rAAV-based gene therapies. G.G. and P.T. are corresponding authors

349. *In Silico* Reconstruction of Genotoxic AAV Integration Events from a Tiling Array Dataset: Proof of Concept and Validation

Tyra G. Wolfsberg[1], Stephanie N. Smith[1], Sumeeta Singh[1], Mark S. Sands[2], Charles P. Venditti[1]

[1]NIH/NHGRI, Bethesda, MD,[2]Washington University School of Medicine, St Louis, MO

Introduction: Prior studies have established that genotoxic vector integrations into the mouse *Rian* locus are associated with hepatocellular carcinoma (HCC) following systemic administration of AAV vectors. The Twitcher (Twi) mouse, a model of Krabbe disease, is deficient in galactosylceramidase (GALC) activity. While CNS-directed AAV2/9-GALC-mediated gene therapy combined with bone marrow transplantation and a substrate reduction drug results in an impressive increase in the lifespan from ~ 110 days to ~ 400 days, >90% of the Twi mice, as well as 100% of the wild type controls, succumb to HCC (PMC7854295). HCC has never been reported in untreated Twi mice. A targeted sequence capture analysis using a tiling array with probes specific for the AAV vector was used to map ITR-containing integrations in or near *Rian*, or other cancer- and cell-growth/death-associated genes, in the HCCs. However, the integrations were not further characterized. Indeed, although several groups have attempted to use targeted PCR and chromosomal walking to recover the full length nucleotide sequence of the genotoxic events in other AAV-associated HCCs, the structure of the integrated vectors has remained elusive. **Methods:** We developed a bioinformatics method designated as AVITA (Assembly of Viral Integrations from Tiling Arrays) to mine tiling array sequence data to reconstruct full length integrations. The first step in AVITA uses the VSeq-Toolkit (PMC7177155) to identify chimeric sequencing reads, i.e., those that span the vector-genome breakpoint at any position in the vector. A pileup of independent reads, aligning to the same vector and genomic coordinates, flags a potential integration junction. Two pileups at nearby genomic regions define the ends of candidate integration sites. The second step assembles overlapping reads from one genome-vector integration junction, through the vector, to the mate vector-genome integration at a nearby genomic position, allowing full length reconstruction of the inserted sequence. One of these complete integrations was selected for validation by locus-specific PCR and Sanger sequencing. **Results:** To test the method, captured sequencing reads from 4 of 10 tumors (PMC7854295) were examined in detail. Each tumor contained two high read count genome-vector breakpoints, which delineated the ends of an integration site. The four integration events, which range in length from 444 - 1326 nt, were fully reconstructed *in silico*. All lack the GALC cDNA, have a single truncated 5' ITR, and contain parts of the enhancer/promoter of the AAV vector transgene. One full-length integration event was confirmed by PCR amplification of genomic DNA, followed by Sanger sequencing. The integration disrupts 12 nt in the mouse *Rian* locus and contains a 444 nt insertion of AAV vector DNA that includes the final 76 nt of the 5' ITR followed by the CMV enhancer. **Conclusions:** Using AVITA, we demonstrate, for the first time, that genotoxic full-length AAV integrations can be fully recovered from a tiling array using an *in silico* approach. Because tiling arrays can capture partial and/or rearranged integrations, hybridization approaches present a less biased method to identify integration events than LM-PCR, which relies upon anchoring amplification in the ITR. Indeed, in 2 of the 4 samples analyzed here, the AAV vector is rearranged and/or the ITR is truncated, both of which would likely preclude capture by LM-PCR. We anticipate applying AVITA to sequence data from all publicly available tiling array datasets to assess global patterns of AAV integration. Enhancements to automate AVITA, coupled with improvements to tiling array performance, might enable AAV integration studies to be conducted in a multiplexed fashion, and amenable to broad implementation.

350. Characterization of AAV Integrations in Preclinical Models of Gene Therapy Using RAAVioli Pipeline with Long and Short Sequencing Reads

Carlo Cipriani[1,2], Laura Rudilosso[1], Giulio Spinozzi[1], Dhwanil Dalwadi[3], Markus Grompe[3], Giuseppe Ronzitti[4], Marco Masseroli[2], Eugenio Montini[1], Andrea Calabria[1], Daniela Cesana[1]

[1]San Raffaele Telethon Institute for Gene Therapy (SR-Tiget), IRCCS San Raffaele Scientific Institute, Milan, Italy,[2]Department of Electronics, Information and Bioengineering, Politecnico Di Milano, Milan, Italy,[3]Papé Family Pediatric Research Institute, Department of Pediatrics, Oregon Health and Science University, Portland, OR,[4]Genethon, Inserm, Univ Evry, Université Paris-Saclay, Evry, France

Adeno Associated Viral vectors (AAVs) have been successfully exploited in gene therapy (GT) applications for the treatment of several genetic disorders. Even though they are considered episomal vectors, it has been shown that fragmented or full-length AAV DNA can integrate within the genome of host cells leading to hepatocellular carcinoma and clonal expansion events in some preclinical models. However, methods and bioinformatic tools that provide a reliable and efficient assessment of AAV integration sites (IS) are required. Here we propose a sonication-based PCR approach combined with short-read sequencing and a bioinformatics pipeline known as RAAVIoli (Recombinant Adeno-Associated Viral Integration analysis) as a new approach to identify and characterize AAV IS and vector rearrangements. The pipeline is based on Python and R scripts that parse the alignments to identify IS and reconstruct vector rearrangements using CIGAR strings. The robustness of our method was evaluated by characterizing AAV IS in a humanized liver mouse model where human primary hepatocytes were transduced with a tomato-expressing AAV. In this model vector insertions were previously characterized using an AAV-specific probe base selection method and

long-reads PacBio sequencing. Sequencing reads were analyzed in both cases using the same RAAVioli pipeline. A greater number of AAV IS were identified by PCR/short-read sequencing (N=811) as compared to the long-read sequence approach (N=370). AAV IS distributed similarly within the human genome showing the typical preference of targeting CpG islands and transcriptional start sites. Moreover, 32 IS were shared among the two datasets, demonstrating the consistency of the results obtained independently from the platform adopted. A comparable number of AAV IS (~25%) were composed of rearranged AAV genomes, although, a higher number of vector re-arrangements (up to 7 AAV fragments) were identified by long-read compared to short-read sequences. Therefore, our PCR-based method produced comparable findings to long-read sequencing approaches regarding the pattern and structure of AAV integration and rearrangements. Nevertheless, it demonstrates significantly greater efficiency in retrieving AAV insertion sites. Thanks to this platform, we observed that in functionally corrected T cells of immune-deficient ZAP70 knock-out mice intra-thymically injected with an AAV expressing the therapeutic transgene, AAV Inverted Terminal Repeats (ITRs) were enriched at DNA breaks created by the enzymatic activity of recombination activating genes (RAG) during V(D)J recombination. Furthermore, AAV IS were successfully identified in the liver and cell-free DNA of Non-Human Primates systemically injected with therapeutic AAVs, underlining the feasibility of the methods as a potential minimally invasive approach for monitoring AAV IS in in-vivo GT applications. In summary, our work indicates that the development of reliable methods for the characterization of AAV integrations is fundamental to providing insights on the safety and efficacy of these vectors in gene therapy applications.

351. A Highly Potent Engineered AAV Capsid, STAC-150, Enables High-Throughput AAV Production and Arrayed Epigenetic Regulator Screening Directly in Cultured Neurons

Patrick Dunn, Jisoo Lee, Ankitha Nanjaraj, Kimberly Marlen, Andrew Olin, Hung Tran, Amy Pooler, David Ojala, Bryan Zeitler

Sangamo Therapeutics, Inc., Richmond, CA

Epigenetic regulators have the potential to transform the treatment of neurodegenerative and neurodevelopmental disorders by specific and tunable modulation of disease-associated genes. Identifying potent and highly specific epigenetic regulators, however, can require extensive empirical testing with iterative rounds of on- and off-target screening. Candidate epigenetic regulators can be evaluated in immortalized cell lines that are well-suited for high-throughput screening, but these cells often fail to recapitulate the gene expression levels, disease biology or native epigenetic signature present in more biologically relevant cells. Alternatively, screening can take place directly in the target cell type of interest, such as primary neurons, but these tend to be less experimentally tractable and can require production of viral vectors for each transgene - a step that increases cost and significantly lowers throughput. We sought to circumvent these challenges by building a robust platform for screening epigenetic regulators directly in primary- or iPSC-derived neurons. We accomplished this by engineering a novel AAV capsid, STAC-150, with two important properties: (1) the ability to transduce neurons *in vitro* at substantially lower MOIs than conventional serotypes, and (2) significant partitioning of total production yield into the cell culture medium during HEK293 capsid production. We leveraged these capsid properties in a microliter-scale, automation-compatible AAV production and purification process capable of efficient and cost-effective generation of thousands of arrayed AAVs directly from crude AAV production media. In the first step of this workflow, we transiently transfected plasmids encoding the viral genome, helper genes and epigenetic regulator transgenes into 1000 µL HEK293 suspension cell cultures in 96-well deep well plates. After 48 hours, we centrifuged the culture plates and purified secreted virus from the production medium supernatants using AAVX magnetic beads. We assessed viral protein ratios and capsid purity by total protein stain and western blot. Purified virus showed the expected viral protein ratios and minimal contaminating proteins. DNAse-resistant viral particles were quantified by qPCR, where we observed yields exceeding 1e10 viral genome copies with corresponding titers up to 5e11 vg/ml. We evaluated the functionality of these purified STAC-150 AAVs by assessing the on-target activity of their epigenetic regulator payloads in primary mouse cortical neurons by RT-qPCR. We observed potent and dose-dependent target gene regulation with strong epigenetic regulators showing EC_{50} values as low as MOI 10. In summary, we identified a secreted, neurotropic AAV capsid, STAC-150, with high potency *in vitro* and built a high-throughput, scalable production workflow to enable epigenetic regulator arrayed library screening in primary- or iPSC-derived neurons. Together, these advancements establish a platform with the potential to accelerate the development of potent and highly specific epigenetic regulators for the treatment of neurological disorders.

AAV Vectors - Immune Modulation

352. C3 Complement Inhibitor Limits Transaminitis and Immune Response Following Liver Targeted Adeno-Associated Virus (AAV) Gene Transfer (GT) in Non-Human Primates (NHPs)

Elizabeth Kropf, Corinne J. Smith, Ali L. Kamal, David M. Markusic, Anna Majowicz, Klaudia Kuranda

Spark Therapeutics, Philadelphia, PA

AAV vector-based gene therapies are shifting the medical paradigm by offering a potentially curative treatment for genetic diseases that previously lacked effective treatments. Although systemic AAV gene therapies are very promising, durability may be limited by liver transaminitis that usually subsides with corticosteroid treatment. Additionally, in clinical trials that use high systemic AAV doses (≥ 1×10^{13} vector genome [vg/kg]), complement activation accompanied by a form of thrombotic microangiopathy (TMA) was reported. TMA is defined by the presence of hemolytic anemia, thrombocytopenia and subsequent organ damage. Excessive complement activation has been observed in multiple trials across a range of disease indications and capsid serotypes. The emergence of severe adverse events at high doses of AAV presents a clear need for more effective immune suppression protocols to address the impact of complement

activation. Further, there is growing evidence that complement mediates immune response to AAV also at lower doses and thus, may warrant complement inhibiting over a broad range of AAV doses. We have previously demonstrated that inhibition of complement C3 activation, *in vitro,* in human whole blood, significantly reduced AAV vector internalization and activation of certain dendritic cells subsets. Additionally, C3 inhibition significantly reduced the levels of proinflammatory cytokines and chemokines secreted in response to AAV stimulation. These findings suggested that complement may play a major role in driving phagocytosis and priming of the immune responses to AAV. To further test this hypothesis *in vivo*, we investigated the role of prophylactic C3 complement inhibition in NHPs administered with high dose of AAV vector. Eight male, *Macaca fascicularis* were injected intravenously on day 0 with 1×10^{14} vg/kg of AAV-Spark100-hFIX (human Factor IX). Four of eight NHPs were treated with 140 mg/kg of C3 inhibitor (Pegcetacoplan, APL-2) by daily subcutaneous injections from days -5 to 23. At week 14 all animals were sacrificed. Systemic administration of high-dose AAV in control NHPs resulted in complement activation and elevated liver enzymes 1.5-fold above baseline for both alanine transaminase and aspartate aminotransferase, as seen in clinical trials. The peak of alternative pathway complement activation (Bb) was observed one week post AAV infusion. C3a showed transient elevation at day 3 post AAV infusion followed by another more pronounced increase around week 4. Interestingly, C3a elevation at week 4 coincided with the onset and duration of liver enzyme elevation. APL-2 treatment significantly lowered AAV-induced complement activation, was well-tolerated and did not interfere with AAV-based GT as measured by plasma levels of hFIX protein, liver hFIX expression, and vector genome copies. As previously observed *in vitro*, C3 inhibition also limited immune response to AAV vector *in vivo*. Compared to control animals, the APL-2 treated group showed lower systemic levels of pro-inflammatory cytokines (*i.e.*, IL-6 and IL-8) and reduced capsid-specific hepatic T cells at week 14. Importantly, C3 inhibition with APL-2 significantly limited hepatotoxicity following AAV gene transfer as demonstrated by lower liver enzyme levels**.** Further studies are ongoing to elucidate the mechanism underlying this observation. These promising results may encourage clinical evaluation of C3 inhibitors' capacity to limit AAV immunogenicity and concomitant transaminitis in gene therapy trials using moderate AAV doses. In trials using high AAV doses, C3 inhibitors may additionally prevent adverse complement activation and TMA, to improve safety of patients.

353. Orthogonal B Cell and Plasma Cell Immunosuppression Strategies Prevent and Suppress High-Titer Antibody Immunity to Enable AAV Vector Re-Dosing

Nicholas Giovannone, Carley Tasker, Nyanza Rothman, Sofia Caruso, Julia Provino, Laura Johnsen, Johanna Napetschnig, Jamie Orengo, Christos Kyratsous, Andre Limnander, Katherine Cygnar, Andrew Baik

Regeneron Pharmaceuticals, Tarrytown, NY

Adeno-associated virus (AAV)-based vectors hold tremendous promise to transform treatment of genetic diseases. Yet, the potential of AAV gene therapies has so far been limited by development of host neutralizing antibodies (nAbs) that block transduction on subsequent exposures. Clinically, the inability to re-dose AAVs presents challenges because efficacy cannot be restored if transgene expression is subtherapeutic or lost (*e.g.* due to cell division, silencing, or a cytotoxic immune response). Moreover, due to natural AAV exposure, many patients develop nAbs prior to treatment that render them ineligible for even a single dose. Therefore, strategies that prevent or attenuate anti-AAV nAb responses could vastly expand the utility and accessibility of existing AAV gene therapies, while safeguarding eligibility for future AAV-based advances. Here, we report on two distinct B cell immunosuppression approaches that enable AAV vector re-transduction at levels equal to seronegative animals, either by preventing development of post-treatment nAbs (via CD40 blockade) or depleting pre-existing nAbs (via combined plasma cell and immunoglobulin depletion). We first tested whether antagonizing CD40, a receptor crucial to generation of long-lived antibody responses, could suppress development of post-treatment AAV nAbs. Using fully human anti-CD40 antibodies and CD40 humanized mice, we found CD40 blockade prior to systemic AAV8 treatment resulted in potent and durable suppression of post-treatment AAV IgG titers. When administered a second AAV8 vector, mice that received CD40 antibody, but not isotype control, achieved levels of re-transduction equal to seronegative control mice. Mechanistically, we observed CD40 blockade prevented B cell activation and germinal center differentiation, including of AAV-specific B cells. Together, these data suggest transient CD40 blockade preserves immunological naivety to AAV to enable repeated AAV dosing. Long-lived plasma cells (LLPC) mediate constitutive antibody production to most antigens and are the likely reservoir of persistent anti-AAV antibody immunity. While CD40 is required for generation of LLPC, it is not known to impact LLPC survival or antibody secretion. Therefore, we evaluated whether the source of pre-existing AAV nAbs could be directly eliminated *in vivo* by LLPC depletion with linvoseltamab, a fully-human T cell-bridging bispecific antibody targeting B cell maturation antigen and CD3 (BCMAxCD3), either alone or in combination with B cell depletion (to eliminate non-LLPC sources of anti-AAV nAbs), and/or FcRn blockade (to accelerate serum IgG clearance). To model a rigorous scenario of pre-existing AAV immunity, we treated dual CD3/BCMA-humanized mice with AAV8 to induce high-titer nAbs. Ten weeks later, we administered weekly doses of BCMAxCD3, anti-CD19/20, and/or FcRn blocker and monitored anti-AAV IgG titers over time. Whereas treatment with BCMAxCD3, anti-CD19/20, or FcRn blocker alone elicited minor titer reductions, mice treated with both BCMAxCD3 and FcRn blocker showed rapid titer declines to naïve or near-naive levels, and mice additionally treated with anti-CD19/20 universally exhibited undetectable titers after five weeks of treatment. Strikingly, upon administration of a second AAV8 vector, 3/6 and 6/6 mice receiving BCMAxCD3 + FcRn blocker or all three agents, respectively, achieved re-transduction equivalent to seronegative control mice. Collectively, these data suggest CD40 blockade and plasma cell depletion are orthogonal approaches that may enable repeated dosing of AAVs, or other immunogenic gene therapy vectors, regardless of serostatus.

354. Vectorized Antibody-Mediated Anti-Eosinophil Gene Therapy

Maria Gioulvanidou[1], Selenay Sarklioglu[1], Hailey C. Lephart[1], Xinlei Chen[2], Irina V. Lebedeva[2], Yeliz Inalman[2], MaryAnn Pohl[2], Lloyd Bourne[2], David Andrew[2], Ivo C. Lorenz[2], Katie M. Stiles[1], Odelya E. Pagovich[1], Neil R. Hackett[1], Miguel de Mulder Rougvie[1], Stephen M. Kaminsky[1], Ronald G. Crystal[1]

[1]Genetic Medicine, Weill Cornell Medical College, New York, NY,[2]Sanders Tri-Institutional Therapeutics Discovery Institute, New York, NY

Chronic hypereosinophilia, characterized by persistent elevated blood levels of eosinophils (≥1500/μl), is characteristic of chronic eosinophilic leukemia, hypereosinophilic syndrome, allergic disorders and helminth parasite infections. Hypereosinophilia is often associated with tissue infiltration of eosinophils and consequent organ damage by toxic mediators released by the eosinophils. The current therapy for chronic hypereosinophilia is systemic corticosteroids, and if that is not successful, patients are treated with imatinib, vincristine, hydroxyurea, mepolizumab, benralizumab or reslizumab all of which require repetitive administration. As a novel approach to treat hypereosinophilia, we hypothesized that adeno-associated virus (AAV)-mediated delivery of an anti-eosinophil antibody would provide one-time therapy that would mediate persistent suppression of blood eosinophil levels. To generate a humanized anti-human eosinophil monoclonal, the AlivaMab kappa/lambda, AlivaMab kappa and Balb/c mouse strains were immunized with the human Siglec8 protein or DNA (pTTS-huSiglec8). This generated 25 anti-human eosinophil IgG1 monoclonals directed against Siglec-8, a sialic-acid binding Immunoglobulin-like lectin, expressed on high levels on the cell surface of human eosinophils and mast cells and to a lesser extent on basophils. Based on ELISA and flow cytometry assays, the 08C07 monoclonal was chosen for further study. The human variable regions of 08C07 were joined to human Ig constant region, creating H08C07, a fully humanized anti-human eosinophil monoclonal. Using the gene sequence of H08C07, we created EN01, an AAVrh.10-based vector with the CAG promoter driving the heavy and light chains of H08C07 separated by the furin-2A cleavage site. Intravenous administration of EN01 (10^{11} gc) to C57Bl/6 mice resulted in elevated serum levels of H08C07 (3.0±1.5 mg/ml at 4 weeks). Serum from the treated mice was used for a series of *ex vivo* assessments of EN01 function. Gene therapy generated H08C07 bound to recombinant Siglec8 protein in a dose-dependent manner and specifically to human eosinophils. Importantly, overnight incubation of human purified interleukin-5-activated eosinophils with the EN01-generated antibody, mediated higher apoptosis of human eosinophils compared to the untreated group (control 17.3% *vs* 74.9% Annexin-V^+ cells, $p<0.001$). In the presence of human purified NK-cells, the EN01-generated antibody mediated higher antibody-dependent cellular cytotoxicity (ADCC) activity against human eosinophils (control 48.4% *vs* 97.7% Annexin-V^+ cells, $p<0.05$). This data supports the conclusion that EN01 is an effective anti-human eosinophil AAV-based vector that, with intravenous administration, generates high levels of H08C07, a fully humanized monoclonal that mediates potent apoptosis of human eosinophils. EN01 holds the potential to offer therapeutic benefit to patients with chronic hypereosinophilia.

355. Modulating the AAV-Specific Immune Response: A Comparison of T Cell Co-Stimulation Blockade with Rapamycin Plus B Cell Depletion

Audry Fernandez[1], Layth Awartani[1], Abbie Svancarek[1], Mason Zlotnik[1], Dylan Southers[1], Rachel Hedinger[1], Charles Krause[1], Rohini Sheth[1], Alan Curtis[1], Erik Wielechowski[1], D'Shawna Burwell[1], Joerg Votteler[1], Yash Shah[1], Rob Junkins[1], Angela Mote[1], Sherif Gabriel[1], Anna Tretiakova[1], Shari Gordon[1], R. Jude Samulski[1,2]

[1]Asklepios BioPharmaceutical, Inc., Durham, NC,[2]University of North Carolina, Chapel Hill, NC

Immune modulation in the context of Adeno-Associated Virus (AAV) gene therapy aims to suppress the adaptive response to prevent immune-related adverse events and ultimately facilitate AAV redosing. To this end, the combination of the T cell inhibitory drug Rapamycin and B cell depletion with anti-CD20 antibody (rapa/aCD20) has become the strategy of choice in several AAV clinical studies. However, few studies have performed a comparative analysis with other regimens and to our knowledge there is no definitive data indicating that this combination can facilitate intravenous (IV) AAV redosing. Our study compares the effects of CTLA4-Ig to rapa/aCD20 on AAV induced adaptive responses in multiple murine models. CTLA4-Ig is a fusion protein containing the extracellular domain of Cytotoxic T-Lymphocyte Antigen 4 (CTLA4-4) and the Fc portion of a human immunoglobulin. This well characterized immune suppressive agent in clinical use (Abatacept) inhibits CD28-mediated T cell co-stimulation through preferential binding to B7 molecules on mature antigen presenting cells. In this work we evaluated the ability of rapa/aCD20 to facilitate AAV8 redosing in acid alpha-glucosidase (GAA) knockout mice, a pre-clinical model of Pompe disease. The vector was administered IV with secreted nano luciferase and GAA as selected transgenes for the first and second dose, respectively. Inhibitory agents were temporarily administered to control the immune response associated with each vector dose in all the mouse redosing models evaluated. Despite causing a significant reduction of AAV8-specific IgG antibodies (Abs) after the first vector dose, the administration of rapa/aCD20 did not facilitate redosing in this model as demonstrated by the evaluation of vector genomes and GAA enzymatic activity. Interestingly, this immune modulation regimen did not prevent the development of AAV8-specific IgG Abs after a second vector dose. These results supported the idea of testing other immune modulatory agents like CTLA4-Ig. In fact, using the highly immunogenic AAVrh32.33 vector as a model, we observed that CTLA4-Ig as a single agent was superior to rapa/aCD20 at blunting the $CD8^+$ T cell response and maintained long-term inhibition of both T and B cell responses specific for this vector. Next, we evaluated the ability of CTLA4-Ig to facilitate AAVrh32.33 redosing as this vector model allows the comparison of intramuscular (IM) and IV administration. Ovalbumin and luciferase were used as model transgenes for the first and second vector dose, respectively. CTLA4-Ig regimen caused an almost complete reduction of AAVrh32.33-specific IgG Abs after the first vector dose irrespective of the vector administration route. In the IV administration setting, CTLA4-Ig was unable to facilitate redosing and combination with other strategies will be tested in future studies. However, when the vector was dosed IM, an increased luciferase transgene expression

was detected in the group treated with CTLA4-Ig suggesting it could facilitate IM redosing when used as a single agent. In conclusion, our results suggest that co-stimulation blockade with CTLA4-Ig could be superior to rapa/aCD20 to control AAV-specific immune response but would need combination with other immune modulatory agents to facilitate intravenous AAV redosing.

356. Vectorized Expression of a Pan-Filovirus Bispecific Monoclonal Antibody in a Murine Model for Protection Against Ebola and Marburg Virus Challenge

Elena S. B. Campbell[1], Wenguang Cao[2], Arielle N. Gillies[1], Yanlong Pei[1], Jordyn A. Lopes[1], Amira D. Rghei[1], Leonardo Susta[1], Logan Banadyga[2,3], Sarah K. Wootton[1]

[1]Pathobiology, University of Guelph, Guelph, ON, Canada,[2]National Microbiology Laboratory, Public Health Agency of Canada, Winnipeg, MB, Canada,[3]Department of Medical Microbiology and Infectious Diseases, University of Manitoba, Winnipeg, MB, Canada

Filoviruses, such as Ebola virus (EBOV), Sudan virus (SUDV), and the more divergent Marburg virus (MARV), have known epidemic potential. Despite this knowledge, there is a lack of funding and resources being allocated to vaccine development for a number of these infectious diseases. Furthermore, elderly, and immunocompromised populations have a limited capacity to respond robustly to classical antigen-based vaccines, and the production of clinical-grade monoclonal antibodies (mAb) for passive immunization remains labor-intensive, technically challenging, and confers short-lived immunity. One novel strategy to circumvent these pitfalls involves the use of the host as a "bioreactor", whereby host cells are stimulated to generate pathogen-specific mAbs capable of accumulating to therapeutic levels, a platform known as vectored immunoprophylaxis (VIP). Vectored mAb expression mediated by adeno-associated virus (AAV) gene delivery can produce protective and sustained concentrations of therapeutic mAbs in animal models for several infectious diseases. Our rationally engineered AAV6 triple mutant capsid, AAV6.2FF, facilitates rapid and robust mAb expression following intramuscular (IM) administration. Using AAV6.2FF mediated expression of anti-EBOV mAbs 100 and 114 and pan-ebolavirus mAbs FVM04, ADI15878, and CA45 as human IgG1 antibodies, we previously demonstrated protection against mouse-adapted EBOV (MA-EBOV) at low serum concentrations. A follow-up study further showed rapid and robust AAV6.2FF mediated expression of two potent human antibodies, MR78 and MR191, protected against mouse-adapted MARV (MA-MARV) infection in a murine model. Notably, both high ($1x10^{11}$ vector genomes [vg]) and medium dose ($1x10^{10}$vg) groups were protected from lethal MA-MARV challenge. Here, we have re-engineered our AAV-VIP platform to create a broadly protective anti-filovirus immunotherapy. Our bispecific human IgG1 mAb design is comprised of the pan-ebolavirus mAb, FVM04, variable heavy and light chain domains and the self-complimentary variable fragment (scFv) of the MARV mAb, MR191. In a preliminary investigation, IM injection of $1x10^{11}$vg AAV6.2FF-FVM04-MR191 was administered to BALB/c mice (n=4). Antibody expression kinetics resulted in serum human IgG concentrations of 85-201 μg/ml for over 8 weeks post vector administration. Binding of FVM04 and MR191 to the EBOV and MARV glycoproteins, respectively, was also confirmed using a glycoprotein binding ELISA. In a subsequent study, IM injection of BALB/c mice (n=16) with $1x10^{10}$ (low dose), $5x10^{10}$(mid dose), and $1x10^{11}$ (high dose) vg of AAV6.2FF-FVM04-MR191-WPRE resulted in average serum human IgG concentrations of 0.62 μg/mL, 1.43 μg/mL, and 23.41 μg/mL respectively, immediately prior to MA-EBOV and MA-MARV challenge. Six of eight mice in the high-dose group and two of eight in the mid-dose group were protected against lethal MA-EBOV challenge, and none were protected against the MA-MARV challenge. In a follow-up experiment, we have re-designed the bispecific antibody orientation to allow for stronger protection against both viruses and are evaluating a higher dosing regimen. Evaluation of human IgG expression kinetics is currently being measured ahead of repeat challenge experiments. Overall, AAV-mediated antibody gene transfer is a viable method for prolonging the therapeutic effect of recombinant mAbs, representing an alternative "vaccine" strategy for those with compromised immune systems or in possible outbreak response scenarios.

357. Evaluating the Effects of IdeS-Generated Anti-AAV IgG Fragments on AAV Gene Delivery

Saghana Muraleetharan, Valeriya Posternak, Conor Dickson, Scott Ashley, Lindsey Peed, Robert Straub, Victor Howard, Pavani Ponnela, Pitchaimani Kandasamy, Heena Beck, Timothy Luongo, Jeffrey Alexander, Christopher Riling

Spark Therapeutics, Philadelphia, PA

Humoral immunity to wild-type adeno-associated virus (AAV) has the potential to present significant challenges for treating patients with AAV-based gene therapy. A considerable proportion of otherwise eligible patients become ineligible due to pre-existing anti-AAV capsid neutralizing (NAb) antibodies. IgG-degrading enzyme (IdeS), a cysteine endopeptidase derived from *S. pyogenes*, has demonstrated efficacy in degrading pre-existing anti-AAV IgG enabling AAV-mediated gene transfer through systemic delivery. IgG fragments are generated following IdeS cleavage (single-chain IgG (scIgG), Fc, $F(ab')_2$) with different levels of neutralizing properties. While the impact of intact IgG NAbs on AAV gene delivery is relatively well-characterized, the neutralizing effect of IdeS-generated $F(ab')_2$ is not well understood. To assess the impact of $F(ab')_2$ on AAV gene delivery, we utilized a human FcRn (hFcRn) transgenic mouse model passively immunized with intravenous immunoglobulin (IVIg) from pooled human plasma containing anti-AAV NAbs. Efficacy of gene delivery was evaluated after the passively immunized mice received pretreatment with IdeS and were administered a single intravenous dose of liver-directed AAV at several timepoints (2, 4, 6, 24, 48, 72 hours) following pre-treatment. In vehicle pretreated mice, anti-AAV IgG remained in circulation for up to 72 hours and neutralized AAV transduction. In contrast, mice pre-treated with IdeS demonstrated complete cleavage of anti-AAV IgG at 2 hours post-IdeS administration. Additionally, anti-AAV $F(ab')_2$ fragments remained in circulation for up to 6 hours in IdeS treated animals. Although anti-AAV IgG was completely cleaved, neutralization was still observed in plasma up to 6 hours following IdeS pretreatment. AAV-derived transgene expression correlated with increasing time post IdeS pretreatment and decreasing $F(ab')_2$ levels, reaching peak expression at 48-72 hours following IdeS pretreatment.

Although pretreatment using IdeS demonstrates improved AAV transduction in seropositive animals, our data suggest that circulating $F(ab')_2$ fragment has the potential to neutralize AAV and impact gene transfer at early timepoints post-IdeS treatment. Taken together, our findings indicate that $F(ab')_2$ fragment clearance and careful selection of the ideal AAV administration window may be important when considering IdeS pretreatment in patients with pre-existing immunity to AAV.

358. IgG Enzymatic Cleavage Prevents Uptake of AAV and Activation of Phagocytic Immune Cells in Seropositive Human Donors

Blake J. Rust[1], Anita Kumari[1], Nathalie Uzcátegui[2], Lena Windstedt[2], Todd Yoder[1], Minnal Gupta[1], Sushmita Paul[1], Gaelle A. Mardy[1], Gavin George[1], Mengyan Du[1], Eisha Clyde[1], Vyohm Neel[1], Daniel J. Hui[1], Sam Hopkins[1], Greg Gojanovich[1], R. Jude Samulski[1], Simon F. Lacey[1]

[1]Asklepios BioPharmaceutical, Inc., Morrisville, NC,[2]Hansa Biopharma AB, Lund, Sweden

Background Adeno-associated viral vector (AAV) gene therapy is a clinical reality, aiming to bring life-altering treatments to subjects afflicted by genetic diseases. However, natural exposure to wild-type AAV results in ~30-70% seropositivity for neutralizing antibodies (nAb), limiting the treatable patient population. IgG-cleaving enzymes, like that from Streptococcus pyogenes (imlifidase), have demonstrated the ability to provide a unique window for treatment with AAV therapy in the context of pre-existing humoral immunity, although the impact on broader cellular immune modulation has not been thoroughly explored. **Purpose** Previous reports have indicated that AAV nAb+ blood has an increased ability to uptake AAV vectors (*Smith et al.*) and that this effect can be mitigated with complement inhibition. Further, imlifidase has been shown to be successful in altering the AAV/antibody interactions that activate complement, but its effects on AAV uptake into blood immune cells are unknown. We hypothesized that the enhanced uptake effect in the context of pre-existing humoral immunity was driven by immunoglobulin/Fc receptor interactions, therefore we sought to leverage imlifidase to determine if capsid uptake could be ablated in seropositive healthy human donor whole blood. **Results** Following 24-hour incubation of AAV with healthy donor whole blood, leukocytes were isolated and assessed with a comprehensive spectral cytometry panel capable of immune cell phenotyping and intracellular capsid detection. Uptake of both AAV8 empty capsid and an AAV8 construct expressing nano-luciferase was observed at a significantly higher degree in both monocytes, granulocytes, and to a lesser degree in dendritic cells (DC), in seropositive donors as compared to seronegative donors. Uptake of capsid was associated with significant upregulation of costimulatory molecules CD80 and CD86 in the monocyte and DC antigen-presenting subsets, but not granulocytes. Treatment with imlifidase prior to coincubation of donor whole blood with AAV not only ablated capsid uptake in seropositive donors, but also reduced costimulatory molecule upregulation. This finding was corroborated by imaging cytometry which revealed visual reduction of capsid uptake in single cells. Decreased levels of proinflammatory cytokines were also observed following treatment of donor blood with imlifidase. **Conclusions** While the enhancement of AAV transduction by imlifidase has been well documented, less is understood about its effect on cellular immunogenicity, which is ultimately related to toxicity and long-term efficacy in the clinical gene therapy space. Here we demonstrate that cleavage of IgG *in vitro* with imlifidase not only prevents AAV capture by phagocytic and antigen-presenting immune subsets within 24 hours, but also limits the ability of these subsets to activate and express costimulatory molecules that allow for the further propagation of adaptive immune responses. Further experiments are needed to clarify the relative contributions of antibodies and complement components to enhance AAV uptake into immune cells, which ultimately reduces target cell transduction and increases immunogenicity. Altogether, this study indicates that *in vivo* imlifidase treatment to ablate pre-existing antibodies may have further utility in attenuating the cascade of cellular immune responses against AAV - particularly in the context of antigen presentation and T-cell activation. Smith CJ, et al. *Front. Immunol.* 2022 Sep;13:999021.

Oncolytic Viruses

359. Additional Expression of T Cell Engager in Clinically Tested Oncolytic Adeno-Immunotherapy Redirects Tumor-Infiltrated, Irrelevant T Cells Against Cancer Cells, Enhancing Anti-Tumor Immunity

Daisuke Morita[1,2,3,4], Amanda R. Shaw[1,2], Caroline E. Porter[1,2], Greyson G. W. Biegert[1,2], Mae L. Woods[2], Spyridoula X. Vasileiou[2,5], Bora Lim[6], Masataka Suzuki[1,2]

[1]Department of Medicine, Baylor College of Medicine, Houston, TX,[2]Center for Cell and Gene Therapy, Baylor College of Medicine, Texas Children's Hospital, Houston Methodist Hospital, Houston, TX,[3]Department of Pediatrics, Shinshu University School of Medicine, Matsumoto, Japan,[4]Institute for Biomedical Sciences, Interdisciplinary Cluster for Cutting Edge Research, Shinshu University, Matsumoto, Japan,[5]Department of Pediatrics, Baylor College of Medicine, Houston, TX,[6]Duncan Cancer Center-Breast, Baylor College of Medicine, Houston, TX

We have developed a binary oncolytic/helper-dependent adeno-immunotherapy (CAdVEC) expressing IL-12p70, PD-L1 mini-antibody and HSV-tk safety switch (CAd*Trio*) currently under clinical investigation in patients with advanced solid tumors (NCT03740256). Results to date are promising; a single, local injection of CAd*Trio* at the tumor site has safely led to complete eradication of localized tumors in some patients, despite being given at doses 100-fold lower than previous clinical trials of oncolytic Ad. However, all patients primarily amplified Ad-specific T-cells (AdVSTs) after treatment, similar to other OAd trials. Here, we investigate the mechanisms by which CAd*Trio* produces superior anti-tumor effects in patients. We demonstrate that HDAd-infected, but not OAd-infected, cells escape recognition by AdVSTs, and HDAd-derived immunomodulatory transgenes enhance tumor-specific T-cell activity. Tumor biopsy samples collected from patients showed increased CD8+ T-cell infiltration after CAd*Trio* treatment. Given the amplification of adenovirus immunity in patients after CAd*Trio*, these tumor-infiltrating CD8+ T-cells are likely enriched for AdVSTs. Since CAd*Trio* is insufficient to cure distant tumors in

some patients, we thus hypothesize that re-directing these irrelevant T-cells against cancer cells will enhance direct anti-tumor effects and tumor-antigen spread, resulting in increased tumor-specific T-cell development and systemic tumor targeting. CD44 variant 6 (CD44v6) is widely expressed in solid tumors and is known as a cancer stem cell marker. Therefore, we incorporated a T-cell engager molecule targeting CD44v6 (CD44v6.BiTE) into CAd*Trio* to form CAd*Tetra*. We confirmed that CAd*Tetra*-derived CD44v6.BiTE enables AdVSTs to kill CD44v6+ cell lines with AdVST proliferation in vitro and in different xenograft mouse models. Since all patients had adaptive immunity against Ad prior to CAd*Trio* treatment, we developed Ad pre-immunized humanized mouse models to evaluate the efficacy of CAd*Tetra*. CAd*Tetra* significantly controlled tumor growth by repolarizing local and systemic immune responses against cancer cells in immunologically "hot" and "cold" tumor models. Increased tumor-specific T cells also controlled re-challenged tumor growth in humanized mice. These results indicate that CAd*Tetra* effectively induces adaptive T cell responses against cancer cells by redirecting tumor-infiltrating irrelevant T cells, creating a more potent CAdVEC immunotherapy applicable to many solid tumor types.

360. Repurposing the Selective Serotonin-Reuptake Inhibitor (SSRI) Paroxetine to Combat Systemic Immunosuppression in an Orthotopic Syngeneic Murine Glioblastoma Model Treated with Oncolytic MV-s-NAP-uPA Based Immunovirotherapy

Georgios M. Stergiopoulos[1], Susanna C. Concilio[1], Kimberly Viker[1], Susan Clark[1], Steven Robinson[1,2], Evanthia Galanis[1,2]

[1]Department of Molecular Medicine, Mayo Clinic, Rochester, MN,[2]Department of Medical Oncology, Mayo Clinic, Rochester, MN

Introduction: Glioblastoma multiforme (GBM) is the most common malignant brain tumor and carries a dismal prognosis. Notably, GBM has yet to benefit from immunotherapy strategies: a major challenge relates to the systemic immunosuppression, in part mediated via sequestration of T cell populations in the bone marrow. The latter occurs through internalization of sphingosine-1 phosphate receptor (S1P1/S1PR1), which acts as an "exit visa" for T cells from lymphoid organs. S1P1 is internalized by G protein-coupled receptor kinase 2 (GRK2), a protein inhibited by the SSRI paroxetine, an FDA-approved antidepressant. Our team has developed an oncolytic measles virus strain armed with the neutrophil activating protein (NAP) a secretory bacterial peptide derived from *Helicobacter pylori*, which is a TLR2 agonist and potent immunomodulator. Preclinical work combining the NAP-armed virus with immune checkpoint inhibitors (ICIs) targeting programmed cell death protein 1 (PD-1) and T cell immunoreceptor with Ig and ITIM domains (TIGIT) demonstrated significant survival benefit in syngeneic GBM mouse models. We hypothesized that relieving the tumor-imposed T cell sequestration would further enhance the therapeutic effect of our previously established triple pronged immunovirotherapy combination. **Methods:** 7-week-old C57/BL6 female mice were implanted with syngeneic CT-2A murine GBM cells orthotopically. Two intratumoral doses of MV-s-NAP-uPA, a mouse-retargeted MV-s-NAP strain, were administered, complemented by six doses of anti-PD-1 + anti-TIGIT, and daily oral paroxetine administration throughout the treatment. Treatment with granulocyte-colony stimulating factor (G-CSF), an agent shown to increase T-cell circulation in C57/BL6 mice, was used as a positive control. Other controls included untreated mice, mice treated with MV-s-NAP-uPA, MV-s-NAP-uPa + anti-PD-1 + anti-TIGIT, and MV-s-NAP-uPa + anti-PD-1 + anti-TIGIT + paroxetine + G-CSF. **Results:** Mice that received paroxetine in addition to the triple treatment demonstrated survival benefit (P=0.008 compared to the untreated) and a higher cure rate, compared to the triple immunovirotherapy group, reaching an approximately 90% long term survival. Survival was comparable in mice receiving triple treatment with paroxetine, G-CSF, or paroxetine + G-CSF. Flow cytometry data from mice that received paroxetine (and/or G-CSF) in addition to immunovirotherapy, demonstrated an increase in circulating lymphocytes with upregulated S1P1 expression (P=0.055), a higher proportion of activated lymphocytes, particularly CD8+ cells expressing α chain of the high-affinity IL-2 receptor [CD25+, (P=0.048)], denser staining of CD25 on CD4+ and CD8+ cells (P=0.022), more circulating NKT cells (P=0.041) and fewer neutrophilic myeloid-derived suppressor cells (P<0.001) compared to the ones receiving only the triple immunovirotherapy. **Conclusions:** Paroxetine, an SSRI antidepressant, further enhances the efficacy of measles-based immunovirotherapy with ICIs in preclinical GBM models by increasing lymphocyte trafficking and promoting their activation. The commercial availability of paroxetine, coupled with its favorable side effect profile, enhances its potential clinical applicability. Ongoing experiments include cytokine analysis, immunohistochemistry of tumors, brain and spleen, and flow cytometry analysis of the bone marrow, spleen and thymus at different timepoints during the treatment. Updated data will be presented at the meeting. This work was supported by R01 CA258239.

361. The Clinical Oncolytic Virotherapy, VET3-TGI, Displays Potent Therapeutic Activity in Multiple Mouse Tumor Models through Blocking TGF-Beta and Augmenting Type-1 Immune Response

Steve Thorne

Kalivir Immunotherapeutics, Pittsburgh, PA

TGF-beta mediated resistance is one of the major mechanisms of immune suppression utilized across multiple solid tumor types. Blockade of TGF-beta (TGFBi) will therefore likely improve response to immunotherapy. Combining TGF-beta blockade with IL-12 expression may maximize therapeutic benefits through simultaneously reducing immunosuppression and enhancing anti-tumor immune response. Current studies have developed a vaccinia-based immunotherapy, VET3-TGI, combining enhanced systemic virus delivery to CXCR3 ligand rich tumors and locally expressed IL-12 and TGFBi within the tumor microenvironment, for efficient control of multiple tumor models.VET3-TGI infected cells expressed CXCR3 and showed enhanced migration to CXCR3 ligands *in vitro* and improved systemic delivery to tumors expressing CXCR3 ligands *in vivo*, even in the face of pre-existing anti-viral immunity. *In vivo* mouse studies using multiple tumor models demonstrated potent therapeutic activity, including 100% CRs, even at doses several logs below equivalent clinical doses.

Mechanism of activity studies suggested that the therapeutic efficacy of VET3-TGI is associated with considerable modification of the tumor microenvironment. In addition, toxicity studies demonstrated the safety of VET3-TGI in mouse models. VET3-TGI demonstrated an ability to reduce immunosuppression and dramatically enhance antitumor immune response leading to safe and potent therapeutic activity in multiple mouse tumor models. This data led to the selection of VET3-TGI as a lead clinical candidate. A human version has been manufactured for clinical use.

362. Where's Waldo: Finding Tumor Antigens in the Circus of the Immune Response to Oncolytic Viruses

Benjamin Kendall, Rosa Diaz, Jason M. Tonne, Richard G. Vile

Mayo Clinic, Rochester, MN

Oncolytic viruses (OVs) are a class of immuno-oncology agents engineered specifically to replicate in and kill tumor cells. OVs have recently entered the ranks of other cytotoxic T-cell focused therapies like chimeric antigen receptor T cells and immune checkpoint blockade (ICB) due to their ability to redirect T cells targeting either viral or tumor antigens to the site of infection. The current paradigm proposes that OV tumor cell killing induces immunologic cell death which triggers the innate and adaptive immune cascade culminating in the presentation of tumor antigens to their cognate T cell receptors. However, this paradigm largely ignores the impact a highly immunodominant antiviral response against the OV has on the subdominant antitumor response, particularly regarding how the relatively low frequency, low avidity tumor antigens (Waldos) can potentially be masked by a circus of viral antigens. To address this issue experimentally, we first studied the interaction between the two responses in the immunologically cold, B16 melanoma expressing the artificial, and potentially immunogenic, antigen ovalbumin (B16-ova) - a situation in which we would expect Waldo to be relatively visible to the immune system. Contrary to the accepted paradigm, the inflammatory Vesicular Stomatitis Virus (VSV) was unable to stimulate an antitumor T-cell response in C57 mice as determined by MHCI tetramer staining, even when transgenic OT-1 T-cells recognizing ovalbumin were added. Multiparametric phenotypic analysis of these T cell populations via cytometry by time-of-flight confirmed that antiviral T cell expansion induced by VSV led to the ablation of active antitumor T cells, shifting the tumor-reactive T cell landscape toward exhaustion via the increase of markers of dysfunction such as LAG3, TIM3, and CD39, correlating with lower rates of survival. Interestingly, we observed the rescue of tumor specific, activated T cell populations when VSV was armed with ovalbumin (VSV-ova), suggesting the chimerization of the antiviral and antitumor responses allowing the latter to overcome the oppressive effect of the immunodominant antiviral response. Finally, we utilized ICB therapy to bolster the therapeutic capacity of the tumor-specific T cells generated when the OV expressed ovalbumin. We observed that combining VSV-ova with αPD1 therapy greatly improved the survival of B16-ova tumor-bearing mice over VSV + αPD1, thus highlighting the therapeutic insufficiency of tumor antigens released from oncolysis alone. Taken together, these data challenge the conception that immunogenic viruses function as *in situ* tumor vaccines. However, our findings offer insight into how we can improve OV therapy by helping tumor-reactive CD8 T cells find Waldo in the crowded antiviral circus.

363. Anti-Tumor Immune Responses of Oncolytic Vaccinia Virus are Synergistically Enhanced by Induction of Cell-Cell Fusion and Delivery of Multiple Immunomodulators

Motomu Nakatake, Emi Kaitsurumaru, Hajime Kurosaki, Takafumi Nakamura

Division of Genomic Medicine, Graduate School of Medical Sciences, Tottori University, Yonago, Japan

Oncolytic virotherapy is a novel cancer treatment which shows remarkable clinical benefits against refractory tumors. Oncolytic virus induces powerful anti-tumor effects by causing the anti-tumor immune response following the local oncolysis. One of the candidates, vaccinia virus, once widely used as a smallpox vaccine, is now utilized as an oncolytic virus. We have developed two distinct oncolytic platforms, MAPK-dependent recombinant vaccinia virus (MDRVV) and fusogenic oncolytic vaccinia virus (FUVAC). MDRVV achieved tumor-specific virus replication by deleting two viral growth factors, VGF and O1L. FUVAC has isolated from the MDRVV as a mutant clone which has the fusogenic phenotype due to the nonsense mutation of viral fusion inhibitor, K2L. FUVAC-mediated cell-cell fusion more efficiently induced oncolysis and immunogenic cell death in the treated tumors, resulting in efficient anti-tumor immune response through decreasing tumor-associated immune suppressive cells locally and increasing cytotoxic T lymphocytes systemically. Thus, FUVAC changed tumor immune microenvironment from "cold" to "hot", especially in the direct treated tumors. However, it was insufficient to cure the distant untreated tumors such as metastatic tumor region which depends only on the induction of anti-tumor immunity. To remodel the tumor immune microenvironment systemically, we have engineered FUVAC armed with two immunostimulatory cytokines, interleukin 12 (IL12) and C-C motif chemokine ligand 21 (CCL21). At first, IL12 or CCL21 single-armed FUVACs were evaluated by alone or in combination. Mice bearing bilateral CT26 tumors were treated with each virus unilaterally. As expected, the combination of IL12-armed and CCL21-armed FUVAC showed much higher therapeutic efficacy than each viral monotherapy. Therefore, the gene cassettes expressing IL12 and CCL21 were inserted into the VGF and O1 gene loci of FUVAC, respectively. This dual-armed FUVAC-IL12/CCL21 was compared with non-armed FUVAC or dual-armed MDRVV-IL12/CCL21, to identify whether the key therapeutic factor was cell-cell fusion and/or cytokine activity. In bilateral CT26-bearing mice, unilateral injection of MDRVV-IL12/CCL21 induced 29% of complete response (CR) in both tumors, whereas non-armed FUVAC couldn't eliminate the non-injected tumors. Notably, FUVAC-IL12/CCL21 more prolonged the survival of mice than MDRVV-IL12/CCL21 and reached 72% of CR. It suggests the therapeutic efficacy of FUVAC-IL12/CCL21 was synergistically enhanced by both cell-cell fusion and cytokine activity. Moreover, biochemical analysis demonstrated that the IL12 and CCL21 was mostly accumulated in the injected tumors, and the levels of those cytokines in blood were tolerable. On the contrary, anti-tumor IFN-γ was elevated systemically by FUVAC-IL12/CCL21 treatment. Furthermore, whole tumor immune microenvironment was analyzed

by single cell RNA-seq. FUVAC-IL12/CCL21 changed the tumor immune microenvironment systemically, by decreasing tumor cells and increasing tumor-infiltrating lymphocytes in the distant untreated tumors. FUVAC-IL12/CCL21 increased the effector memory T cells while decreasing the exhausted T cells. The detailed analyses including TCR repertoire are ongoing. Our results demonstrated that fusogenic oncolytic vaccinia virus armed with IL12 and CCL21 augmented the antitumor activity via inducing potent and durable antitumor immune responses following extensive viral oncolysis. Thus, FUVAC would be a next generation platform of oncolytic immunotherapy.

364. Oncolytic Adenovirus Armed with a Type I Interferon Exerts Systemic Antitumor Immunity in Immunocompetent Replication-Permissive Models

Kazuho Inoko[1], Shuhei Shinoda[1], Natalia Calixto Mancipe[2], Margarita Romanenko[1], Sacha Robert[1], Mizuho Sato-Dahlman[1], Kari Jacobsen[1], Takuro Noguchi[3], Masato Yamamoto[1], Julia Davydova[1]

[1]Department of Surgery, University of Minnesota, Minneapolis, MN,[2]Minnesota Supercomputing Institute, University of Minnesota, Minneapolis, MN,[3]Department of Medical Oncology, Hokkaido University, Sapporo, Japan

Background: Oncolytic adenoviruses (OAds) are emerging as a promising class of oncolytic virotherapy. The appeal of OAds relies on their intrinsic ability to overcome tumor immunosuppression by inducing immunogenic cell death (ICD). In addition, OAds are capable of highly efficient delivery of immune-stimulating genes to cancer cells with the intent of improving antitumor immune responses. Type I interferons (IFNs), the class of cytokines employed in this study, are known for their pivotal role in both antiviral and antitumor responses. Thus, understanding IFN interactions with replicating viruses, tumor cells, and immune cells is particularly important. However, such fundamental insight is still poorly understood in the field of OAds. Here, we assessed the immunological activities of a replication-competent OAd expressing a syngeneic IFN-α (OAd-IFN) in immunocompetent, replication-permissive Syrian hamster models. **Methods and Results:** We developed novel immunological tools, including spatial transcriptomics (ST), to assess the immunomodulatory role of OAds in Syrian hamsters. Unlike commonly used mouse models, Syrian hamsters are permissive to OAd replication, providing an advantage in simulating OAds behavior in humans. We first evaluated the cytotoxicity of OAd-IFN in hamster pancreatic adenocarcinoma (PDAC) cell lines. OAd-IFN showed significantly higher cytotoxicity compared to the identical luciferase-expressing control virus (OAd-Luc). Next, we examined inflammatory responses by RT-PCR, and found that a variety of proinflammatory chemokine genes, including CXCR3 ligands, and MHC I were upregulated in OAd-IFN infected cells compared to OAd-Luc infected or uninfected cells. The level of extracellular ATP measured by bioluminescent assay was also significantly increased in OAd-IFN infected cells, suggesting the potential of OAd-IFN to induce ICD. We then investigated *in vivo* immunomodulatory activities of OAd-IFN. Hamsters bearing PDAC subcutaneous tumors were treated intratumorally with OAd-Luc or OAd-IFN ($2.5x10^9$ pfu/injection on days 0, 3, 6, 9), and analyzed on day 12. ST analysis revealed that a cluster enriched for various immune-related processes was more prevalent in the OAd-IFN treated responder compared to the OAd-IFN treated non-responder, or the OAd-Luc treated tumors. Interestingly, the immune-rich cluster spatially overlapped with the regions enriched for IFN-α response. We further evaluated *in vivo* systemic efficacy ("abscopal effect") of OAd-IFN. Hamsters bearing PDAC tumors on both flanks were treated intratumorally with PBS, OAd-Luc, or OAd-IFN unilaterally as above. Compared to the control groups, OAd-IFN showed significant tumor growth inhibition in not only the injected tumors, but also in the non-injected distant sites. Infectious viral particles (as quantified by TCID50 assay) were restricted to only the injected sites and were not responsible for the abscopal effect. To reveal the underlying cellular immunity responsible for the abscopal effect, we investigated tumor infiltrating lymphocytes by flow cytometry and found that natural killer cell population was significantly increased in the OAd-IFN group in both injected and non-injected tumors. **Conclusions:** This study demonstrated the potential of OAd-IFN to induce systemic antitumor immunity in immunocompetent OAd-permissive models and will provide crucial knowledge for clinical translation of OAd-type I IFN-based therapies for immunosuppressive tumors, such as PDAC.

365. Novel Vesiculovirus Library Characterization for Repeat Dosing Strategies

Natalie M. Elliott[1], John Vant[2], Yumei Zhou[1], Alex Baker[3], Mitesh Borad[1]

[1]Molecular Medicine, Mayo Clinic, Scottsdale, AZ,[2]Biodesign Center for Applied Structural Discovery, Arizona State University, Tempe, AZ,[3]Division of Cancer and Genetics, Cardiff University, Cardiff, United Kingdom

Vesicular stomatitis virus (VSV) is a negative strand oncolytic RNA virus with a pro-inflammatory life cycle that can immunomodulate the tumor microenvironment. In early phase clinical trials, recombinant VSV vectors have yielded preliminary evidence of anti-tumor activity. Combinatorial pre-clinical studies have shown additive/synergistic effect with checkpoint inhibitors providing the impetus for development as cancer vaccines and in conjunction with cell therapies. A critical limitation in virotherapy is repeat dosing when given intravenously due to host generated neutralizing antibodies. As such, we pursued the development of a library of novel pseudotyped vesiculovirus vectors. Herein we describe host antiviral responses, vector kinetics, and cross-neutralization of these vectors with an ultimate goal of attaining repeat dosing. We obtained five novel vesiculoviruses: Morreton (MORV), Jurona (JURV), Malpais Springs (MSPV), Isfahan (ISFV), and Radi virus (RADV). Neutralization assays with commercially available αVSV-G antibodies, clones 1E9F9 and 8G5F11, showed evasion of cross neutralization with all tested novel vesiculovirus glycoproteins. Protein modeling identified key amino acid residues in the αVSV-G antibody epitopes, followed by sequence alignment that confirmed epitope variability amongst novel vesiculovirus glycoproteins. Patient sera collected from VSV-IFNβ trial NCT01628640 mediated neutralization assays that corroborated these findings. Kinetics assays showed high titer production of all novel vesiculovirus vectors within 24-hours of viral infection. Plaque assays yielded equivalent plaque sizes in wild type vesiculoviruses compared to the respective pseudotyped VSV vector, indicative of the role the glycoprotein serves in efficient viral budding from the host cell. To

assess the ability of the novel vesiculoviruses to antagonize interferon responses we compared IFNβ release from a panel of 32 cancer cell lines following viral infection. ISFV was able to inhibit IFNβ expression at a similar capacity as VSV, with more variable IFNβ inhibition in MORV and JURV. MSPV displayed a surprising lack of interferon response inhibition. Sequence alignments identified matrix protein mutations comparable to the VSV-ΔM51 variant, engendering interest for additional mechanistic studies. Overall, our *in vitro* characterization of these novel vesiculoviruses provides a framework for logical vector engineering strategies and a toolkit that can be advanced towards clinical translation.

Other Cellular and Regenerative Therapies

366. Abeta-Responsive Cells as a Therapy in Alzheimer's Disease

Madeline R. Spetz, Dylan J. Conger, Hyosung Kim, Matthew S. Schrag, Ethan S. Lippmann, Jonathan M. Brunger

Vanderbilt University, Nashville, TN

Introduction: Alzheimer's Disease (AD) afflicts over 6.5 million Americans and has an estimated national cost of $321 billion annually. Biochemically, AD is characterized by aggregation of amyloid beta (Aβ) into plaques and tau into neurofibrillary tangles. Despite significant effort, clearance of Aβ from the brain via monoclonal antibody (mAb) therapies has not demonstrated clear cognitive benefit in clinical trials. Thus, new treatment approaches that do not rely solely on the clearance of protein aggregates are needed. Here, we present a potential cell therapy for AD. Astrocytes are engineered to express a synthetic receptor that recognizes Aβ and allows them to respond in a therapeutic manner via expression of a programmed transgene. **Methods:** We are leveraging the synthetic Notch (synNotch) platform to program cells. We have exchanged Notch domains for synthetic components to construct receptors Aβ-specific receptors: the extracellular domain for a single-chain variable fragment (scFv) of an anti-Aβ mAb and the intracellular domain for a synthetic transcription factor. As in Notch signaling, recognition of the input (ie. Aβ) will result in cleavage of the transcription factor, driving expression of programmed transgenes (Fig 1A). We built a panel of receptors by repurposing mAbs that have been tested in clinical trials. The panels were expressed in fibroblasts with reporter transgenes (mCherry, luciferase) to characterize signaling dynamic range. We then expressed high-performing receptors in human iPSC-derived astrocytes with neuroprotective (BDNF) or anti-inflammatory (soluble TNF receptor, sTNFr) transgenes. Receptor expression in engineered cells was measured by flow cytometry; receptor activity was measured by microscopy, luminescence, qPCR, and ELISA. **Results:** As measured by luciferase expression, Aβ receptors constructed from bapineuzumab, gantenerumab, and donanemab recognize synthetic $A\beta_{42}$ and $A\beta_{40}$. Each receptor exhibits a wide dynamic range - up to an 80-fold increase in transgene expression in response to Aβ - with limited background activity (Fig 1B). Human astrocytes programmed with the bapineuzumab synNotch (Bap-Notch) recognize human brain-derived Aβ, as demonstrated by mCherry (Fig 1C). Bap-Notch astrocytes produce BDNF upon recognition of synthetic $A\beta_{42}$ (Fig 1D). When stimulated by inflammatory cytokines (IL-1α, TNFα), astrocytes take on a reactive state with increased *IL6*, complement *C3*, and *SERPIN3A* expression. This inflammatory gene signature is partially attenuated by synthetically regulated sTNFr in Bap-Notch astrocytes. In astrocytes expressing a reporter transgene (SEAP) via Bap-Notch, Aβ trends toward exacerbating the inflammatory phenotype; this is not seen when synNotch drives the production of the sTNFr transgene (Fig 1E). **Conclusion:** Aβ synNotch receptors represent a promising new therapeutic approach to treating AD. Capitalizing on their native surveillance functions in the brain, astrocytes expressing these receptors can specifically recognize Aβ as a marker of disease and respond via direct upregulation of a programmed therapeutic transgene. Due to the versatility of the synNotch platform, it is possible to produce many different transgenes under control of Aβ receptors (Fig. 1A). Additionally, the expression of synNotch receptors in other cell types, such as microglia or neurons, opens the possibility of alternative cell therapies. Future studies will investigate Aβ synNotch as a gene therapy in mouse models of AD.

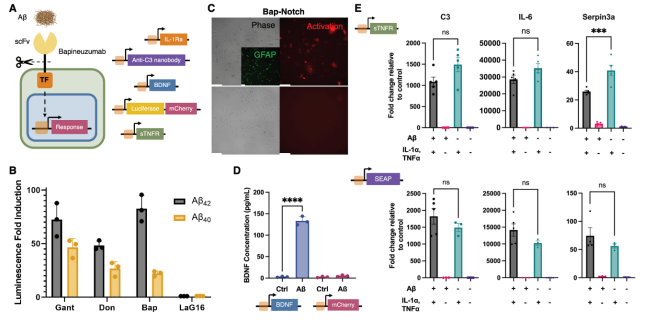

Fig. 1. Testing of Aβ synNotch receptors. **(A)** Replacement of the Notch extracellular domain by an Aβ scFv results in an Aβ-specific receptor. Recognition of Aβ cleaves the synthetic transcription factor from the transmembrane core and results in subsequent transgene expression. An mCherry-luciferase transgene was used for receptor panel screening; sTNFr and BDNF are candidate therapeutic transgenes tested. The modularity of synNotch allows for many possible transgenes. **(B)** Aβ-dependent expression of luciferase in L929 fibroblasts. LaG16 is an off-target synNotch receptor. **(C)** Activation (nCherry) in Bap-Notch astrocytes by patient-derived Aβ. GFAP confirms astrocyte phenotype. Scale bar = 200 μm. **(D)** SynNotch-driven production of BDNF transgene in Bap-Notch astrocytes cultured on synthetic $A\beta_{42}$. Magenta bars represent Bap-Notch astrocytes without BDNF transgene. ****p<0.00005. **(E)** Gene expression analysis of Bap-Notch astrocytes show partial attenuation of inflammation when Aβ results in sTNFr transgene expression; Aβ results in exacerbation of inflammatory gene signature in Bap-Notch astrocytes with control SEAP transgene. ***p<0.0005.

367. Improvement of Disease Phenotype in Beta-Thalassemic Mice with a Novel Radiation-Free Conditioning Regimen of Pro-Apoptotic mRNA

Laura Breda[1], Michael Triebwasser[2], Naoto Tanaka[1], Ariel Rivera[1], Tyler Papp[3], Awarama Akyanu[3], Jayalakshmi Ramani[3], Barbara Mui[4], Ying K Tam[4], Drew Weissman[3], Peter Kurre[5], Hamideh Parhiz[3], Stefano Rivella[1]

[1]Pediatrics, Hematology, Children's Hospital of Philadelphia, Philadelphia, PA,[2]Pediatrics, University of Michigan, Ann Arbor, MI,[3]Infectious Diseases, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA,[4]Acuitas Therapeutics, Vancouver, BC, Canada,[5]Bone Marrow Failure, University of Pennsylvania, Philadelphia, PA

Hematopoietic stem cells (HSC) are the precursors of all blood cells. HSC with inherited genetic defects can be replaced with healthy HSC through allogeneic HSC transplantation (HSCT). However, current conditioning protocols carry significant short- and long-term side effects (i.e., sterility, secondary malignancies), and can significantly delay patient recovery after HSCT, putting them at risk of additional

complications. We previously developed CD117/LNP-mRNA, a lipid nanoparticle (LNP) targeted to stem cell factor receptor (CD117), which can significantly increase the delivery of mRNA to HSC *in vivo*. We sought to test the ability of CD117/LNP to deplete BM cells using a pro-apoptotic p53 upregulated modulator of apoptosis (PUMA) mRNA that acts on the anti-apoptotic gene Mcl-1, which is implicated in survival of human and mouse HSC. We had found that treatment of murine C57BL/6 BM cells with particles loaded with (PUMA) mRNA reduced short and long-term HSC (LT-HSC) viability in culture. Competitive transplants using a combination of *ex vivo* CD117/LNP-PUMA-treated bone marrow and untreated GFP$^+$ congenic donor bone marrow, confirmed selective survival and engraftment of untreated GFP$^+$ HSC over time, indicating effective *ex vivo* depletion of the LT-HSC by CD117/LNP-PUMA. To minimize PUMA off-target expression in the liver, we modified mRNA cargo to incorporate liver-specific miRNA binding sites for mir-122 into the 3'UTR of our PUMA mRNA. Non-genotoxic conditioning by direct I.V. administration of pro-apoptotic CD117/LNP-PUMA^{mir122} accomplished the engraftment of donor HSC at rates sufficient to improve or cure congenital immune disorders, like severe combined immunodeficiencies (SCID). To improve and test the ability of this technology to correct the phenotype of diseases that require higher levels of donor chimerism (i.e. hemoglobinopathies), we utilized our conditioning regimen in a murine model of beta-thalassemia (*Hbb$^{th3/+}$*). In *Hbb$^{th3/+}$* mice, we observed that 0.125mg/kg of CD117/LNP-PUMA^{mir122} injected I.V., followed by transplantation of GFP$^+$ bone marrow, led to up to 30% red blood cells (RBC) donor chimerism. Anemia was improved: hemoglobin raised from 7.5g/dL in control mice up to 11g/dL in treated mice. Other blood parameters that are major features of ineffective erythropoiesis (RBC morphology, hematocrit levels, RBC number, and reticulocytosis) were all improved. Additionally, secondary transplantation of the bone marrow obtained from the primary chimeras showed continued GFP expression in blood cells, suggesting self-renewing and multilineage capacity of the HSC engrafted after conditioning with CD117/LNP-PUMA^{mir122} particles. Together our data indicate that *in vivo* targeting with CD117/LNP-PUMA^{mir122} particles can effectively deplete endogenous HSC, allowing successful donor engraftment without toxic chemotherapy or irradiation. The improved administration regimen allowed us to correct the phenotype of thalassemic animals, expanding the range of application of this technology to diseases that require higher level of engraftment, such as thalassemia. The ability to target and selectively deplete HSC *in vivo* offers a novel non-genotoxic conditioning regimen for HSCT and could overcome some of the limitations with current genotoxic conditioning, offering a potential new and advantageous tool to the HSCT armamentarium.

368. A Gene Agnostic Stem Cell Therapy for Mid-Stage Retinitis Pigmentosa Treatment

Deepti SIngh[1], Pierre Dromel[2]

[1]Ophthalmology, Ingel Therapeutics, Allston, MA,[2]Ophthalmology, InGel Therapeutics, Allston, MA

Retinitis pigmentosa (RP) comprises a group of progressive inherited retinal dystrophies characterized by sequential loss of rod then cone photoreceptors, resulting in disabling vision impairment. Our investigational treatment, IGT001, aims to rescue diseased photoreceptors by utilizing encapsulated human rod precursor cells that act by secreting protective protein factors. We demonstrate robust anatomical and functional efficacy across three mutant mouse models of RP. Additionally, unbiased proteomic analysis identified a subset of key secreted proteins underlying these phenotypic improvements in models. **Methods:** Rho, rd10, and P23H mutant mouse lines were used and IGT001 was intravitreally injected at disease stage analogous to mid-stage RP. IGT001 comprises hRPs encapsulated within a biomimetic hydrogel scaffold for intravitreal injection using a translational delivery platform. Testing included histological, electrophysiological, and behavioural assessments longitudinally. In parallel experiments, conditioned media harvested from hRP cultures underwent quantitative mass spectrometry-based profiling followed by sequential in vitro and in silico screening steps to delineate key factors and mechanisms conferring neuroprotective and repair properties. **Results:** Across models, IGT001 elicited >40% increased cone photoreceptor survival versus sham controls based on central retinal histology. Rescued cells maintained outer segment integrity, suggesting preserved function. This anatomical preservation was accompanied by significant gains in electrical responses to light stimuli, with x2 fold greater photopic b-wave amplitudes and cognitive optomotor reflexes, together indicating recovery of visual capacity compared to rapid deterioration in control. Proteomics identified over 300 secreted proteins, of which subsequent target validation studies functionally confirmed 10 factors modulating pathogenic processes from glycolysis dysfunction to protein misfolding as central drivers of the multifaceted treatment effects observed. **Conclusions:** In three distinct genetic RP models, sustained delivery of trophic factors by intravitreally injected allogeneic hRPCs safely preserved cone photoreceptors and visual function. Elucidating responsible protein agents and mechanisms enables optimizing potency. This platform technology may enable mutation-agnostic intervention amidst disease heterogeneity by restoring cone functions.

369. REGEN-HEPS: Expandable and Functional Hepatocytes Derived from Primary Cells

Arnav Chhabra, Sunil Mallanna, Soujanya Karanth, Sophie Cazanave, Maxwell V. Buskirk, Joseph Marturano, Tim Norman, Esha Uddin, Abhijith Kudva, Andrew M. Hashkes, Mehar Cheema, Lindsay Tomczak, Aarohi Thakkar, David Broderick, Billy Scholl, Kevin Macera, Michael Ret, Julie Morse, Eric Vanderploeg, Tom Lowery, Alireza Rezania

Satellite Biosciences, Watertown, MA

Introduction The current landscape of liver disease in the United States is alarming, with 4.5 M patients affected and over 50,000 deaths annually[1]. Cellular therapy holds promise as a potential solution, yet its progress has been hampered by the lack of a sustainable source of highly functional hepatocytes. Although primary cells function well, their availability for widespread patient use is severely limited. On the other hand, progenitor-derived cells can be produced in large quantities but do not recapitulate mature hepatocyte functions[2]. To address this critical gap, we leveraged insights from developmental biology and liver regeneration to generate REGEN-HEPS (Regenerative Expansion, Growth, and ENgraftment of primary HEPatocyteS), a novel source of primary cell-derived hepatocytes that combines

expansive growth with retention of mature hepatocyte phenotype and functions. **Methods** We utilized primary human hepatocytes (PHHs) from multiple donors, subjected them to our expansion protocol, and verified growth through a cell count assessment. During the expansion process, we confirmed maintenance of hepatic identity through immunofluorescent co-staining of HNF4α and albumin. For hepatic functional assessment, we evaluated markers across axes of synthesis, metabolism, and detoxification. To engineer the expanded cells, we employed lentiviral vectors and overexpressed a protein of interest. For in vivo assessments, we conducted intrasplenic injections of REGEN-HEPS, PHHs, and iPSC-derived hepatocytes (iPSC-Heps) into *Fah*$^{-/-}$*Rag2*$^{-/-}$*Il2rg*$^{-/-}$ (FRG) mice[3] and evaluated engraftment using secreted biomarkers like human albumin and explant assessment of Fumarylacetoacetate hydrolase (FAH) staining. **Results** Our process effectively expanded primary human hepatocytes from several different donors, with 36% (4 out of 11) of the donors showing more than 20-fold expansion in the first passage (Fig. 1Ai). We achieved > 1,000-fold expansion over two passages for one donor (Fig. 1Aii). Post-expansion, the cells retained key hepatocyte lineage markers, HNF4α and albumin, ensuring preservation of cellular identity (Fig. 1Bi). Moreover, we successfully engineered REGEN-HEPS with high transduction efficiency (94%), which is typically unattainable with standard, non-cycling PHHs (Fig. 1Bii). When placed in a three-dimensional culture, REGEN-HEPS demonstrated functional capacities on par with those of PHHs, across both synthetic and metabolic functions (Fig. 1C). Most notably, REGEN-HEPS exhibited robust repopulation abilities in vivo within the FRG mouse model, markedly outperforming iPSC-Heps, which highlights their potential for future clinical applications (Fig. 1D). **Conclusions** REGEN-HEPS offers a scalable, cGMP-compatible hepatocyte source that maintains hepatic identity during expansion and exhibits functionality on par with primary hepatocytes, both in vitro and in vivo in the FRG model. This breakthrough addresses a vital gap in the field of liver cell therapy and potentially represents a substantial step forward in the ability to treat chronic liver diseases.

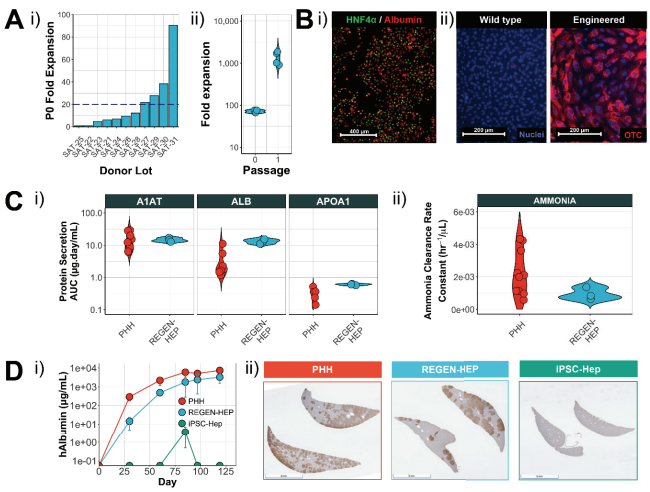

Figure 1: Comprehensive analysis of REGEN-HEP expansion, function, and therapeutic potential in vivo. **A)** Expansion of primary human hepatocytes (PHHs): i) Expansion across multiple donors with >20-fold expansion observed in 4 out of 11 donors during the initial passage (P0); ii) Over 1,000-fold expansion across two passages for one donor. **B)** i) Retention of key hepatocyte lineage markers (hepatocyte nuclear factor 4 alpha, HNF4α, and albumin) post-expansion; ii) Lentiviral-mediated overexpression of a specific protein (ornithine transcarbamylase, OTC, indicated in red) in REGEN-HEPS with 94% transduction efficiency. **C)** Functional comparisons: i) Secretion levels of liver-specific proteins (A1AT, ALB, APOA1) as measured by ELISA area under the curve (AUC) values, and ii) ammonia clearance capabilities as measured by in vitro rate constant, showing equivalence between REGEN-HEPS (n = 3 lots) and PHHs (n = 10 donors) in a 3D culture environment. **D)** In vivo validation: Successful repopulation of REGEN-HEPS in Fah$^{-/-}$/Rag2$^{-/-}$/IL2rg$^{-/-}$ (FRG) model, comparable to PHHs and superior to iPSC-derived hepatocytes (iPSC-Hep), as determined by i) circulating human albumin (hAlbumin) levels and ii) Fumarylacetoacetate hydrolase (FAH) staining.

370. A Synthetic Receptor Platform to Program Mesenchymal Stromal Cells for the Detection and Treatment of Osteoarthritis

Bonnie L. Walton[1], Rebecca Shattuck-Brandt[1], Catherine A. Hamann[1], Victoria W. Tung[1], Juan M. Colazo[1], David D. Brand[2], Karen A. Hasty[3], Craig L. Duvall[1], Jonathan M. Brunger[1]

[1]Biomedical Engineering, Vanderbilt University, Nashville, TN,[2]Microbiology, Immunology and Biochemistry, University of Tennessee Health Science Center, Memphis, TN,[3]Department of Orthopaedic Surgery and Biomedical Engineering, University of Tennessee Health Science Center, Memphis, TN

Introduction: Osteoarthritis (OA) is a joint disease that affects over 32 million Americans, leading to pain and limited mobility. No disease-modifying drugs exist. Cartilage catabolism, which exposes a collagen II (CII)-rich extracellular matrix, is a biophysical hallmark of OA brought about by several factors including inflammation from cytokines such as IL-1. Current cell engineering strategies to treat OA rely on unregulated expression of therapeutic transgenes and thus do not guide cell behaviors based on disease-specific pathology. Here, we present a synthetic receptor design strategy to activate therapeutic transgene expression by engineered cells that is spatially constrained to damaged cartilage. **Methods:** We leveraged the synthetic Notch (synNotch) receptor platform, which is based on native Notch signaling and requires an immobilized ligand for receptor activation. By engineering a scFv from a monoclonal antibody targeting CII (mAbCII) as an extracellular receptor domain, as well as a synthetic intracellular transcription factor to regulate inducible transgene expression, we engineered a CII-synNotch receptor that allows cells to recognize an OA-specific biomarker and perform regenerative functions that ameliorate the disease (**Fig. 1A**). Lentiviral vectors encoding the

receptor and inducible transgenes were used to co-transduce primary marrow-derived murine mesenchymal stromal cells (MSCs). For CII-decorated surface experiments, purified CII was adsorbed to culture vessels overnight for ligand presentation to CII-synNotch MSCs. In tissue-based activation experiments, porcine cartilage explants were cryosectioned and enzymatically degraded with 0.25% trypsin-EDTA to expose the CII network, mimicking arthropathy. Activation was assessed via bioluminescence and fluorescence microscopy. Gene expression was quantified with qRT-PCR. **Results:** CII-synNotch MSCs demonstrate robust (40-fold) activation on 25 µg/ml CII (**Fig. 1B**). Engineered cells expressing activation-dependent mCherry on porcine cartilage explants reveal spatially regulated expression, but do not activate when occupying regions out of contact with the cartilage substrate (**Fig. 1C**). SynNotch-induced expression of pro-anabolic TGFβ3 led to an increase in *Acan* and *Col2a1* gene expression, as well as a decrease in hypertrophic *Col1a1* (**Fig. 1D**). CII-synNotch mMSCs engineered to inducibly express anti-inflammatory IL-1 receptor antagonist (IL-1Ra) were plated in a co-culture with ATDC5 chondrocytes stimulated with IL-1 (**Fig. 1E**). IL-1Ra-producing synNotch MSCs antagonized chondrocyte inflammation in a CII-dependent manner (**Fig. 1F**). **Conclusions:** Using CII as an OA biomarker for synNotch transgene expression enables cells to be functional detectors of arthropathy and serve as living therapies. The regulation conferred by CII-synNotch MSCs may circumvent off-target effects of biologic drugs by restricting expression to niches displaying direct signatures of OA pathology. This work demonstrates the first use of the synNotch platform for therapeutic transgene expression in the context of musculoskeletal systems.

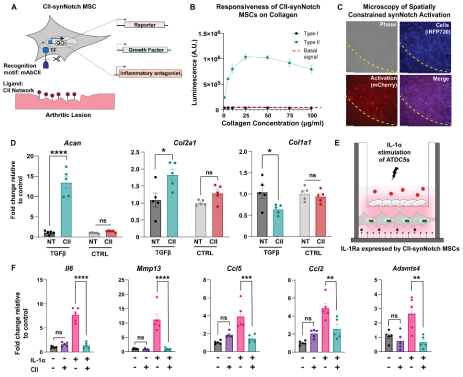

Figure 1: CII-synNotch MSCs detect CII in arthritic cartilage for programmable transgene expression. **(A)** The synNotch receptor works by 1) receptor recognition of exposed CII; 2) transmembrane cleavage; 3) release of a transcription factor that regulates gene expression. **(B)** Engineered cells activated potenty on 25µg/ml CII (t=72hr). **(C)** Cells (constitutive near-infrared fluorescent protein, or iRFP, false-colored blue for visualization) activate spatially restricted transgene expression (inducible mCherry) on physically damaged cartilage cryosections (t=48hr, scale=200µm). **(D)** Gene expression of engineered cells with either pro-anabolic TGFβ3 or control transgenes (t=72hr). **(E)** Trans-well schematic of co-culture with or without stimulated chondrocytes (top) and engineered MSCs with or without CII (bottom). **(F)** Gene expression of chondrocytes demonstates antagonism of inflammation when co-cultured with activated IL-1Ra-expressing CII-synNotch MSCs (t=5d). *p<0.05, **p<0.01, ***p<0.001,****p<0.0001.

371. Genetic Modification of Vascularized Composite Allografts via *Ex Vivo* Machine Perfusion

Raphaela Bento[1,2,3], Irina C. L. J. Filz von Reiterdank[1,2,4], Antonia T. Dinicu[1,2], A. B. Mink van der Molen[4], J. H. Coert[4], Curtis J. Cetrulo[2], Biju Parekkadan[1,3], Korkut Uygun[1,2]

[1]Center for Engineering in Medicine and Surgery, Massachusetts General Hospital, Harvard Medical School, Boston, MA,[2]Organ Reengineering Laboratory, Shriners Children's Boston, Boston, MA,[3]Biomedical Engineering, Rutgers University, Piscataway, NJ,[4]UMC Utrecht, Utrecht University, Utrecht, Netherlands

Introduction: Lentiviral vectors have been extensively explored as gene delivery tools due to their ability to provide long-term and stable transgene expression, being promising candidates to promote genetic modification of organs. Ex vivo machine perfusion can be used in clinic to improve graft function, providing hours during which an organ can be preconditioned and modified as desired. This study aims to determine the feasibility of combining both approaches to enable targeted modifications of Vascularized Composite Allografts (VCA). VCA transplantation is one of the only options to restore motor function and reconstruct severe defects arising from trauma and burn injuries. However, its use in clinic remains limited due to the high incidence of acute rejection and side effects. Therefore, the field would significantly benefit from genetic engineering applications to locally resolve inflammation and rejection. This proof-of-concept study demonstrates the first successful genetic modification of VCAs post-transplantation. **Methods:** Lentiviral vectors expressing a secreted biomarker (*Gaussia Luciferase* - GLuc) under the constitutive promoter EF1α were generated using triple-transfection methods. Viral supernatant was collected, filtered, centrifuged, purified, and stored at -80oC. Vector titer was determined by qPCR. In vitro transduction efficiency studies were performed with primary rat myocytes and supernatant was analyzed for GLuc secretion. In vivo, hindlimbs of male Brown Norway rats were perfused at 37°C for 12h. $1.3x10^9$ viral particles were injected and recirculated for 11h. Perfusate was collected for gas and tissue injury marker analyses. Partial hindlimbs were transplanted to male Lewis rat recipients; animals were monitored for 8 days. Blood was drawn on post-operative days (PODs) and analyzed for biomarker secretion. Protein was extracted from tissue samples and analyzed for biomarker expression. **Results:** Viral transduction efficiency in primary cells exhibited a dose-dependent response (**Fig. 1 A-B**), guiding the selection of parameters for in vivo applications. Perfusion apparatus was used for ex vivo delivery of viral vectors before transplantation (**Fig. 1C**). Plasma at POD3 showed significantly increased GLuc levels compared to pre-operative levels, and signal strengthened over time. (**Fig. 1D**). In vivo bioluminescent imaging on POD8 showed a stark difference compared to control graft, with a 10-fold increase in radiance signal and comparable clinical evolution (**Fig. 1E**). Tissue assessment showed significant GLuc levels in transplanted tissues only, suggesting lack of off-target effects (**Fig. 1F**). **Conclusions:** This study demonstrates the feasibility of using ex vivo machine perfusion as a delivery system to achieve successful genetic modification of VCAs. Lentiviral vectors are effective in transducing primary cells and perfused grafts, however higher doses and longer exposure times are necessary to obtain such results. Post-

transplantation, transgene is increasingly expressed in target tissues. This approach opens many possibilities for graft modification and extended preservation.

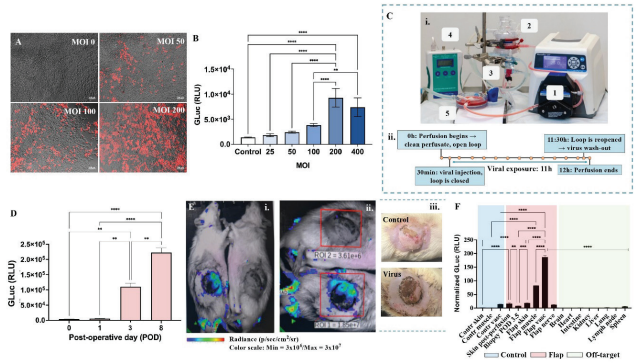

Figure 1. Genetically modified VCAs exhibit transgene expression post-transplantation. (A) Primary cells were treated with increasing MOIs (multiplicity of infection) of lentiviral vectors and exhibited dose-dependent transgene expression. **(B)** Similarly, biomarker secretion confirmed dose-dependent transduction efficiency (One-way ANOVA, **p≤.01; ***p≤0.001; **** p≤.0001). **(C) i.** *Ex vivo* machine perfusion apparatus, consisting of: 1) Roller pump; 2) Oxygenator; 3) Bubble trap; 4) Pressure monitor and 5) Basin with limb. **ii.** Schematic of viral perfusion protocol, with viral exposure of 11 hours. **(D)** GLuc expression in plasma increased significantly over time (POD = post-operative day). **(E) i.** Luminescent signal in transplanted partial hindlimb (left) compared to no signal in control transplant (right); **ii.** Enlarged regions of interest (ROI) show a 10-fold lower radiance signal in control hindlimb (top) compared to viral-perfused hindlimb (bottom). **iii.** Clinical state of VCA transplants at POD 7. **(F)** Each VCA tissue type and other organs exhibited significant local transduction without off-target effects (One-way ANOVA, **p≤.01; ***p≤0.001; **** p≤.0001).

372. Nongenotoxic CD45-ADC-Based Conditioning Maintains Potent Suppression of Plasma Viremia in Nonhuman Primate Model of HIV

Jason D. Murray[1], Teresa Einhaus[1], Carly Starke[1], Stefan Radtke[1], Christopher W. Peterson[1,2], Hans-Peter Kiem[1,2]

[1]Fred Hutchinson Cancer Center, Seattle, WA,[2]University of Washington, Seattle, WA

Introduction: Although hematopoietic stem and progenitor cell (HSPC) gene therapies provide lifelong benefit in numerous hematological diseases and disorders, safety and toxicity remain a critical barrier for routine application. In the setting of immunodeficiency syndromes and infectious diseases such as human immunodeficiency virus (HIV) infection, conditioning regimens may exacerbate immune dysfunction, undercutting measures of efficacy. We previously showed this in our nonhuman primate (NHP) model of HIV, where myeloablative conditioning with total body irradiation potentiated rather than reduced viral reservoirs due to a conditioning-induced loss of immune control. Our NHP model is ideally suited to identify regimens that replace or augment hematopoietic subsets with minimal impact on host immunity. In this study, we further sought to maximize engraftment of CRISPR-edited HSPCs and redirect cytoreductive approaches to i) reduce the number of infected cells *in vivo*, and ii) maintain robust virus-specific immunity. Methods: Enriched CD34$^+$ HSPCs were edited with NHP *CCR5*-specific CRISPR ribonucleoprotein (RNP) complexes, then cryopreserved. Three conditioning regimens were compared: antibody-drug conjugate (ADC) regimens targeting either CD117 or CD45 and myeloablative busulfan. We quantified extent of myeloablation/immunosuppression, time to hematopoietic recovery, long-term engraftment of CRISPR-edited autologous HSPC, and resistance to infection when challenged with increasing concentrations of an HIV-like virus. We further compared busulfan and CD45-ADC in our preclinical model of antiretroviral (ART)-suppressed HIV infection. Results: We observed myeloablation with similar rates of hematopoietic recovery, preserved lymphocyte counts, and long-term engraftment of *CCR5*-edited cells with all three conditioning regimens. Neither ADC conditioning nor busulfan augmented SHIV susceptibility in a prophylaxis model. Engraftment of edited cells was highest with busulfan conditioning, with frequencies as high as 40% in peripheral blood. While both CD117-ADC and CD45-ADC conditioning supported similar levels of editing, some CD45-targeted animals showed engraftment with reduced or no neutropenia. In our preclinical model of HIV latency, both busulfan and CD45-ADC elicited myeloablation and mild lymphopenia while maintaining potent suppression of plasma viremia and similar long-term *CCR5* editing efficiencies in peripheral blood. In animals assessed shortly after transplantation, we observed tissue-specific depletion of CD45$^+$ cells after conditioning with ADC. Conclusions: We have advanced our model of HIV-specific HSPC gene therapy in a clinically relevant model and observe long term persistence of CCR5-edited HSPC and progeny *in vivo* after targeted conditioning. Myeloablative busulfan, CD117-ADC and CD45-ADC conditioning all supported engraftment without impaired resistance to SHIV. In our model of antiretroviral therapy-suppressed HIV infection, hematopoietic recovery and engraftment of edited cells after CD45-ADC conditioning was comparable to busulfan and achieved tissue-specific depletion of CD45$^+$ cells. We are investigating the ability of this approach to clear latent viral reservoirs at these sites, and the ability of *CCR5*-edited HSPC to synergize with treatment strategies utilizing anti-HIV broadly neutralizing antibodies. These results are a promising step towards developing targeted strategies to engraft cells with therapeutic edits and antibody-based selection without the need for alkylating chemotherapies which are also relevant for malignancies and hemoglobinopathies.

Novel Immune Effector Cell Manufacturing

373. Single-Chain Variable Fragment Affinity Tuning Can Optimize Anti-AML CAR-NK Cell Functionality

Ruyan Rahnama[1], Huilin Yang[2], Monika Kizerwetter[2], Natalie Holl[1], Jun Choe[1], Stamatia Vorri[1], Arjun Modi[1], Jamie Spangler[2], Challice Bonifant[1]

[1]Johns Hopkins School of Medicine, Baltimore, MD,[2]Johns Hopkins University, Baltimore, MD

Background: CD123 is overexpressed on AML blasts relative to healthy myeloid progenitor cells. We hypothesize that CD123 targeting Chimeric Antigen Receptor (CAR)-modified NK cells with affinity tuned single-chain variable fragments (scFvs) can be engineered to discriminate target based on surface density for enhanced killing of leukemic cells. **Methods:** We designed CD123 targeting CARs using published scFv sequences of empirically validated affinity (7G3 WT K_d 8.75nM; variant K_d range 23.9-64.9nM) fused to intracellular portions of the NK-activating receptors 41BB and CD3ζ. CARs were retrovirally transduced into primary NK cells and surface expression measured by flow cytometry. CD123 negative Raji parental cells were engineered to generate pure model cell lines with low (Raji.CD123Low: 4.7x10^4

CD123/cell) and high (Raji.CD123High: 5.8x10^5 CD123/cell) CD123 expression correlative to healthy cells and AML blasts, respectively. We tested antigen-specific CAR NK cell activation and cytotoxicity using short- and long-term coculture assays. We used confocal microscopy to quantify membrane polarization at the CAR-NK and target cell immunological synapse. We studied CAR-NK activity in vivo with systemic inoculation of the AML cell line MOLM13. Firefly Luciferase (ffLuc) expressing CAR-NK cells were injected via tail vein and trafficking and persistence monitored with bioluminescence imaging. **Results:** CAR-NK cells showed antigen-specific cytotoxicity against CD123$^+$ target cells compared to non-transduced control NK cells. Low affinity (7G3L) CAR-NK cells demonstrated more powerful short-term cytotoxicity when compared to higher affinity (7G3M, 7G3 WT) CAR-NK cells against Raji.CD123High (7G3L vs 7G3 WT $p < 0.5$) and MOLM13 (7G3L vs 7G3 WT: $p<0.5$; 7G3L vs. 7G3M <0.001) at a 1:2 effector to target ratio. 7G3L CAR-NK discriminated on antigen density with significantly higher short-term cytotoxicity against Raji. CD123High compared to Raji.CD123Low in vitro (7G3L vs 7G3 WT: $p<0.01$) at 1:2 and 1:1 effector to target ratios. 7G3L CAR-NK demonstrated greater persistence in killing relative to 7G3 WT CAR-NK with serial stimulation of the AML cell lines MOLM13 and MV411, though overall persistence of activity was limited. 7G3 and 7G3L CAR-NK had significantly higher polarization of perforin granules at the immune synapse when compared to non-transduced control NK cells but no differences were observed related to binding affinity. 7G3L CAR-NK cells displayed more robust expansion in vivo relative to 7G3 WT CAR NK cells. **Conclusions:** Lower affinity 7G3L CAR-NK cells demonstrate greater short-term and long-term cytotoxicity against high CD123-expressing targets and can discriminate antigen density in vitro with preferential killing of high CD123-expressing targets. 7G3L CAR-NK demonstrate greater expansion in a systemic AML mouse model. These data support the role of affinity tuning to fully optimize cellular therapy designed to treat cancer.

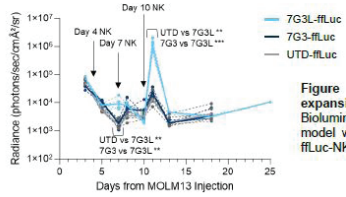

Figure 2. 7G3L CAR-NK demonstrate superior expansion in a systemic AML mouse model. Bioluminescent quantification of NK cells in systemic AML model with MOLM13 inoculation on Day 0 followed by ffLuc-NK cells administration on Day +3, +7, and +10.

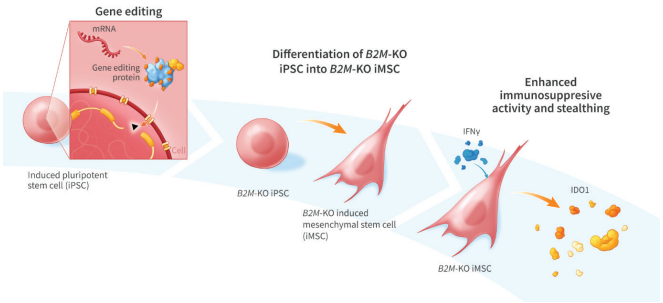

374. iMSCs Derived from mRNA-Engineered B2M-KO iPSCs Exhibit Enhanced Immunosuppressive Activity and Stealthing Features

Raven Dance Hinkel[1], Elizabeth Belcher[1], Christopher B. Rohde[2], Matthew Angel[2], Kyle M. Garland[1]

[1]Eterna Therapeutics Inc., Cambridge, MA,[2]Factor Bioscience Inc., Cambridge, MA

While mesenchymal stem cells (MSCs) have repeatedly demonstrated significant therapeutic potential in numerous preclinical models, their clinical translation has been greatly impeded by variability in therapeutic responses. This variability is often attributed to donor and source heterogeneity and limited expansion potential. Furthermore, MSCs can exhibit limited *in vivo* persistence due to clearance by host immune cells, which can also contribute to deficient therapeutic responses. Induced pluripotent stem cell (iPSC)-derived MSCs (iMSCs) promise to directly address many of the fundamental challenges facing MSC translation. We have previously shown that iMSCs generated using mRNA reprogramming exhibit ~4-fold greater population doublings *in vitro* relative to tissue-derived MSCs and can significantly attenuate the severity of sepsis-induced acute lung injury in an ovine model of acute respiratory distress syndrome (ARDS). In addition to improved consistency and therapeutic potency, the upstream iPSCs are an ideal platform for cell engineering applications, where a clonal population of edited cells is desired. Here, we report the development of a beta 2 microglobulin-knockout (*B2M*-KO) iMSC line with enhanced immunosuppressive activity and stealthing features that may further augment the therapeutic potential of MSCs in treating inflammatory diseases by precluding batch-to-batch inconsistencies, promoting *in vivo* persistence, and enhancing the effector function of the cells. *B2M* was inactivated in iPSCs by introducing a biallelic 14 bp deletion at exon 2 of the *B2M* gene using mRNA encoding NoveSlice™, a proprietary dimerizing chromatin-context-sensitive gene-editing endonuclease. Following colony selection and knockout verification via amplicon sequencing, *B2M*-KO iPSCs were differentiated to *B2M*-KO iMSCs using our previously published protocols. Successful MSC differentiation was confirmed by flow cytometry (CD90+, CD73+, CD105+, TRA-1-60-, TRA-1-80-, CD34-) and trilineage differentiation (adipogenesis, osteogenesis, and chondrogenesis). *B2M*-KO iMSCs displayed no evidence of HLA-I or HLA-II expression both before and after interferon gamma (IFNγ) stimulation, whereas wild-type iMSCs expressed HLA-I (59% HLA-ABC) and no HLA-II (0% HLA-DR) prior to IFNγ stimulation and both HLA-I (99%)

and HLA-II (94%) after IFNγ stimulation. Additionally, *B2M*-KO iMSCs significantly upregulated the immunoregulatory enzyme Indoleamine 2,3-dioxygenase 1 (IDO1) upon IFNγ stimulation relative to wild-type iMSCs as demonstrated by both western analysis and immunofluorescence staining. The immunomodulatory potential of the *B2M*-KO iMSCs was evaluated using a PBMC-proliferation assay. Cells were co-cultured with CFSE-labeled PBMCs in the presence of a CD3/CD28 T cell stimulator for 96 hours. Cells co-cultured with *B2M*-KO iMSCs exhibited significant reduction in PBMC proliferation (92% suppression), as compared to wild-type iMSCs (82% suppression; p=0.04) and tissue-derived MSCs (40% suppression; p<0.0001). *B2M*-KO iMSCs are more likely to evade immune clearance and exert their immunomodulatory effects, as demonstrated by their enhanced sensitivity of IDO1 expression and their improved ability to inhibit PBMC proliferation. Our data suggest that *B2M*-KO iMSCs may be a promising therapeutic agent for T-cell mediated autoimmune and inflammatory indications.

375. Massively Parallel CAR-T Cell Phenotyping Enables Identification of High Efficiency Candidates

Yanping Yang[1], JangKeun Kim[2], Richard Yau[3], Ronan Russell[3], Pier Federico Gherardini[3], Magnolia Bostick[3], Liz Wu[3], Tarun Khurana[3], Moonsoo M. Jin[1], Christopher E. Mason[2], Mostafa Ronaghi[3], Gary Schroth[3]

[1]Houston Methodist, Houston, TX,[2]Cornell University, Ithaca, New York, NY,[3]Cellanome, Palo Alto, CA

Chimeric Antigen Receptor - T cell (CAR-T) therapy is a rapidly progressing field within cancer treatment and beyond, aiming to harness the immune system to fight disease. Despite early successes, there are remaining hurdles to making this treatment strategy more efficacious, safe, and applicable to larger patient populations. One hurdle is the heterogeneity of cell products typically generated through lentiviral CAR delivery to patient T cells. Considerable interest exists in identifying and deeply characterizing which cell populations are most amenable to target cell killing to enable the next generation of CAR-T's. However, current efforts to characterize cell products are inefficient or yield limited results because they utilize multiple independent assays and reconstruct a patchwork overview of cellular states, leading to experimental noise. Here, we describe a novel platform integrating multiple assays on live single cells or heterogenous groups of cells, with the aim to accelerate and streamline cell product characterization. By employing photo-guided polymerization of hydrogels, we can create tens of thousands to hundreds of thousands of individual semi-permeable compartments per run, configurable in size from microns to millimeters. This enables continuous reagent delivery to integrate cellular phenotypes, including cell proliferation, morphology, cell-cell interactions (e.g. cell killing), cytokine secretion, and intracellular or cell surface immunostaining coupled with real-time live cell imaging. Our image analysis tools are trained to accurately differentiate heterogeneous cell populations, providing automated quantification of cell phenotypes and numbers, thereby simplifying data analysis. Following the desired period of longitudinal functional analysis, cells can then be lysed directly on the flow cell to generate barcoded libraries for downstream sequencing (e.g. single-cell RNA). We applied this technology to investigate and characterize an affinity-tuned CAR T (AIC100) targeting intercellular adhesion Molecule 1 (ICAM1). ICAM1 is a cell surface glycoprotein overexpressed in many types of tumors and the associated stroma. AIC100 is generated via lentiviral transduction ICAM1 with myc-tag to human primary T cells and is currently being assessed in clinical trials in patients with anaplastic thyroid cancer. Using this platform, we co-cultured individual CAR-T effector cells with HeLa target cells that overexpress ICAM1 in hydrogel compartments and tracked target cell killing with Sytox live/dead dye. We could simultaneously differentiate between myc-tagged CAR+ and CAR- cells and further characterize them as CD4+ or CD8+ T cells. We further coupled this with cytokine analysis (e.g. IFNγ and Perforin) to identify subsets of CAR-T cells that have higher target cell-killing efficiency. Single-cell RNA seq data of the heterogenous CAR-T populations, linked to phenotype and function, is being mined for detailed cell annotation, differential gene expression, and pathway analysis to interrogate whether there are unique gene signatures that correlate highly potent cells. Taken together, these data demonstrate the power of the Cellanome platform to incorporate multiple functional readouts from heterogeneous cell therapy products and elucidate complex phenotypes via longitudinal proteomics, imaging, and transcriptomics in a single workflow. This technology is well-suited to characterize the functionality of cells longitudinally and multi-modally correlate their properties to patient outcomes (e.g. durable response, cytokine release syndrome) and improve cell engineering and cell product criteria.

376. Chimeric Antigen Receptor Engineered Tregs with Donor Specificity and Enhanced Functional Stability for the Induction of Liver Transplantation Tolerance

Madhav Kishore, Jenny Louise McGovern, Georgios Eleftheriadis, Eva Crespo-Rodriguez, Nathalie Belmonte, Julieta Karegli, Anthony Sowerbutts, Marc Martinez-Llordella

Quell Therapeutics, London, United Kingdom

Regulatory T cells (Tregs) are essential for the maintenance of immune tolerance and to regulate inflammatory responses. It has been reported that Tregs can mediate donor-specific responses and induce allograft tolerance in multiple transplantation models. Therefore, multiple strategies have been proposed to modulate Treg function in the clinic to induce transplantation tolerance. However, several challenges are limiting their therapeutic effectiveness, such as the lack of antigen specificity to allow the activation and accumulation of Tregs in

the allograft, and the loss of phenotypic stability in inflammatory microenvironments hampering their suppressive function. QEL-001 is an autologous engineered Treg therapy designed to overcome the limitations encountered in previous clinical approaches to induce donor-specific tolerance in liver transplanted patients. Natural Tregs from liver recipients are selected and transduced with a multi-modular lentiviral construct that mediates constitutive expression of a chimeric antigen receptor (CAR) specific for the donor graft, a phenotype lock™, and a safety switch. The use of an anti-HLA-A2 CAR mediates the specific targeting of liver allograft in those HLA-A2 negative recipients that received an organ from HLA-A2 positive donors. Furthermore, the transduction of the exogenous FOXP3 gene safeguards the constitutive expression of the Treg master transcription factor independently of microenvironmental cues. The CAR-Tregs from QEL-001 products show consistent expression of the 3 transgenes, while preserving the transcriptional and protein expression patterns of non-transduced Tregs. Optimal expression levels of hallmark Tregs-associated markers such as FOXP3, HELIOS and CTLA4, together with persistent demethylation status of the TSDR region of FOXP3 gene and minimal expression of pro-inflammatory cytokines characterise the phenotype of the QEL-001 product. The in vitro culture of QEL-001 with HLA-A2 expressing cells promotes antigen-specific activation of the CAR-Tregs driving the expression of CD69 and CD137 markers and triggering cellular proliferation. In addition, the CAR-Tregs show efficient suppression of effector T cell proliferation and modulation of B cell costimulatory receptors in an antigen-specific matter. The addition of the phenotype lock™ maintains the suppressive capacity of CAR Tregs in the presence of pro-inflammatory cytokines. Finally, QEL-001 displays durable immunoregulation of inflammatory responses in a humanized model of xenoGvHD supporting its therapeutic efficacy and product safety. Overall, the QEL-001 multi-modular approach overcomes the limitations of previous Treg-directed therapies and pioneers the clinical implementation of autologous cell therapies for the induction of immune tolerance in liver transplanted patients.

377. NK510, a Small Genetic Edit, a Giant Leap for NK Cells

Han Ying[1], Chao Yao[2], Cheng Fang[2], Guanglei Li[3], Lixin Wang[2], Yufu Zhou[2], Chenyuan Gong[2], Juewan Li[3], Yiming Wang[3], Wenwen Fan[3], Fenghua Lv[3], Xiaohu Shao[3], Haiyang Zhao[3], Liling Wang[3], Jun Yan[3], Tianhong Xu[3], Shiguo Zhu[2]

[1]Base Therapeutics (US) Co., Ltd, San Mateo, CA,[2]Shanghai University of Traditional Chinese Medicine, Shanghai, China,[3]Base Therapeutics (Shanghai) Co., Ltd, Shanghai, China

Natural Killer (NK) cells hold great promise for cancer therapy owing to their innate ability to detect cells expressing signs of stress or infection. However, NK cell-based therapeutics face significant challenges: 1. Limited Expansion: It has been challenging to grow a sufficiently large quantity of NK cells for costeffective therapeutic infusions. 2. Genetic Modification Resistance: NK cells have exhibited notable resistance to genetic modifications that could enhance their ability to target specific cancer cell types. In response, we present our pioneering work in the development of Base Editing-Directed NK cell products, known as BED-NK, tailored for cancer treatment. We used the second-generation High-Fidelity Base Editor AccuBase™ developed within our company to knockout inhibitory proteins that bind to the receptors that are overexpressed by many cancer types. AccuBase™ (ceBE) has the highest editing efficiency in the industry, with zero off target events. This was achieved by strategically inserting deaminases into Cas9 at specific, tolerance-verified sites, a process guided by an extensive transposon-based genetic screening, protein engineering, and direct evolution approach. AccuBaseTM protein forms a complex with the sgRNA, but the inserted deaminase has not yet engaged with the target DNA and is not in contact with any non-targeting dsDNA because it is hidden inside the protein. This mechanism avoids guide RNA independent indiscriminate offtarget mutations that was a common problem of the first-generation base editing tool. Upon guided by sgRNA, the AccuBaseTM protein associates with the target double-stranded DNA, triggering structural alterations within the AccuBaseTM protein. This results in the outward exposure of the deaminase domain, facilitating the editing of the target base. AccuBaseTM (ceBE) substantially reduces off-target effects while maintaining on-target editing when compared to BE4max. This improvement has been confirmed in multiple human cell lines, mouse cell lines, human primary T and NK cells, human embryonic stem cells, and in animal embryos and liver. Through a meticulously planned optimization process, we have achieved over 90% editing efficiency in Peripheral Blood Mononuclear Cell (PBMC) NK cells using our high-fidelity Base Editor, AccuBase™. Additionally, we established NKBoost+ expansion system that is capable of generating a millionfold expansion of BED-NKs, referred to as NK510, within a 21-day expansion protocol. Notably, NK510 cells exhibit exceptional levels of purity, cytotoxicity, and viability. By knocking out inhibitory receptors in NK cells, we have prompted tumor cell-derived inhibitory ligands to interact with activating receptors (AR), initiating activating signals within the NK cells. This transformation effectively converted an inhibitory ligand into an activating one, resulting in tumor regression in multiple mouse models, including sarcoma. These results underscore the feasibility of combining base editing with ex vivo expansion of NK cells, significantly enhancing their therapeutic potential in clinical settings.

378. G Protein-Coupled Receptor Class C Group 5 Member D (Gprc5d) and B-Cell Maturation Antigen (BCMA) Bi-Specific Dual Chimeric Antigen Receptors (CARS) Effectively Address Antigen Escape and Tumor Heterogeneity Challenge in Multiple Myeloma (MM)

Chia-Wei Chang, Hui Ding, Lukasz Wlodarek, Kevin Nguyen, Yonghua Luo, Mandana Karimi, Shailaja P. Rao, Arpita S. Pal, Yi-shin Lai, Sihui Guan, Weimin Li, Weijie Lan

Overland Pharmaceuticals (CY) Inc, South San Francisco, CA

BCMA-directed CAR-T therapy shows remarkable efficacy in multiple myeloma (MM) patients, however, challenges like heterogeneous tumor BCMA expression, antigen escape, and limited treatment options upon resistance still post significant hurdles in relapsed patients. Dual targeting of MM-associated antigens could address these challenges and offer durable efficacy in BCMA-resistant MM patients. In this study, we present the development of a bi-specific CAR targeting GPRC5D

and BCMA simultaneously, demonstrating its efficacy, both *in vitro* and *in vivo*. Altogether, 41 GPRC5D and 36 BCMA VHH binders were identified from synthetic library screening and alpaca immunization. These binders were incorporated into lentiviral CAR constructs and tested for NFAT mediated signals in a Jurkat reporter platform. CARs with high antigen specific response and low non-specific and tonic signaling (Table 1) against antigen positive and negative target cell lines were prioritized for downstream functional assessments. Multiple GPRC5D and BCMA CARs were shown with better *in vitro* efficacy than benchmark (BM) GPRC5D and BCMA CARs (Table 1). Long-term and repetitive tumor challenge assays were performed using MM tumor lines OPM-2, NCI-H929 and RPMI-8226 to assess *in vitro* anti-tumor activities of the selected CARs. Several CARs were proved to have superior durable tumor growth inhibition comparable to BMs (Table 1). Next, bi-specific CARs (bsCAR) targeting both GPRC5D and BCMA were created using validated monovalent binders. During *in vitro* tumor restimulation assay against NCI-H929 tumor line, multiple bsCAR designs demonstrated superior long-term tumor growth control versus BM (Table 1). In this setting, our lead bsCAR T cells showed comparable antigen specific proliferation to BCMA BM and GPRC5D BM after 2 rounds of NCI-H929 challenging *in vitro* (Table 1). For cytokine production, the lead bsCAR T cells also generated high levels of GM-CSF, Granzyme-B, IFN-γ and TNF-α upon antigen stimulation (Table 1). Furthermore, in antigen escaping models, GPRC5D and BCMA bsCAR T cells efficiently suppressed growth of cells expressing only GPRC5D or BCMA antigens but spared double negative cells. Finally, in a disseminated NSG mouse model bearing MM cell line OPM-2, our top bsCAR T cells demonstrated highly efficient tumor growth inhibition, exhibiting competitive profiles to BCMA and GPRC5D BMs (Table 1) with an improved survival rate observed at Day 34 post-infusion. In conclusion, we have developed a novel VHH-based GPRC5D and BCMA bi-specific CAR product that efficiently suppresses tumor growth *in vitro* and *in vivo*. The dual-antigen targeting bi-specific CAR-T cells maintained robust anti-tumor efficacy even in models of antigen-escape. Together, these findings suggest the promising potential for treating MM patients resistant to BCMA-directed therapies due to antigen-escape or heterogenous BCMA expression.

Table 1. Characterization of tonic and antigen-specific signaling and anti-tumor activities of GPRC5D CAR, BCMA CAR and bi-specific CARs

Tonic and antigen specific NFAT signaling and anti-tumor activities of monovalent CAR leads						
	Tonic signal (%GFP)	Antigen-specific signal against NCI-H929 (%GFP)	Tumor growth suppression against OPM-2 (AUC normalized to BM)			
GPRC5D CAR#1	9.2%	89.1%	0.69			
GPRC5D CAR#2	5.0%	85.6%	0.84			
GPRC5D CAR#3	5.5%	87.6%	0.69			
GPRC5D BM	5.3%	82.2%	1.00			
BCMA CAR#1	12.0%	81.0%	0.61			
BCMA CAR#2	13.2%	79.9%	1.00			
BCMA CAR#3	13.3%	79.7%	0.83			
BCMA BM	15.1%	78.1%	1.00			
***In vitro* expansion and anti-tumor activities of bi-specific CAR leads**						
	Fold of expansion (2 rounds with NCI-H929)	*In vitro* tumor growth suppression against NCI-H929 (AUC normalized to BCMA BM)	Antigen-specific cytokine production against OPM-2 (concentration normalized to GPRC5D BM)			
			GM-CSF	Granzyme B	IFN-γ	TNF-α
bsCAR#1	289x	1.06	11.38	2.58	2.15	25.16
bsCAR#2	227x	0.88	3.43	1.66	1.84	5.41
bsCAR#3	313x	1.07	4.26	1.61	2.51	12.52
GPRC5D BM	384x	-	1.00	1.00	1.00	1.00
BCMA BM	282x	1.00	4.68	1.85	2.53	17.22
***In vivo* anti-tumor activities of bi-specific CAR: tumor growth suppression against OPM-2**						
	Total flux (D20 relative AUC)*		% Survival at D34			
bsCAR#1	1.74		0%			
bsCAR#2	2.38		20%			
bsCAR#3	0.44 (p=0.05, vs.BCMA BM)		80% (p=0.0719, vs.BCMA BM)			
GPRC5D BM	8.97		0%			
BCMA BM	1.0		10%			

Abbreviation: AUC, Area under the curve; BM, Benchmark
*Total flux at day 20 relative to AUC for tumor alone = 8.69

379. A Same-Day Manufacturing Platform Leveraging an RNA-Based Lipid Nanoparticle (LNP) Gene Writer System to Generate Chimeric Antigen Receptor (CAR) T Cells

Kassi T. Stein, Jason Rodriguez, Kevin Johnson, Elise Lambalot, Sayli Chavan, Michael S. Magee, Alberto De Iaco, James B. Rottman, Yu Cao, Rebecca Levy, Mohit Gupta, Jane Wang, Bill Querbes, Cecilia Cotta-Ramusino, Michael C. Holmes, Madhusudan V. Peshwa
Tessera Therapeutics, Somerville, MA

Autologous *ex vivo* chimeric antigen receptor (CAR) T-cell therapies have demonstrated significant clinical benefit across B-cell driven hematological malignancies. Despite these successes, there remain several challenges with respect to patient access, eligibility, cost, scalability and manufacturing. These barriers to patient therapy are beginning to be addressed through shortening CAR-T manufacturing times and reducing dose through improvements in potency. However, a true same-day bedside manufacturing paradigm or *in vivo*-based CAR-T has not been reached. We are combining our Gene Writing and delivery platforms to target primary human T cells in an effort to reduce the challenges associated with conventional autologous CAR-T approaches. RNA Gene Writers are designed to introduce a broad range of alterations to the genome, from writing in a transgene, inserting an exon, or introducing single nucleotide changes, providing an attractive toolkit for sophisticated cell engineering. RNA Gene Writers are inspired by the biology of non-LTR retrotransposons, a class of mobile genetic elements that can edit the genome through target-primed reverse transcription, or TPRT. RNA Gene Writers are designed to be delivered as all-RNA composition, which is intended to facilitate *in vivo* delivery by lipid nanoparticles, or LNP. In preclinical studies, we have observed that our RNA Gene Writers, delivered by our LNP platform as all-RNA compositions, drove stable integration of a green fluorescent protein (GFP) transgene in >70% of human T cells *in vitro*. Further, we demonstrated one of our RNA Gene Writers achieved the integration and CAR expression in an average of ~21% of T cells *in vitro*. These CAR-T cells also exhibited tumor cell killing *in vitro* and *in vivo* in an established human tumor xenograft model. Next, we demonstrated proof-of-principle of same-day manufacturing of CAR-T cells *in vitro* using RNA Gene Writers by packaging mRNA for RNA Gene Writer and an RNA template for CAR transgene into proprietary LNP formulations. The LNP-RNA composition was delivered to primary human T cells in fresh platelet-washed leukapheresis from healthy donors to generate CAR-T cells through this same-day manufacturing process. These CAR-T cells were subsequently expanded and evaluated for functionality both *in vitro,* where tumor cell killing and cytokine secretion was tested, and *in vivo* in immunodeficient NSG mice, where robust tumor clearance was observed post infusion compared to untransduced and vehicle controls. Lastly, as we begin to test our LNP-RNA compositions directly *in vivo* in murine models, we observed an average of ~6% GFP reporter gene expression in T cells in a humanized mouse model. In summary, we believe Tessera's Gene Writing and delivery platforms are uniquely positioned for same-day delivery of all-RNA components to enable more efficient manufacturing of CAR-T therapies, potentially removing the need for long expansion times and freeze-thaw cycles associated with conventional *ex vivo* CAR-T therapies.

Base Editing and Prime Editing II

380. Addressing the dNTP Bottleneck Restricting Prime Editing Activity

[1]Molecular, Cell and Cancer Biology, UMass Chan Medical School, Worcester, MA,[2]Molecular Medicine, UMass Chan Medical School, Worcester, MA,[3]RNA Therapeutics Institute, UMass Chan Medical School, Worcester, MA,[4]Wellstone Program, Department of Neurology, UMass Chan Medical School, Worcester, MA,[5]Biochemistry and Molecular Biotechnology, UMass Chan Medical School, Worcester, MA

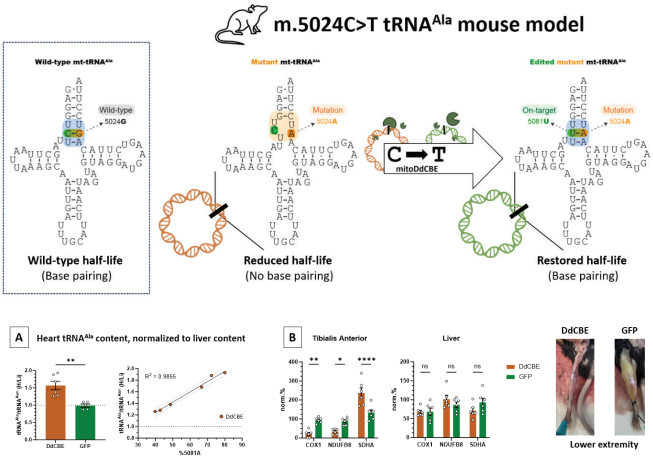
The goal of this project is to increase the efficiency of prime editing in post-mitotic cells and tissues. Prime editing has the potential for broad therapeutic application in the treatment of a variety of human diseases due to its versatility in performing targeted base conversions, deletions and insertions. Since the initial description of prime editing, many system components have been further optimized including: Cas9 nickase, M-MLV reverse transcriptase (MMLV-RT), nuclear localization sequences, pegRNA designs and DNA repair pathway activity. The original PE2 system utilizes a pentamutant M-MLV reverse transcriptase (MMLV-RT) that increases thermostability, affinity for the RNA-DNA template and processivity. To improve prime editing outcomes researchers have introduced additional point mutations into MMLV-RT to improve its functionality, substituted alternate RTs in the context of fused or split prime editor systems, or utilized molecular evolution to enhance the properties of multiple RTs for prime editing. Despite these improvements, precise editing rates remain modest in some primary cell types or in some tissue types *in vivo*. We believe that prime editing efficiency in challenging cellular scenarios can be enhanced by harnessing the wealth of optimization performed on MMLV-RT for *in vitro* applications. For example, protein aggregation observed during purification of the PEmax prime editor protein appears to be associated with the MMLV-RT domain, which suggests that its solubility may be one limiting factor. Additionally, most characterization and optimization of prime editing systems has been carried out in rapidly dividing mammalian cells, where high intracellular dNTP levels facilitate prime editing efficiency. Cellular dNTP levels can be more than 100-fold lower in post-mitotic or quiescent cells than cycling cells, which would restrict MMLV-RT activity due to its modest affinity for dNTPs. Consequently, we assessed the impact of two MMLV-RT mutations on prime editing activity: V223M, which increases dNTP affinity, and L435K, which increases MMLV-RT solubility. The presence of the L435K mutation translated into improved prime editing for every tested delivery modality (protein, mRNA and plasmid), as well as increasing prime editor protein yields when purifying from bacterial expression systems. Interestingly, the presence of the V223M mutation provided no appreciable benefit to precise editing rates in rapidly dividing transformed cell lines. However, the effect of the V223M mutation was pronounced (~2-fold improvement) in a variety of primary cell types (fibroblasts, induced myoblasts and primary human T cells). Combining the L435K and V223M mutations on the PEmax prime editing framework (PEmax**) yielded 2- to 3-fold improvement in precise editing rates in primary cells and *in vivo*. To further facilitate MMLV-RT processivity, we knocked down SAMHD1, which is involved in maintaining low intracellular levels of dNTPs, using VPX, a viral accessory protein that targets SAMHD1 for proteasome-mediated degradation. Using VPX with PEmax** increased prime editing rates up to 4-fold over PEmax alone in patient-derived fibroblasts and primary human T cells. We believe that the PEmax** variant in conjunction with SAMHD1 knockdown via VPX co-delivery will have broad utility for precise editing in quiescent and post-mitotic cells.

381. Characterization of Guide RNA Site Consistency Across Ancestries and the Potential for Off-Target Editing with the Clinical-Stage Base Editing Medicine, VERVE-101

Alexandra C. Chadwick, Jamie DeNizio, Sara Garcia, Anthony Federico, Manashree Damle, Hui-Ting Hsu, Estela Shabani, Daniel Weiner, Amit V. Khera, Joseph Biedenkapp, Sekar Kathiresan, Troy Lister, Andrew M. Bellinger

Verve Therapeutics, Boston, MA

Introduction: VERVE-101 is an investigational in vivo base editing medicine composed of an mRNA encoding an adenine base editor (ABE) and guide RNA (gRNA) packaged in a lipid nanoparticle (LNP). It is designed to permanently inactivate the *PCSK9* gene in the liver with a single base pair change and lead to durable reductions in low-density lipoprotein cholesterol (LDL-C). In an ongoing first-in-human clinical trial, a 55% reduction in LDL-C from baseline was observed after a single infusion of VERVE-101 in a patient treated with the highest dose studied to date. VERVE-101 is designed to enable robust editing at the intended *PCSK9* gene target site in hepatocytes while minimizing the risk for off-target edits 1) at other locations in the genome in any tissues and 2) at the *PCSK9* gene in tissues outside the liver. Here we describe the consistency of the gRNA target site at a population level to provide insight on the expected therapeutic utility of VERVE-101 across diverse ancestries. Rigorous off-target evaluations incorporating twenty different genomic backgrounds were performed to assess for potential off-target edits, as well as chromosomal structural variant formation. **Methods:** Consistency of the VERVE-101 *PCSK9* gRNA site was assessed using the Genome Aggregation Database (gnomAD v4.0) that aggregates gene sequencing data from approximately 800,000 individuals of diverse ancestral background (Chen, et al. *Nature*, 2024). Off-target analysis was performed in multiple lots of primary human hepatocytes and other liver, splenic, adrenal, and bone marrow cells. Cells were treated in vitro at doses $\geq EC_{90}$ for on-target editing and compared to untreated controls. To evaluate gRNA-dependent off-target editing, multiple orthogonal methods were used (ONE-Seq, ABE-Digenome-seq, and in silico analysis) to nominate approximately 6000 candidate sites. Hybrid capture was used to screen candidate sites for evidence of editing. gRNA-independent off-target assessments were performed using whole genome sequencing (WGS) to screen for excess deamination. Structural variant detection methods included optical



genome mapping and anchored Tn5-mediated unidirectional PCR (ATUP). **Results:** The VERVE-101 PCSK9 gRNA site was consistent in >99.9% of individuals in the total population captured in gnomAD (n=784,318) and in each separate ancestry group. None of the approximately 6000 candidate sites in the gRNA-dependent off-target screen showed evidence for editing in primary human hepatocytes, adrenal cells, or bone marrow. One candidate site in a liver cell line and one in primary human splenic cells showed evidence of editing. Targeted amplicon sequencing across a range of doses confirmed that editing at these two sites was a small fraction of on-target editing. Bioinformatic risk assessment of the off-target sites showed they were not in coding regions, were not near genes associated with cancer, and were not likely to impact gene expression. Editing of these two sites is also unlikely to occur at pharmacological doses in vivo. The WGS analysis showed no increase in global deamination, and there was no evidence for structural variant formation in VERVE-101 treated cells with either the optical genome mapping or ATUP method. **Conclusions**: VERVE-101 is the first in vivo base editing medicine to demonstrate proof-of-concept in humans. The consistency of the gRNA target site across populations suggests the potential therapeutic benefits of VERVE-101 should apply broadly across individuals with diverse ancestries. Comprehensive off-target assessment in different cellular contexts demonstrated VERVE-101 to be highly specific with a low risk for clinically relevant off-target edits.

382. The mitoDdCBE System as a Mitochondrial Gene Therapy Approach

Jose Domingo Barrera-Paez[1], Sandra Bacman[2], Till Balla[3], Beverly Mok[4], David R. Liu[4], Danny Nedialkova[3], Carlos T. Moraes[2]

[1]Genetics, University of Miami, Miami, FL,[2]University of Miami, Miami, FL,[3]Max Planck Institute of Biochemistry, Martinsried, Germany,[4]Broad Institute, Harvard University, and HHMI, Cambridge, MA

Introduction and Methods The mitoDdCBE system can induce cytosine-to-thymine transitions (C>T) in double-stranded, mitochondrial DNA (mtDNA). To test the therapeutic potential of this gene editing tool, we decided to make use of the m.5024T mutant mouse, one of the few existing animal models of heteroplasmic mtDNA mutations. This pathological mtDNA mutation disrupts a Watson & Crick base pair in the mitochondrial tRNA alanine (tRNA^{Ala}) secondary structure, reducing its half-life. Because the mutation (C>T) cannot be directly corrected with this approach, we created a compensatory edit (at position m.5081C>T) to restore the secondary structure and stability of the tRNA^{Ala} (Fig.1). **Results** AAV9-DdCBE viral preparations were retro-orbitally injected into young m.5024C>T mice. No expression nor editing was observed on the liver, whereas different muscle tissues (heart, Tibialis Anterior) were successfully transduced and edited. Using several AAV9 dosages, we achieved different levels of on-target editing, and noticed an exponential correlation with the generation of concomitant off-target editing. Furthermore, we also validated that DdCBE rescued the levels of tRNA^{Ala} exclusively on edited tissues in a dose-dependent manner (Fig. 2A). The highest AAV9 dosage generated numerous mtDNA off-target edits, causing a myopathic phenotype (myotonia, muscular hypoplasia, complex IV deficiency) with a corresponding lower steady-state levels of COX1 and NDUFB8 proteins (Fig. 2B). Next Generation Sequencing data generated using a specialized tRNAseq pipeline confirmed an increase in stability in the edited tRNA^{Ala} and showed that aminoacylation was not affected by the original or edited alterations. **Conclusions** We have successfully edited a cytosine in the mouse mtDNA that acts as a second site suppressor for the pathological m.5024C>T. We are thus showing, for the first time, that although the mitoDdCBE system has therapeutic potential *in vivo*, it is crucial to assess off-target editing performance to avoid a negative outcome.**Figure 1. Base editing in the mouse mitochondrial tRNA alanine gene.** The m.5024C>T mutation (G>A in the tRNA^{Ala}), present in the mouse mitochondrial tRNA^{Ala}, disrupts the base pairing at the acceptor stem, reducing the half-life of the molecule. Using the mitoDdCBE system, we have edited the m.5081C to a U, thereby restoring the base pairing. **Figure 2. Characterization of the phenotypical consecuences of the m.5081U edit in vivo.** (A) The steady state levels of mt-tRNA^{Ala} increased in mice injected with different doses of AAV9-DdCBE in a linear correlation with the amount of on-target editing achieved on edited tissues (heart) when compared to unedited tissues (liver). (B) The highest AAV9 dosage achieved 92% on-target editing but also high off-target editing, and therefore showed muscular hypoplasia and lower steady-state levels of COX1 and NDUFB8 proteins on edited tissues (tibialis anterior) but not on unedited tissues (liver).

383. Engineered IscB-ωRNA System with Expanded Target Range for Base Editing

Qingquan Xiao[1,2], Dingyi Han[2], Haoqiang Wang[1], Guoling Li[1], Yuan Yuan[1], Yingsi Zhou[1], Tong Li[1], Shaoran Wang[1], Xuan Yao[1], Alvin Luk[1], Xiangfeng Kong[1], Hainan Zhang[1], Hui Yang[1,2]

Background: As a miniature RNA-guided endonuclease, IscB is likely the ancestor of Cas9 and shares similar functions. Cas9 has proved challenging to deliver the protein into target cells due to the size, a feature reflecting the packaging limit associated with viral vector delivery such as adeno-associated virus (AAV). IscB is less than half the size of Cas9 and thus more suitable for *in vivo* delivery by a single AAV vector. We previously engineered the OgeuIscB protein and its corresponding ωRNA to generate a highly efficient OgeuIscB system.

Further work was conducted to generate miniature IscB-derived base editors (miBEs) with robust editing efficiency to induce DNA base conversions. Here, we identified several new variants of IscB with different transposon-associated motif (TAM) sequences, broadening the target range of miBEs. **Methods:** We employed a computational pipeline to annotate IscB orthologs and their corresponding ωRNAs by mining bulk metagenomic data (>200 GB). An EGFP-activation reporter system was designed and used to screen functional IscB systems in HEK293T cells. Protein engineering combined with sgRNA optimization was used to generate enhanced IscB variants with high editing efficiency and broad TAMs. *In-vivo* editing efficiency of engineered IscB variants was further evaluated in a mouse model of Duchenne muscular dystrophy (DMD). **Results:** By screening for IscB homologs in the metagenomic database, we identified 10 out of 19 uncharacterized IscB proteins from uncultured microbes showing activity in mammalian cells (Figure 1). Through protein and ωRNA engineering, we further enhanced the activity of IscB ortholog IscB.m16 and expanded its TAM scope from MRNRAA to NNNGNA, resulting in a variant named as IscB.m16* (Figure 2a-e). By fusing the deaminase domains with IscB.m16* nickase, we generated IscB.m16*-derived base editors that exhibited robust base editing efficiency in mammalian cells and effectively restored DMD proteins in disease mice via single AAV vector delivery (Figure 2f-h). **Conclusions:** Our research has successfully developed a suite of compact base editing tools originating from the IscB protein, which hold significant promise for both fundamental scientific inquiries and therapeutic interventions.

384. Development of Deaminase-Free Base Editors by Engineering DNA Glycosylases

Huawei Tong[1], Haoqiang Wang[1], Nana Liu[1], Guoling Li[1], Yingsi Zhou[1], Danni Wu[1], Yun Li[1], Ming Jin[2], Xuchen Wang[3], Hengbin Li[1], Yuan Yuan[1], Tong Li[1], Shaoran Wang[1], Alvin Luk[1], Xuan Yao[1], Linyu Shi[1], Hui Yang[1,3]

[1]HuidaGene Therapeutics Co., Ltd., Shanghai, China,[2]Department of Neurology and Institute of Neurology of First Affiliated Hospital, Fujian Medical University, Shanghai, China,[3]Institute of Neuroscience, Center for Excellence in Brain Science and Intelligence Technology, Chinese Academy of Sciences, Shanghai, China

Background: Two categories of DNA base editors, deaminase-based base editor (dBE) and deaminase-free glycosylase-based base editor (gBE), enable direct editing of adenine (A), cytosine (C), or guanine (G), but there is currently no base editor for direct thymine (T) editing. Certain dBEs (e.g., AYBE, CGBE) enable transversion editing following a second-step generation of apurinic/apyrimidinic (AP) sites by engineered glycosylases after the deamination of A or C. **Methods**: To facilitate direct T and C base editing, we generated two prototype gBE versions, a deaminase-free glycosylase-based thymine base editor (gTBE) and a deaminase-free glycosylase-based cytosine base editor (gCBE), by fusing the two corresponding variants of nuclear UNG2 (Y156A and N213D, respectively) at the N-terminus of Cas9 D10A nickase (nCas9), respectively. To enhance the editing activity of gTBE or gCBE, we performed rational mutagenesis for engineering the UNG moiety based on structural and functional analyses. We characterized the editing profile of gTBE and gCBE by targeting dozens of endogenous

genomic loci in cultured mammalian cells as well as mouse embryos. Recently, we further improved the efficiency of gGBE and investigated its therapeutic potential by disrupting the *PCSK9* gene in mice. **Results**: We constructed UNG-NTD-truncated gTBE and gCBE versions to eliminate undesired protein-protein interactions. The gTBEv0.3 with UNG2Δ88-Y156A and gCBEv0.3 with UNG2Δ88-N213D fused at the N-terminus showed much higher editing activity than those at the C-terminus (10.2% vs. 1.0% and 51.4% vs. 13.3%, Fig. 1c-e), a 10- and 3.9-fold enhancement in the editing efficiency, respectively. After multiple rational mutagenesis screening, we obtained a variant gTBEv3 with elevated editing efficiency by 3.09-fold as compared with gTBEv0.3 and a variant gCBEv2 with enhancement of C-to-G editing activity by 1.3-fold compared to gCBEv0.3. We further characterized the editing profiles of gTBEv3 and gCBEv2 by targeting dozens of endogenous genomic loci and found that gTBEv3 achieved efficient T base editing activity (range of 24.3% to 81.5%) and obtained efficient C base editing activity (range of 31.8% to 77.7%) for gCBEv2. We then co-injected the gTBEv3 mRNA and sgRNA targeting the SD site of *DMD* exon 45 into zygotes of humanized DMD mice. 100% (20/20) mouse embryos harbored efficient base conversion (range of 35.0% to 97.0%) at the desired position T3, resulting in exon skipping which would be applicable to restore dystrophin expression in DMD. Finally, when targeting *PCSK9* with further engineered gGBE for exon skipping and the introduction of premature termination codons (PTCs), we obtained an editing efficiency superior to that of targeting ABE8e in cultured human cells. Additionally, we also developed a deaminase-free glycosylase-based adenine base editor (gABE) with direct A editing ability following one-step generation of AP sites. **Conclusions**: Our findings indicate that certain DNA glycosylases could be engineered into enzymes that selectively excise specific nucleotide bases and be applied to develop novel base editors with various features. The gBE novel base editors provide additional options for the sites that dBEs could not target, largely expanding the targeting scope of base editors.

385. Systemic Delivery of LNP mRNA In Utero Permits Editing in a Mouse Model of Spinal Muscular Atrophy (SMA)

Nicole Kus[1], Marco Carpenter[1], Rosa Choi[1], Ana Maria Dumitru[1], William Johnston[1], Hooda Said[1], Mohamad Gabriel Alameh[2], William Peranteau[3]

[1]Children's Hospital of Philadelphia, Philadelphia, PA,[2]Ecole Polytechnique de Montreal, Montréal, QC, Canada,[3]The Children's Hospital of Philadelphia, Philadelphia, PA

Spinal muscular atrophy (SMA) is a leading heritable cause of infant mortality and is caused by a mutation of the SMN1 gene. Pathogenesis of the disease begins prenatally and is often irreversible. The fetus has unique properties that make it favorable for gene editing: cells are highly proliferative and amenable to mRNA delivery, the fetus is immunological immature and tolerant, and diseases with a high morbidity and mortality in the prenatal and perinatal period can be targeted. In this novel study, we used *in utero* delivery of CRISPR-Cas9 via lipid nanoparticles to target the SMN2 gene in severe SMA mice. We hypothesized that in utero LNP-assisted mRNA delivery permits efficient base editing at the SMN2 locus, thereby improving survival in a SMA mouse model. To test this hypothesis, severely diseased SMA mice were injected intravenously (IV) prenatally (E14) and postnatally (P0) via either the vitelline vein or facial vein, respectively, and compared to direct ICV injections. Survival and weight data were collected. Brains, spinal cords, and peripheral organs were harvested from mice and analyzed for editing efficiency, SMN protein levels, and mRNA splicing. Editing levels in intravenously injected mice at E14 were significantly higher than P0 injected mice. An increase in editing was correlated with enhanced survival, with improvement in mouse lifespan from P7 - P8 days to P15-19. Mice with the longest lifespan demonstrated the largest improvement in SMN protein levels. This study demonstrates that adenine base editing technology can be used to increase SMN2 exon splicing and produce a functional protein through IV *in utero* LNP assisted mRNA delivery in a severe mouse model of SMA. These results highlight the potential for further studies to improve brain and spinal cord targeting.

386. Traceless Delivery of Genome Editors

Jakob Hansen Haldrup[1], Deborah R. Gill[2], Stephen Hyde[1]

[1]Nuffield Division of Clinical Laboratory Science, University of Oxford, Oxford, United Kingdom,[2]University of Oxford, Oxford, United Kingdom

Genome editing has enormous potential to transform the future of genetic medicines. Current delivery strategies suffer from several shortcomings including insufficient packaging capacity, long-term expression, and risk of unwanted genomic integration. Thus, there is an urgent need for developing new and clinically relevant vehicles to fulfil the vision of correcting genetic defects directly in patients. Not only should such vehicles accommodate large base and prime editors, but they should also deliver their cargo in a transient fashion to minimize issues surrounding genotoxicity. By incorporating ribonucleoprotein (RNP) complexes instead of vector genomes into lentivirus-derived nanoparticles (LVNPs), we address key limitations of viral and non-viral delivery modalities, including: (i) overcoming limited packaging capacity, (ii) preventing unwanted genomic integration, and (iii) reducing exposure to the therapeutic payload. LVNPs provide a short burst of gene editing RNPs that rapidly engages the target loci (within 12 hours) and undergo quick degradation (within 72 hours), resulting in reduced genotoxicity without compromising efficacy. Importantly, the practical utility of this LVNP platform has been demonstrated, directing robust levels of genome editing in both primary human T cells *ex vivo* and the murine retina *in vivo*. In addition to simple Cas9-based gene editors, we have also demonstrated LVNP-mediated delivery of larger base- and prime editors; however, the substitution of Cas9 with larger RNP complexes does cause a decline in both potency and viral yield (Haldrup et al., PMID 37678882). With a strategic emphasis on clinical applications, successful vehicles should converge in terms of potency, safety, and manufacturing. To improve potency of LVNPs loaded with prime editors, we attempted to reduce the number of "empty" particles by omitting co-transfection of Gag/GagPol-D64V during manufacturing. Despite achieving comparable prime editing levels with an equal (p24 normalized) amount of LVNP, we observed a ~2.5-fold decrease in manufacturing yield without any further advantages. To enhance our LVNP structure, we added (additional) effector domains to favour membrane anchoring during manufacturing and removed redundant viral proteins to improve LVNP packaging capacity. In addition, we incorporated protein/RNA aptamers to increase (e)pegRNA loading. Collectively, these

substantially improved prime editing efficacy (~3.9fold; ~8.7% versus ~34% across targeted loci (p-value ≤0.031). We also tested prime editor configurations that lack the RNAseH domain but observed a trend for slightly reduced efficacy. Finally, we established protocols for large-scale manufacturing by transitioning from (i) adherent cells to suspensions cells, (ii) ultracentrifugation to anion exchange chromatography, and (iii) tangential flow filtration for buffer exchange and final concentration. Encouragingly, early evidence supports that LVNPs are sufficiently robust to withstand the rigors of manufacturing processes at large-scale, when pseudotyped with the widely used VSV-G or novel Sendai F/HN glycoproteins. Collectively, these improvements in our LVNP platform will enable preclinical testing in patient-derived cells and *in vivo* settings to assess potency and safety.

AAV Vector Biology and Development III

387. Analyzing and Improving AAV Vector Design with Long Read Sequencing and Analysis

Amicia Elliott[1], Eric Talevich[1], Alpha Diallo[1], Brandi Cantarel[1], Nam Tonthat[2], Pranam Chatterjee[3], Douglas McCarty[4], Phillip WL Tai[5], Claire Aldridge[1], Elizabeth Tseng[6], Nadia Sellami[7]

[1]Form Bio, Austin, TX,[2]AskBio, Research Triangle Park, NC,[3]Department of Biomedical Engineering, Duke University, Durham, NC,[4]Nationwide Children's Hospital, Columbus, OH,[5]UMass Chan Medical School, Worcester, MA,[6]Pacific Biosciences, Menlo Park, CA,[7]PacBio, San Diego, CA

Recombinant adeno-associated viruses (rAAVs) are currently the dominant gene therapy vectors used in preclinical and clinical settings, with more than 200 vector platforms being tested in human trials to date. To ensure the safety and efficacy of the drug product, it is essential to have a comprehensive understanding of the purity and integrity of the product, as well as identify impurities of the vector genome. Long-read sequencing is a powerful analytical tool for characterizing rAAV vector genomes, with the ability to cover the entire 4.7-kb vector as a single intact read. However, the lack of standardized nomenclature on impurities and report metrics for analyzing long-read sequencing data have hindered comparability between production runs and have reduced the potential for improving vector designs. To address this need, we convened a working group of academic and industry experts in gene therapy, long-read sequencing, and bioinformatics analysis to draft the first standardized nomenclature and report metrics. Consensus emerged around reporting on analyses that addressed questions relevant to both vector design and critical quality attributes (CQAs) corresponding to the product's purity (such as full-length vs fragmented genomes) and identity of contaminations (such as host DNA or helper or rep/cap plasmids), which can have potential impacts on product quality and efficacy. Here, we will present our standardized report with non-proprietary data and sample output. The report includes measures that have not regularly been included in the past, such as normalizing and quantifying sequencing reads using lambda phage DNA, as well as higher resolution of partial and truncated species that PacBio long read sequencing enables. We will also present results from the re-analyses of published datasets and *de novo* manufacturing runs with reporter constructs that reveal specificity into the contents of filled and partially filled capsids that has higher resolution of full therapeutic genomes than today's commonly used assays such as analytical ultracentrifugation (AUC). While different payloads will vary between high fidelity sequencing as compared to orthogonal approaches such a AUC and Droplet Digital PCR (ddPCR) based on vector design and manufacturability, we will share data from multiple studies to show the improved accuracy with long read NGS. This work enables a deeper understanding of therapeutic vs non-therapeutic capsid content for AAV based drug products. This insight is crucial to inform dosing and safety risks due to chimeric or truncated vector genomes and the presence of viral or host residuals. To enable transparency and community adoption, we have implemented these standardized computational characterization and reporting methods as open-source software. We invite the community to freely use this code and potentially participate in guiding its future development. This software is publicly available under the permissive MIT license at: https://github.com/formbio/AAV

388. Unwanted Concatemeric Knock-Ins Occur Frequently with Cas9/AAV-Mediated Gene-Editing: Detection and Prevention

Fabian P. Suchy[1], Daiki Karigane[1], Yusuke Nakauchi[1], Maimi Higuchi[1], Jinyu Zhang[1], Katja Pekrun[2], Ian Hsu[1], Amy C. Fan[1], Toshinobu Nishimura[1], Carsten T. Charlesworth[2], Joydeep Bhadury[1], Toshiya Nishimura[1], Adam C. Wilkinson[1], Mark A. Kay[3], Ravindra Majeti[1], Hiromitsu Nakauchi[1]

[1]Institute for Stem Cell Biology and Regenerative Medicine, Stanford University, Stanford, CA,[2]Stanford University, Stanford, CA,[3]Stanford University School of Medicine, Stanford, CA

Background: The combination of CRISPR/Cas9 protein and adeno-associated virus (AAV) has proven to be a highly efficient pair for generating targeted gene knock-ins. Indeed, the use of AAV6 to deliver homology-directed repair templates may boost gene knock-in rates ~100 fold compared to plasmid transfection for various cell types in vitro. However, when isolating dozens of human induced pluripotent stem cell (iPSC) colonies after knock-in and clonal expansion, we found inconsistent results across various PCR genotyping methodologies. In addition, subclones with seemingly identical genotypes often had highly variable levels of transgene expression. ***Problem:*** Since PCR failed to reliably genotype the iPSC subclones, Southern blots were used for clarification. Remarkably, over half of the edited cells contained concatemeric knock-ins of the AAV genome at the target editing site. These concatemers occurred at regular intervals, contained the full vector genome, were linked by the viral inverted terminal repeats (ITRs) in a head-to-tail fashion, and sometimes reached sizes greater than 25 kb (10 repeats). Although AAV is known to form episomal concatemers, they have not been shown to frequently integrate in the context of precision gene editing. Frustratingly, the chimeric ITRs found in the concatemeric knock-ins were significantly more resistant to PCR amplification/sequencing than the ITRs found in reported end-joining mediated knock-ins. This PCR resistance led to allelic dropout during target site amplification. Genotyping just the left and/or right side of the knock-in site with in-out PCR revealed no abnormalities,

further masking the editing error. Unfortunately, these frequent concatemeric knock-ins can cause adverse and unreliable phenotypes that are antithetical to the goal of precision genome engineering. ***Solution:*** Before seeking methods to disable concatemerization, we first sought to readily detect the concatemers by developing novel ddPCR-based assays for complex genotyping. We then characterized their frequency in clinically relevant cell-types (human iPSCs and hematopoietic stem and progenitor cells—HSPCs). Strikingly, ~60% of biallelically edited cells contained at least one concatemeric knock-in, independent of cell line, locus, or vector concentration. Finally, we sought to decrease the concatemer rate through post-transduction cleavage of the viral ITR, which decreased the concatemer rate ~10 fold and had minimal change on editing efficiency. Since this approach is compatible with established gene-editing pipelines, we hope to enable more robust genetic knock-ins that are safer, more reliable, and more reproducible. ***Summary:*** **(1)** AAV6-delivered homology-directed repair templates form on-target concatemeric knock-ins in ~60% of biallelically edited cells. **(2)** These concatemeric knock-ins differ from end-joining mediated knock-ins and are not detectable by common PCR/sequencing genotyping strategies. **(3)** Although Cas9/AAV6-mediated gene editing is used extensively in preclinical and clinical pipelines, these concatemeric knock-ins have not yet been well-characterized and could lead to unexpected phenotypes or possibly dangerous clinical outcomes. **(4)** We developed strategies to prevent these concatemeric knock-ins in clinically relevant cell types (human iPSCs and HSPCs) with minimal change to already established gene editing pipelines.

389. Molecular Origami: AAV Genome Recombination Patterns Mediated by ITRs in the Liver

Liujiang Song[1,2], Bethany Kuszlewicz[1], Lauren Nufer[1], Sinclair Cooper[1], Ross Fraser[1], Sherif Gabriel[1], R. Jude Samulski[1,2]

[1]AskBio, Durham, NC,[2]University of North Carolina at Chapel Hill, Chapel Hill, NC

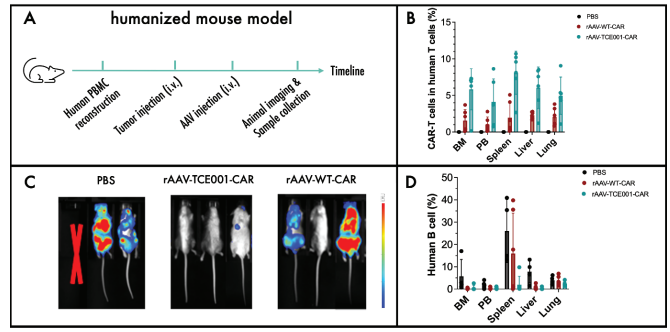
In the livers of experimental animals, Adeno-Associated Viral (AAV) vectors transduce cells, leading to an initial increase and ultimately establishing steady-state levels of transgene expression in most cases. Earlier studies have shown that uncoated AAV genomes can rapidly undergo circularization and intermolecular recombination within the Inverted Terminal Repeat(ITR) region, forming extrachromosomal AAV episomes. However, it remains unclear how these episomes could persist long-term and in what genome configuration and molecular state. In the present study, a practical strategy and a bioinformatics pipeline were developed to profile AAV episomes' genome configuration, with a focus on genome intermolecular and/or intramolecular junctions, over time in both wild-type mice and a Pompe disease Acid alpha-Glucosidase (GAA) Knock Out mouse model. Additionally, we evaluated pattern similarities and differences between self-complementary (sc) and single-stranded (ss) AAV in the liver of wild-type mice. The long-read sequencing data from our current study demonstrates that irrespective of dose, capsid, promoter cassettes, ITR sequences, and mouse models, a prevalent head-to-tail configuration was observed in ITR junctions, while the head-to-head configuration appeared to be the least common. Notably, a nucleotide-level examination revealed that double D structures are common in ITR arrays (for ssAAV), accompanied by a remarkable, previously undiscovered deletion pattern at ITR junctional regions. Deletions with varying lengths at the junctions and across the ITR regions were observed, suggesting relatively sloppy viral genome recombination. Analysis of ITR Flip and Flop orientation at the junctions suggested that, while Flip and Flop configurations were not exactly equally distributed in either pre- nor post-transduction genomes, no conclusive data supported a preference for one configuration over the other. Notably, a substantial number of reads containing a tail-to-tail configuration were also observed at 8 weeks post-injection in Pompe disease mice injected with ssAAV8 carrying a liver-specific promoter and a GAA cassette. In addition, AAV genome configuration at 8 weeks compared to 16 weeks showed a similar pattern, suggesting that the genomes remain relatively stable during the time frame examined. Furthermore, scAAV exhibited a predominant head-to-tail junction pattern with lengths less than 200 nucleotides at 14-days post-injection. In contrast to ssAAV, scAAV carries the initial deletions of the D element at the mutated ITR ends pre-transduction. It displayed unique further truncations at the mutated ITR ends post transduction in most of the Head-to-Tail reads. This distinct pattern underscores the impact of specific ITR sequences on biological recombination processes. Epigenetic regulation of AAV genomes, including CpG/5mC modification across the genome cassette and analysis of histone modifications (H3K27me3, H3K4me3, and H3K27Ac) is under investigation. Collectively, this comprehensive investigation into AAV episomes and ITR-mediated recombination patterns may represent a significant advancement in understanding AAV virology, shedding light on the roles of ITRs in AAV genome conversion and episome durability, providing crucial optimization targets for enhancing the durability of future AAV-based gene therapy drugs and non-viral gene transfer.

390. Orthogonal Characterization of rAAV Genomes Reveals Vector Attributes That Drive Dimer Encapsidation and ITR Repair

Carla Llinares[1], Mitchell Yip[2], Ngoc Tam L. Tran[2], África Vales[1], Cristina Olagüe[1], Sergio Isola[1], Gloria González-Aseguinolaza[1], Phillip WL Tai[2,3], Carmen Unzu[1]

[1]DNA & RNA Medicine Division, Centro de Investigación Médica Aplicada, CIMA, Navarra, Spain,[2]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[3]Microbiology and Physiological Systems, UMass Chan Medical School, Worcester, MA

Recombinant adeno-associated viral vectors (rAAVs) are the flagship vehicles for delivering DNA payloads for human gene therapy. However, in the past decade, only a few outstanding therapies have reached the market. One reason for the slow development of rAAV-based gene therapies has been our limited knowledge of basic AAV biology. Therefore, the goal of this work is to perform orthogonal evaluation of design elements within the packaged rAAV genomes and assess their impact on potency. Specifically, we investigated the influence of inverted terminal repeat (ITR) design, promoter use, and serotype on vector heterogeneity and transduction. We first analyzed the integrity of AAV-*Egfp* vectors containing either an alpha-1 antitrypsin (AAT) promoter (2 kb in vector genome size) or a chicken beta-actin (*CBA*) promoter (3 kb in size), packaged with six different



serotypes (AAV2, AAV3B, AAVLK03, AAV5, AAV8, and AAV9) by native agarose and automated electrophoresis. Whereas most of the packaged genomes migrated at their expected size, additional larger and smaller bands were also identified. Most of the bands were consistent among serotypes and were eliminated when the vector genomes were digested with SmaI, suggesting these DNA species were unresolved (*i.e.*, un-nicked and bound at the ITRs). Banding patterns were more heterogeneous with vectors harboring the CBA promoter, especially for those packaged with AAV8. We next produced constructs flanked by different ITR designs: two wildtype (wt)ITRs, a commercially available 11-nt deletion in the C arm of the 5'-ITR (dITR), or a 22-nt deletion in the B arm of the 3'-ITR (tITR). Alkaline gel analysis revealed monomer and dimer genomes for AAV3B, AAV5, AAV8, and AAV9 packaged vectors that carried the wtITR and dITR. However, only dimers were observed for vectors packaged with dITR-AAVLK03 and tITR-AAV8. Again, genome heterogeneity was observed for the dITR.AAV8.CBA.*Egfp* vector, but not for the dITR.AAVLK03 or dITR.AAV5.CBA.*Egfp* vectors; although, the three vectors showed an intriguing faint band larger than 5 kb. To validate these findings, long-read single molecule, real-time (SMRT) sequencing was performed on the vector genomes. Our analyses confirmed the presence of genome dimers with self-complementary configurations, including vectors over 3 kb in size. To determine whether the detection of oversized genomes was due to artifacts from target ligation/recombination during SMRT library preparation steps, 2-kb and 3-kb vector genomes were extracted and mixed before library preparation. Clear individual peaks and their respective self-complementary forms were detected, with no sign of recombination between the two genomes. Mutated ITRs have been shown to be repaired during rAAV genome replication and packaging, using the more functional of the two ITRs as a template. Interestingly, our bioinformatic analyses revealed that the promoter sequence has an impact on ITR repair. Finally, *in vitro* transduction studies confirmed superior expression from tITR genomes (dimers only) versus wtITRs, similar to classic self-complementary vectors. In conclusion, self-complementary dimer genome encapsidation is favored under specific ITR designs and can be influenced by other elements such as the promoter or the AAV capsid. C.L. and M.Y. are co-first authors.

391. An Evolved AAV Variant Enables *In Vivo* CAR-T Cell Generation, Tumor Cytotoxicity, and B Cell Elimination

Ke Ni[1], Ming Wei[1], Yanyi Cong[1], Lina Wei[1], Jing Wang[2], Qingkai Song[2], Hui Chen[1], Zhike Lu[1], Lijia Ma[2]

[1]Westlake Genetech, Hangzhou, China,[2]School of Life Sciences, Westlake University, Hangzhou, China

Background: While chimeric antigen receptor T (CAR-T) cell therapy has shown significant therapeutic benefits, its complex and expensive manufacturing process hinders its clinical use. A more viable approach is the in vivo generation of CAR-T cells, which could make CAR-T cells a universally applicable treatment. To achieve this, we must develop a delivery tool that primarily transduces payload to T cells while minimizing toxicities. **Results:** Here, we showed that T cells could be engineered into CAR-T cells in humanized mice by intravenous injection of rAAV-TCE001, an AI-generated novel AAV variant. We conducted a capsid screening to identify rAAV variants with high transduction to primary human T cells, from which the data was used to train an AI model to generate novel capsids. We validated that the rAAV-TCE001 exhibited a higher transduction efficiency to primary human T cells by more than two orders of magnitude in vitro. From the humanized mouse model **(Fig. A)**, data demonstrated that about 4.1-8.1% of human T cells could be successfully engineered into CAR-T cells across different organs **(Fig. B)**, in addition to a lowered liver transduction. When rAAV-TCE001 was loaded with an anti-CD19 payload, the in vivo generated CAR-T cells demonstrated potent tumor cytotoxicity compared to the control groups **(Fig. C)**. Further, the in vivo generated CAR-T cells also effectively eliminated human PBMC-derived B cells in humanized mice **(Fig. D)**. Finally, we applied whole-genome CRISPR screening on primary human T cells and identified receptors that promote the transduction of rAAV-TCE001 but not the parental wild-type AAV. **Conclusion:** Together, we proved the concept of in vivo CAR-T therapy by systematically injecting an rAAV variant evolved in silico from the parental serotype. The application of in vivo CAR-T in a humanized mouse model demonstrated its potential to treat tumors and autoimmune diseases, which promised great therapeutic potential in the clinic.

392. Deep Learning and RNN-Enhanced Models for Tissue-Dependent Codon Optimization

Tapan Sharma[1,2,3], Sandhiya Ravi[1,2,3], Mitchell Yip[1], Qin Su[1], Jialing Yang Liang[1], Huiya Yang[1], Joae Wu[4], Dan Wang[1,5], Jun Xie[1,2], Guangping Gao[1,2], Phillip Tai[1,2]

[1]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[2]Department of Microbiology and Physiological Systems, UMass Chan Medical School, Worcester, MA,[3]Co-first authors, Worcester, MA,[4]Department of Pediatrics, UMass Chan Medical School, Worcester, MA,[5]RNA Therapeutics Institute, UMass Chan Medical School, Worcester, MA

A critical aspect of gene therapy design is enhancing the expression of protein-coding transgenes through codon optimization. Traditional approaches that are guided by codon-usage tables and/or species-specific expression of aminotransferases and transfer RNAs, typically rely on broad eukaryotic versus prokaryotic usage rules. This approach often neglects transcript expression levels, protein size, function, and tissue- or cell-type differences. These omissions highlight a significant gap in gene therapy vector engineering, and present avenues for innovation. In addition, publicly available tools typically yield various versions of codon-optimized sequences for the same transgene, which can show differences in expression - antithetical to being optimized. In response to tissue-related synonymous codon biases, our team

developed an advanced recurrent neural network (RNN)-based codon optimization tool, tailored for cell type-dependent expression. We trained a deep learning model with comprehensive datasets of genes highly expressed in mouse myocytes, neurons, and liver. This approach enabled the prediction of effective codon usage patterns for different cell types. To test the models' performances, the enhanced green fluorescent protein (EGFP) and firefly luciferase (FLuc) reporter genes were codon-optimized using the muscle-, liver-, or brain-trained models. *In vitro* testing showed enhanced expression of these transgenes as compared to wildtype and optimized sequences using a publicly available tool. *In vivo* testing through systemically-delivered adeno-associated virus (AAV) vectors in mice, showed that EGFP versions optimized for liver and muscle expression were detected at significantly higher levels than the wildtype version in their cognate target tissues. Moreover, we also discovered that the first version of our algorithm reduced expression of secretory proteins, which make up a significant portion of the gene replacement and addition platforms being tested in the clinic. We therefore retrained our algorithms with additional data to design new models tailored to secretory proteins of human and mouse. Our initial tests on benchmark secretory genes showed marked improvements in key metrics, such as codon adaptation index (CAI), GC content, codon frequency distribution (CFD), and CpG dinucleotide content. Our *in vitro* results showed that our DL-trained secreted gene (*Gaussia* luciferase) outperformed commercial optimization tools and demonstrate differential codon biases between secreted and non-secreted proteins. We are now validating the optimized transgenes *in vivo* to test our new DL-based models. Our findings so far represent a novel DL-based approach for codon optimization with a potential to improve gene therapy drugs. **TS and SR are equal contributors.** G.G. and P.T. are corresponding authors**.**

393. A Strong and Compact Bidirectional Neuronal Promoter for AAV-Mediated and CNS-Directed Delivery of Dual Transgenes

Xiupeng Chen, Hong Ma, Phillip WL Tai, Guangping Gao*, Jun Xie*

Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA

The recombinant adeno-associated viruses (rAAVs) vectors hold promise for delivering transgenes for human gene therapy. However, the packaging capacity of AAV is limited to <5 kb, which excludes larger and especially multiple therapeutic genes from conventional vector designs, necessitating the development of compact and efficient bidirectional promoters for transgene expression. Recently we identified a 155-bp promoter derived from the human survival motor neuron (SMN1) gene and demonstrated its robust and specific neuronal activity in rAAV-mediated *in vivo* gene delivery. In the present study, we aimed to test if this compact and CNS-specific promoter can direct the expression of two transgenes bidirectionally. To this end, we constructed an AAV plasmid harboring the 155-bp SMN1 promoter in the middle flanking with the mCherry gene in the upstream and EGFP gene in the downstream (i.e.mCherry-155-SMN-EGFP). By plasmid transfection into HEK293 cells, the 155-bp promoter is capable of efficiently driving both mCherry and EGFP expression at comparable levels. In contrast, a longer 900-bp SMN1 promoter can only drive its downstream transgene expression. We then packaged this dual reporter construct into rAAV9 for facial vein administration to neonatal C57BL/6 mice at P1 with a dose of 4E11 vgs/mouse. At the same time, we produced a rAAV9 with a flipped 155-bp SMN1 promoter in the dual reporter construct as control(mCherry-155-SMN_{flip}-EGFP). Four weeks after injection, we found that the 155 bp promoter directs neuron-specific expression in the brain and spinal cord with the GFP signals largely overlapped with mCherry. Interestingly, the flipped 155-bp SMN1 is also bidirectional but favors its upstream transgene expression over the downstream one. Taken together, our findings indicate that the 155-bp promoter is strong and bidirectional both in the cultured cells and mice.* **G.G., and J.X are co-corresponding authors**

Musculo-Skeletal Diseases

394. Ten-Year Durability of AAV8-MTM1 Gene Transfer in a Canine Model of X-Linked Myotubular Myopathy

SiWei Luo[1], Jessica M. Snyder[2], Julie Crudele[3], Robert W. Grange[4], Louise Mangin[5], Edith Renaud-Gabardos[6], Michael Lawlor[7], Alan H. Beggs[8], Martin K. Childers[9], Ana Buj Bello[6], David L. Mack[1]

[1]Rehabilitation Medicine, Bioengineering, Physiology & Biophysics, University of Washington, Seattle, WA,[2]University of Washington, Seattle, WA,[3]Department of Neurology, University of Washington, Seattle, WA,[4]Virginia Tech, Blacksburg, VA,[5]Gene Therapy Branch, Genethon, Evry, France,[6]Genethon, Evry, France,[7]Diverge Translational Science Laboratory, Milwaukee, WI,[8]Boston Children's Hospital / Harvard Medical School, Boston, MA,[9]Kinea Bio, Inc., Edmonds, WA

Mutations in the myotubularin gene (*MTM1*) result in X-linked myotubular myopathy (XL-MTM), a fatal congenital skeletal muscle disease characterized by small immature centrally nucleated myofibers, internal disorganization of mitochondria (ring fibers) and an absence of the T-tubule network. Patients typically present with severe hypotonia and respiratory insufficiency, and if patients survive infancy, about half die by 2 years of age from respiratory failure. The MTM1-mutant N155K canine model recapitulates all hallmarks of the disease observed in patients except the pre-cholestatic liver dysfunction identified in the ASPIRO clinical trial. Previous work from our group demonstrated that a single systemic infusion of AAV8-MTM1 driven by the muscle-specific desmin promoter prolongs survival, restores muscle strength and improves respiratory, gait and neurological function to near normal levels in the canine model[1]. Currently, several AAV-mediated gene transfer clinical trials for neuromuscular diseases are in progress, with initial cohorts receiving treatment approximately 5 years ago. However, critical questions remain about the longevity of transduced myonuclei over the span of years while undergoing normal turnover and how long transgene expression from AAV episomes will persist above therapeutic levels. Herein, we report that two MTM1 mutant dogs treated at 10 weeks of age with 2e14 vg/kg via regional hindlimb perfusion thrived to 11 years of age with no loss of effectiveness. Yearly efficacy readouts included neurological assessments, gait analysis, respiratory function (flow volume loops and peak inspiratory flow) and bilateral hindlimb force testing. Annual biopsies of the vastus lateralis, cranial tibialis, biceps brachii, and/or triceps brachii were analyzed for vector copy

number, MTM1 mRNA by qRT-PCR, and protein expression using western blots. Functional readouts between years 5-10 post dosing were similar to those from years 1-4[2,3] for neurological assessment scores, gait performance and hindlimb force output and were indistinguishable from one littermate carrier female control. Myotubularin protein expression remained stable, at or above normal endogenous levels in all muscles tested. Muscle histology at 11 years displayed nonspecific myopathic features (focal fiber size variation, internal nucleation, and endomysial fibrosis) but no findings that were characteristic of XL-MTM. Together, these data demonstrate that AAV-mediated gene therapy for a congenital myopathy is durable for at least a decade in a large animal model. [1]Systemic AAV8-mediated gene therapy drives whole-body correction of myotubular myopathy in dogs. Mack DL, et.al. Mol Ther. 2017 Apr 5;25(4):839-854. PMID: 28237839[2]Gene therapy prolongs survival and restores function in murine and canine models of myotubular myopathy.Childers MK, et.al. Sci Transl Med. 2014 Jan 22;6(220). PMID: 24452262[3]Long-term effects of systemic gene therapy in a canine model of myotubular myopathy. Elverman M, et.al. Muscle Nerve. 2017 Nov;56(5):943-953. PMID: 28370029

395. RGX-202, an Investigational Gene Therapy for the Treatment of Duchenne Muscular Dystrophy: Interim Clinical Data

Jahannaz Dastgir[1], Aravindhan Veerapandiyan[2], Vamshi Rao[3], Paulo Falabella[1], Stephen J. Pakola[1], Sarang Rastogi[1], Dawn Phillips[1], Catherine Wilson[1], Nidal Boulos[1], Michelle Gilmor[1], Lin Yang[1], Hiren Patel[1], Michele Fiscella[1], Olivier F. Danos[1]

[1]REGENXBIO Inc., Rockville, MD,[2]Arkansas Children's Hospital, Little Rock, AR,[3]Ann and Robert H. Lurie Children's Hospital of Chicago, Chicago, IL

Objective: To evaluate safety and efficacy of RGX-202 in patients with Duchenne muscular dystrophy (DMD) aged 4 to 11 years. **Background:** Duchenne is a rare, X-linked, progressive muscle disease due to pathogenic variants in the *DMD* gene which encodes dystrophin. The absence of functional dystrophin results in muscle cell damage and ultimately death with progressive weakness of skeletal muscle, loss of ambulation, and cardiac/diaphragm weakness. **Design/Methods:** RGX-202 is an investigational, one-time AAV therapeutic for Duchenne, using the NAV® AAV8 vector to deliver a transgene for a novel microdystrophin that includes the functional elements of the C-Terminal domain as well as a muscle-specific promoter to support a targeted therapy for improved resistance to muscle damage associated with Duchenne. **Results:** As of September 28, 2023, RGX-202 was reported to be well tolerated with no drug-related serious adverse events in three patients at dose level 1, $1x10^{14}$ genome copies (GC)/kg, with 3 weeks to over 5 months follow-up. The prophylactic immune suppression for RGX-202 gene therapy has been well tolerated. Initial biomarker data from two patients indicate increased expression of RGX-202 microdystrophin from bicep biopsies taken three months following one-time RGX-202 administration. RGX-202 microdystrophin expression measured via western blot (Jess) was 38.8% compared to control in the 4.4 year old and 11.1% compared to control in the 10.6 year old. Additionally, RGX-202 microdystrophin was detectable by immunofluorescence staining in muscle at three months, with RGX-202 microdystrophin protein localized to the sarcolemma. Updated interim results will be presented. **Conclusions:** RGX-202 has been well tolerated in 3 participants up to 25 weeks post-administration of RGX-202, with readily detectable RGX-202 microdystrophin levels at 12 weeks.

396. Sustained Clinical Effects of Single-Dose Intraarticular PCRX201 Injection in Moderate-to-Severe Osteoarthritis of the Knee

Cecilia Barese[1], Emily Walsh[2], Stanley Cohen[3], Alan Kivitz[4], Masato Nakazawa[1], Mary DiGiorgi[1], Jonathan Slonin[1]

[1]Pacira Biosciences, Inc., Tampa, FL,[2]Tremont Therapeutics Consulting, Boston, MA,[3]Metroplex Clinical Research Center, Dallas, TX,[4]Altoona Center for Clinical Research, Duncansville, PA

Osteoarthritis of the knee (OAK) is a severe disease associated with high disability, and current therapies are limited to providing temporary symptomatic relief. Targeting interleukin-1β (IL-1β) in OAK holds therapeutic potential for reducing pain, increasing function, and slowing structural progression. PCRX201 is a helper-dependent adenovirus serotype 5 vector for intraarticular (IA) injection in patients with OAK. This nonintegrating, nonreplicating vector is engineered to express the IL-1 receptor antagonist (IL-1Ra), an inhibitor of IL-1β, under the control of a nuclear factor-κB-inducible promotor in response to inflammation in the target knee, thereby reversing OAK pathology. This 52-week, open-label Phase 1 trial (NCT04119687) investigated the safety and efficacy of a single dose of PCRX201 in 72 participants aged 30-80 years with moderate-to-severe OAK. The first cohort (n=36) received an ultrasound-guided IA PCRX201 injection in the study knee at 3 ascending doses. The subsequent cohort (n=36) received pretreatment with IA 40 mg methylprednisolone immediately before PCRX201 administration at the same 3 ascending doses. PCRX201 was well tolerated in all participants at all dose levels and cohorts. The most common adverse event (AE) was dose-related index knee effusion reaction (23 participants [63.9%] in the noncorticosteroid cohort, most occurring with mid and high doses, versus 12 participants (33%) in the corticosteroid cohort). There were no serious AEs related to the study drug or treatment procedure. The effectiveness of PCRX201 was measured as percent change from baseline in pain (Western Ontario and McMaster Universities Osteoarthritis Index [WOMAC]-A). A substantial reduction in WOMAC-A pain was reported at all dose levels and cohorts by week 8 and through week 52 after injection (≥25%-50% decrease in noncorticosteroid cohort, ≥50%-75% decrease in corticosteroid cohort). A similar percent change improvement was observed in WOMAC-A stiffness. Favorable improvements were also observed in knee function as assessed by an independent patient-reported outcome (Knee injury and Osteoarthritis Outcome Score). Radiographic changes such as joint space narrowing and joint space width remained unchanged after 52 weeks for all dose levels, demonstrating PCRX201 was safe in the study knee. Additionally, bone shape changes in femur and tibia, candidates as imaging biomarkers of disease progression, revealed no demonstrable increases in B-score during the first 52 weeks of treatment. Last, the pharmacologic activity of PCRX201 measured by concentrations of IL-1Ra in synovial fluid of the study knee indicated that in participants with paired samples available from baseline and week 4 (n=4), increases in IL-1Ra levels ranging from 1.4- to 132.9-fold were detected. Collectively, these data

suggest the IA PCRX201 has an acceptable safety profile and provides sustained clinical effects at all dose levels up to 52 weeks postinjection as measured by validated patient-reported outcome assessments. These promising preliminary results warrant further investigation of PCRX201 in an ongoing randomized controlled Phase 1b trial.

397. Correction of Myotonia and Reduction of Toxic DMPK Foci After Treatment of the HSALR Mouse Model of Myotonic Dystrophy Type 1 Using an Adeno-Associated Virus Delivering U7snRNA Interfering with CTG Repeat Expansion

Camila Almeida[1], Alex Brinkman[2], Andrea Sierra Delgado[2], Liubov V. Gushchina[1], Dave Arnold[3], Robert Weiss[4], Nicolas Wein[2]

[1]Center for Gene Therapy, Abigail Wexner Research Institute at Nationwide Children's Hospital, Columbus, OH,[2]Center for Gene Therapy, Abigail Wexner Research Institute at Nationwide Children's Hospital, Columbus, OH,[3]Department of Physical Medicine and Rehabilitation, University of Missouri School of Medicine, Columbia, MO,[4]Department of Human Genetics, The University of Utah School of Medicine, Salt Lake City, UT

Myotonic dystrophy type 1 is the most common form of muscular dystrophy in adults affecting the skeletal muscle, heart, and brain. It is caused by a CTG repeat expansion in the 3'UTR of the *DMPK* gene. Antisense oligonucleotides aiming to knock down *DMPK* expression or bind to the CTGs have been explored but require repeated injections to sustain therapeutic effects. To overcome this limitation, we designed modified U7 small nuclear RNAs containing a promoter and antisense sequences targeting the 3'UTR region to promote steric hindrance of the CUG repeats. We derived and characterized FibroMyoD cell lines from DM1 skin fibroblasts that were transdifferentiated into myotubes. We used several patient cell lines to test our approach, and the effect of the treatment was evaluated using RNA FISH combined with MBNL1 immunostaining for *foci* quantification and MBNL1 localization. Gene expression and splicing profiles were assessed by RNAseq and selected candidate genes were confirmed by RT-PCR. The AAV treatment reduced the *foci* number, changed MBNL1 localization, and shifted the splicing profile. Based on the *in vitro* results, we selected one vector candidate to test *in vivo*. We injected AAV1.U7snRNAs in the tibialis anterior (TA) and gastrocnemius (Gas) of HSA^{lr} mice, which express CTG repeats in skeletal muscles only. Eight weeks post-injection, we submitted the animals to electromyography (EMG) test and collected the muscles for further analysis. EMG revealed reduced mechanical myotonia (a major phenotype in DM1 muscles) and even absence of electrical myotonia in individual muscles. RNA FISH quantification showed reduced number and intensity of foci in TA and Gas. The reduction in foci led to improved splicing of *Serca1* and *Clcn1*. In conclusion, U7snRNAs interfering with the CUG-expanded mRNA can reverse DM1 pathology with the restoration of molecular features *in vitro* and *in vivo*, accompanied by significant amelioration of muscle physiological properties.

398. CSF Delivery of INS1201 AAV9-Micro-Dystrophin Demonstrates Efficacy in a Mouse Model of DMD

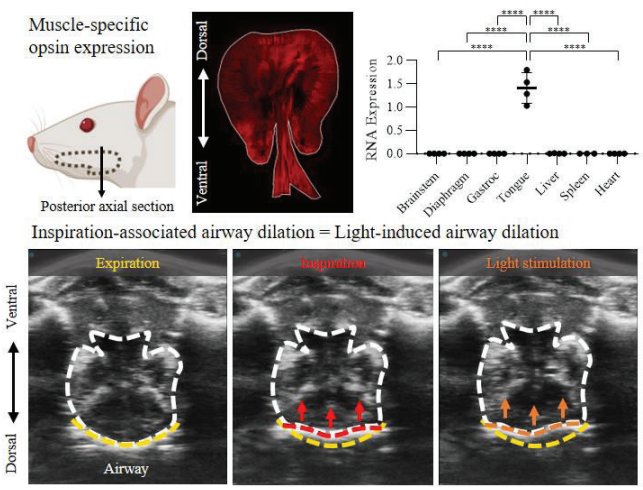
Gretchen Thomsen[1], Allan Kaspar[1], Laura Ferraiuolo[1], Binh Chu[1], Veronica Garcia[1], Theresa Slaiwa[1], Ryan Weiss[1], Robert Cano[1], Ashley Helmuth[1], Hana Julazadeh[1], Haunani Bautista[1], Melissa McAlonis Downes[2], W. David Arnold[3], Brian Kaspar[1]

[1]Insmed Gene Therapy, San Diego, CA,[2]UCSD, San Diego, CA,[3]University of Missouri, Columbia, MO

Insmed has developed INS1201, an AAV9-micro-dystrophin construct for thetreatment of Duchenne muscular dystrophy (DMD). INS1201 expresses a segment ofthe dystrophin protein that demonstrates efficacy in the *mdx* mouse and is delivered via a single intrathecal (IT) administration. IGT has shown that cerebrospinal fluid (CSF) delivery of AAV9 efficiently targets muscle and cardiac tissue in mice and non-human primate (NHP) models at lower dose levels than systemic administration. Biodistribution and efficacy of INS1201 was assessed in the *mdx* mouse model of DMD when delivered via a single-dose intracerebroventricular (ICV) injection at postnatal day (p) 31±4 with either 8.0E+09, 2.0E+11, 4.0E+11, or 8.0E+11 vector genomes (vg) peranimal. Tissue samples from INS1201-treated mice were analyzed by ddPCR using a probe specific to the INS1201 micro-dystrophin gene construct that is not present in untreated mice.INS1201 biodistribution studies were also performed in NHP following a one-time intrathecal delivery. These studies demonstrated that CSF delivery of 8.0E+11 vg per mouseresulted in .410 and 1.357 vg per nuclei in the gastrocnemius and heart, respectively, and a dose of 2.0E+14 vg per NHP resulted in .240 and 1.057 vgper nuclei in the gastrocnemius and heart, respectively. Comparable biodistribution among skeletal and cardiac muscle between mouse and NHP supports the equivalency of the intrathecal CSF route of administration by means of ICV in the mouse relative to intra-lumbar in larger animal models. Immunostaining of muscle tissues in *mdx* mice showed that membrane micro-dystrophin levels were significantly increased in each muscle examined in nearly every INS1201-treated *mdx* dose group, with 83% and 87% of all fibers positive for dystrophin in the gastrocnemius and TA, respectively at the 8.0E+11 vg dose. Relative to *mdx* vehicle controls, H&E-stained muscle from INS1201-treated *mdx* mice exhibited larger myofibers, fewer inflammatory cells, and reduced endomysial connective tissue. Picrosirius red staining for collagen provided quantitative evidence suggesting that fibrosis was significantly reduced in each muscle examined following INS1201 treatment in *mdx* mice. Quantitative analysis of fiber size measurements using laminin staining revealed significant increases in average fiber diameter in the gastrocnemius, TA and diaphragm across INS1201 treatment doses, relative to *mdx* vehicle controls, demonstrating an improvement of dystrophic pathology in the mouse model. INS1201 functional efficacy was demonstrated in *mdx* mice dosed with 2.0E+11, 4.0E+11 and 8.0E+11 vg. Significant improvement in grip strength was observed at all doses at postnatal day (p) ~115, and this was maintained at ~275 days when tested in the higher dosed animals. Using the Aurora Scientific Whole Animal System for Mice to assess plantarflexion muscle contractility, significant increases were observed in peak twitch torque following a single supramaximal stimulation and peak tetanic torque following a 200 ms train of stimuli delivered at 125 Hz. Significant torque improvement was

also noted across stimulation rates 20-160 Hz. These studies show that CSF delivery of INS1201 broadly transduced muscle tissues, leading to reduced DMD disease pathology and improved muscle function in a mouse model of DMD. This preclinical data provides support for further evaluation of therapeutic benefit in DMD patients.

399. Evaluation of Novel Muscle-Specific Promoters in Mice and Non-Human Primates



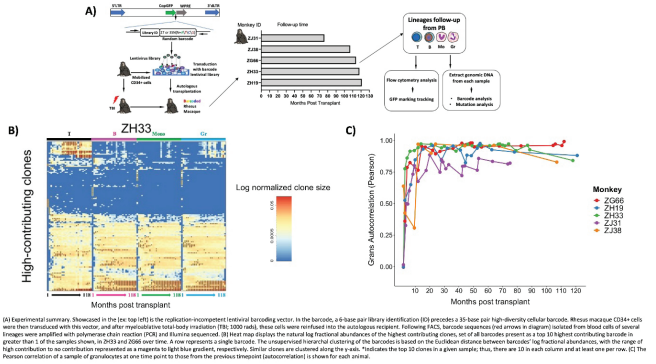
Randolph Qian, Steven J. Foltz, Kirk W. Elliott, Subha Karumuthil-Melethil, Olivier F. Danos, Ye Liu
REGENXBIO Inc., Rockville, MD

Many gene therapies for the treatment of muscle diseases require high systemic doses of AAV, which could pose risks to patients. Engineering stronger and more specific muscle promoters could enable lower therapeutic doses and decrease off-target activity, thereby enhancing the safety profile of these therapies. However, promoter size is an important consideration, as AAV vectors have a limited packaging capacity of 4.7 kb. Small promoters may enable the design of larger therapeutic transgenes and the inclusion of additional regulatory elements. Here, we describe a bioinformatics-guided design of several small but potent muscle enhancers and core promoters that were experimentally validated in mice and non-human primates (NHP) through a barcoded vector library or individual vectors. To create compact muscle-specific promoters, we first generated several small core promoters derived from the human and mouse alpha-actinin 2 (ACTN2) promoter region using a bioinformatics-guided approach. Each candidate core promoter was paired with a strong muscle enhancer to drive the expression of a barcoded Td-Tomato transgene and enable high-throughput screening via next-generation sequencing. Promoters were first screened for activity in differentiated C2C12 mouse myoblasts via plasmid transfection. Top candidates were packaged into AAVHu32 capsid and pooled at equal genome copies to produce an input AAV vector library. Evaluation of this AAV library in *mdx* mice identified a compact novel muscle promoter, EMP1, that drove robust expression in mouse skeletal and cardiac muscle compared to a commonly utilized muscle-specific promoter, CK7. EMP1, with a size of 280 bp, exhibited 5-, 7-, and 9-fold more activity in skeletal muscle, heart, and diaphragm, respectively, compared to CK7, despite being around half its length. The liver activity of EMP1 was similar to CK7, indicating high muscle specificity. Next, EMP1 was subjected to a second round of engineering by modifying the enhancer and core promoter sequences. Two additional muscle promoters were identified from a library study in *mdx* mice. EMP3 (500bp) demonstrated 8-, 14-, and 10-fold more activity in skeletal muscle, heart, and diaphragm, respectively, compared to CK7. EMP4 (400bp) exhibited 6-, 15-, and 8-fold increased activity in skeletal muscle, heart, and diaphragm, respectively, compared to CK7. Liver activity was similar between CK7, EMP3, and EMP4, indicating high muscle specificity. The top hits from the mouse studies were then cloned into a barcoded expression cassette encoding a microdystrophin to allow for their evaluation in association with a therapeutically relevant transgene. Twelve individually produced AAVhu32 vectors were pooled and intravenously administered into 2 cynomolgus monkeys at 1E14 GC/kg total dose. Necropsy was performed 3 months post-dosing, and barcoded microdystrophin mRNA expression levels were measured in multiple tissues, including muscle and liver. This NHP study confirmed the strong cardiac and skeletal muscle-specific promoter activities of EMP1, EMP3, and EMP4. Utilizing these novel muscle-specific promoters has the potential to improve the efficacy and safety of AAV gene therapies for muscle indications. Additionally, with their compact size, these promoters could enable the design of larger therapeutic payloads with additional functional domains or encode full-length human proteins that otherwise could not fit into the AAV genome.

400. An Optogenetics-Based Gene Therapy for Obstructive Sleep Apnea

Fiona L. Knapman[1,2], E. Myfanwy Cohen[2], Tom Kulaga[2], Nigel Lovell[2], Leszek Lisowski[3,4], Simon McMullan[5], Peter G. R. Burke[5], Lynne E. Bilston[1,2]
[1]NeuRA, Sydney, Australia,[2]UNSW, Sydney, Australia,[3]Children's Medical Research Institute, Sydney, Australia,[4]Military Institute of Medicine, Warsaw, Poland,[5]Macquarie University, Sydney, Australia

INTRODUCTION**:** Obstructive sleep apnea (OSA), where the upper airway collapses repeatedly during sleep, is challenging to treat as current therapies are poorly tolerated or have variable and unpredictable efficacy. We propose a novel, optogenetics-based gene therapy where direct light stimulation to the upper airway dilator muscles able to restore contraction, and prevent airway collapse. For proof-of-concept, a rodent model of human sleep-associated upper airway muscle atonia was developed. Using this model, we evaluated candidate viral vector constructs that generate the expression of light-sensitive proteins (opsins), including a muscle-targeted approach that is expected to provide a favorable safety profile. METHODS: Adeno-associated viral vectors (serotype 9, AAV9) expressing a standard opsin (channelrhodopsin-2, ChR2) and driven by either a muscle-specific (tMCK) or non-specific (CAG) promoter were injected into rat tongues to compare the strength and specificity of ChR2 expression. Light-evoked electromyographic (EMG) responses were recorded in an acute, isoflurane-based, rodent model of upper airway hypotonia and atonia. The promoter that generated the greatest expression in the tongue was then used with a highly myotropic AAV serotype (AAVMYO). ChR2 expression and light-evoked EMG responses were compared to that achieved with AAV9. Finally, ultrasound imaging measured light-evoked contractions of the upper airway muscles and the resultant airway dilation. RESULTS: The muscle-specific promoter tMCK produced 4.7-fold greater opsin expression across the tongue (RM-ANOVA, $F(1,8)=10.0$, $p=0.013$) despite a 3.6-fold lower viral load than the non-specific promoter(CAG). Moreover, the tMCK promoter abolished opsin expression in the brainstem, and viral DNA copy numbers and RNA expression were low or absent in all non-tongue tissues. Light stimulation on the tongue surface increased muscle activity by ~66% compared to unstimulated breaths (linear mixed model, $F=140.0$, $p<0.001$). AAVMYO produced greater response to light than AAV9, with light stimulation increasing EMG activity by ~194% (linear mixed model, $F=38.2$, $p<0.001$). Ultrasound imaging confirmed that light evoked muscle activity was sufficient to dilate the upper airway. CONCLUSIONS: Light stimulation of optogenetically modified tongue muscle cells was able to restore normal muscle activity and dilate the upper airway in a rodent model. This provides proof-of-concept for a non-invasive, optogenetic gene therapy for patients with OSA.



Molecular and Cellular Methods and Technologies

401. Long-Term Tracking of Hematopoietic Clonal Dynamics and Mutations in Nonhuman Primate Post-Autologous Lentiviral-Barcoded Hematopoietic Stem and Progenitor Cell Transplantation

Rohan V. Hosuru[1], Jack Yang[1], Yifan Zhou[1,2], Taha B. Hayal[1], Sogun Hong[1], Chuanfeng Wu[1], Cynthia Dunbar[1]

[1]Translational Stem Cell Biology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD,[2]Wellcome-MRC, Cambridge Stem Cell Institute, Cambridge, United Kingdom

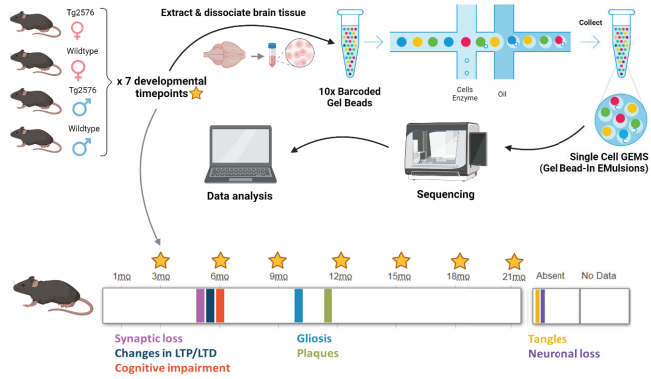
Hematopoietic stem and progenitor cells (HSPCs) autologous transplantation-based gene therapies are promising for treatment of genetic blood disorders. Lentiviral vectors serve as clinically important vehicles for delivering therapeutic transgenes to HSPCs. Investigating the long-term clonal dynamics of HSPC output and disease-related mutations following lentiviral-mediated gene therapy is important to gain insights regarding efficacy and safety. We established an autologous lentivirally-barcoded HSPC transplantation rhesus macaque (RM) model allowing quantitative interrogation of many aspects of primate hematopoiesis, with relevance to human HSPC biology. Healthy RMs underwent total body irradiation, followed by transplantation of autologous HSPCs transduced with a lentivirus library containing high diversity genetic barcodes, uniquely labeling HSPCs and their progeny. Quantitative genetic barcode recovery enabled accurate assessment of HSPCs with greater accuracy than insertion site retrieval. The macaque model allowed repeated sampling of peripheral blood, which underwent a clonal tracking workflow (Figure A), in the absence of an underlying disease state that could impact on hematopoiesis. We characterized a broad range of clonal behaviors, including contribution levels, clonality, diversity, stability, and lineage biases in 5 barcoded RMs for up to 121 months post-transplantation. We revealed stable multipotent long-term hematopoietic clonal output of T, B cells, monocytes (Mono), and granulocytes (Gr) produced by a highly polyclonal repertoire of HSPCs in all 5 macaques for up to 121 months post-transplantation. Distinct clonal differences existed between early short-term (prior to 2 months post-transplantation) and long-term clones (persisting up to 121 months), excluding the emergence of some large T cell clones due to adaptive peripheral expansions likely in response to environmental cues. Clonal succession after stable hematopoietic reconstitution was minimal (Figure B). Granulopoiesis, reflecting active HSPC production, remained stable over time in terms of clone number and clonal diversity across all animals (Figure C). We also examined clonal bias, observing unbiased progenitor cells contributing to both Mono and Gr. For both B cell- and Gr-producing cells, the larger clones seem biased toward B cells but others biased to Gr, stabilizing over time. Interestingly, progenitors contributing to both T and B cells display high bias, with certain clones exclusively contributing to T cells at times. Our data suggests steady-state hematopoiesis is driven by multipotent progenitor cells. Recent research (Chapman et al., 2023) highlights an increased frequency of mutations associated with myeloid neoplasms and clonal hematopoiesis (CH) in both modified and nonmodified cells following gene therapy for sickle cell disease. Tracking of a panel of CH-related gene mutations comparing pre-/early timepoint samples with the longest follow-up timepoint post-transplantation is ongoing.

402. A Genotoxicity Mouse Model of HSPC Gene Therapy to Identify Early Biomarkers in the Interaction between Senescent Cells and the Immune System

Cristina Colleoni, Daniela Cesana, Pierangela Gallina, Laura Rudilosso, Leonardo Ormoli, Fabrizio Benedicenti, Ivan Merelli, Francesca Sanvito, Eugenio Montini

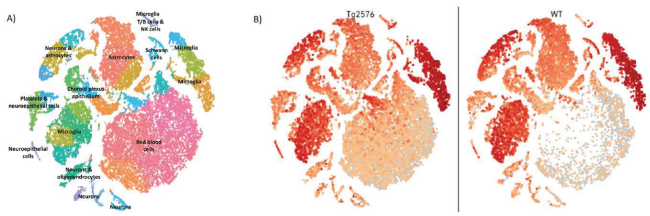
San Raffaele Telethon Institute for Gene Therapy (SR-Tiget), IRCCS San Raffaele Scientific Institute, Milan, Italy

Gene therapy (GT) product approval relies on costly in vivo safety studies that characterize the genotoxic potential, or lack thereof, of an integrating vector. Past pre-clinical and clinical studies in hematopoietic stem and progenitor cell (HSPCs) GT have extensively described that semi-random integrations of retroviral vectors can occur near oncogenes, activating them and leading to tumorigenesis. However, adverse events after oncogene activation may occur before or beyond tumorigenesis. We previously showed that oncogene BRAFV600E expression in human HSPCs transplanted into immune-deficient (NSG) mice triggered senescence, causing lymphoid impairment and



altered secretion of pro-inflammatory cytokines, leading to lethal bone marrow (BM) failure. Thus, senescence after oncogene activation may be detrimental before tumorigenesis, by inducing early aging in HSPCs. Our study aimed to characterize whether the interaction between senescent cells (SCs) and a functional immune system in an immune-competent (WT) mouse model can ameliorate the detrimental outcome observed in NSG mice. Secondly, we wanted to identify SCs signatures to ideally use them as genotoxicity biomarkers in future studies. To achieve these goals, we transplanted NSG or WT mice with mouse HSPCs transduced with lentiviral vectors expressing either the mouse oncogene BrafV600E or GFP as a control. Our results showed that oncogene expression in NSG mice (n=12) caused dose-dependent lethality (median survival = 36 days), while 40% of WT mice (n=7) survived up to 498 days post-transplant. The same mice that survived long-term exhibited elimination of SCs 12 weeks post-transplant. Both models showed histiocyte infiltration in the organs, reduction in peripheral blood cellularity, and altered levels of pro-inflammatory cytokines, but NSG mice had IL-9 and IL-10 levels, which exert immune suppression, correlating with the percentage of SCs. WT mice, instead, showed levels of IL-17a and IL-1α inversely correlating with engraftment levels, while senescence markers such as CCL-2 and IL-6 directly correlated with the engraftment of donor cells and inversely correlated with the number of recipient B and T cells. RNA-seq data revealed upregulation of inflammatory signaling (IFN-γ, IL-6, and TNF-α) in both mice backgrounds, as well as the upregulation of MHC Class II molecule genes and biological processes, suggesting an activation of the antigen presentation process in myeloid SCs. Intriguingly, gene set enrichment analysis revealed that donor myeloid and B cells of WT mice upregulated previously published SCs signatures (SenMayo, Purcell, Sencan) while NSG mice did not, despite showing other signs of senescence (i.e. upregulation of cell-cycle inhibitor gene *Cdkn2a*). Moreover, genes linked to immune suppression (*Il10, Pdcd1*) were upregulated in NSG myeloid SCs, while WT SCs upregulated immune response genes (*Cd80, Cd86, Icosl*), especially in B cells. This data hinted that functional recipient B and T cells, absent in NSG but present in WT mice, were able to recognize donor SCs, eliminate them, and partially dampen the inflammation. We tested our hypothesis by performing the same experiment on Rag1KO mice that lack B and T cells. Indeed, all Rag1KO mice transplanted with oncogene expressing HSPCs died just as NSG, showing B and T cell impairment. Altogether, these results identified SCs signatures in HSPCs and emphasized how their elimination is influenced by the immunological background of recipient mice. In the future, we will investigate SCs signatures, such as the cited cytokines and the identified genes, as genotoxicity biomarkers for cost-effective in vitro assays.

403. Exploring Novel Mechanisms of Alzheimer's Disease Pathophysiology through High-Dimension Transcriptomic Technology



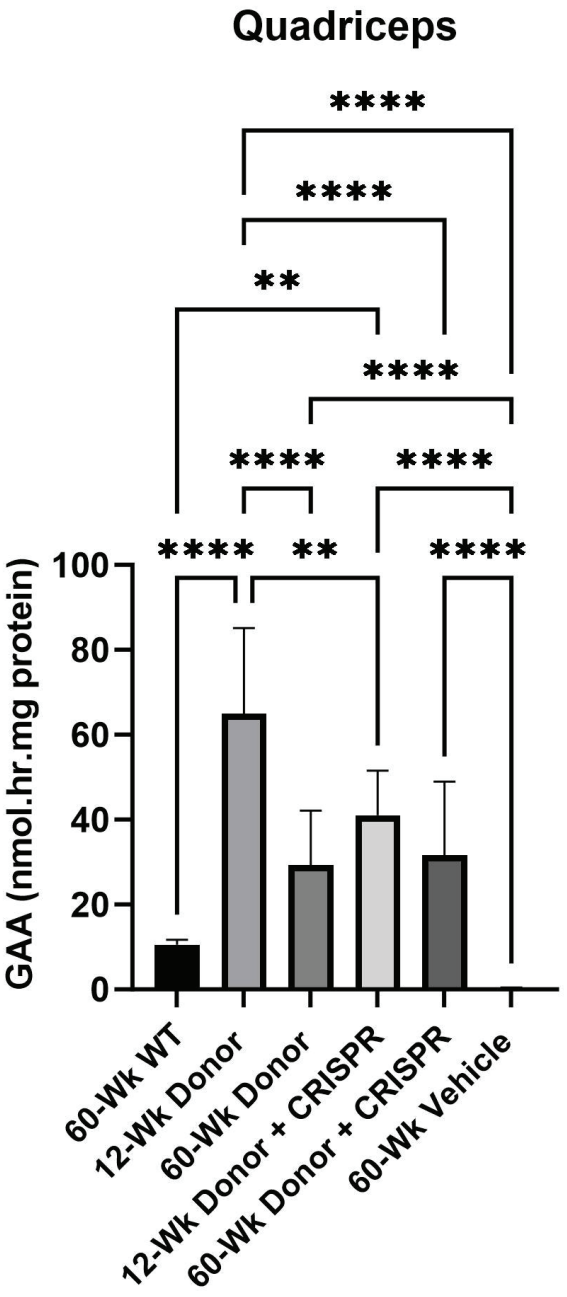
Marie Johns, Giorgia Caspani, Chaahat S. B. Singh, Maria-Elizabeth Baeva, Wing Yan Leung, Cheryl Pfeifer, Wilfred Jefferies

Medical Genetics, University of British Columbia, Vancouver, BC, Canada

BACKGROUND: Alzheimer's disease (AD) is a debilitating neurodegenerative condition characterized by cognitive decline, progressing to eventual dementia and death. Recent discoveries have challenged AD's traditional "amyloid hypothesis", warranting new approaches and prospective treatment agents in the AD therapeutic pipeline. Angiogenesis, the formation of new blood vessels, is characteristic of early AD. Growing evidence suggests that modulating angiogenesis may repair damage in the AD brain, though transcriptomic data is currently lacking. **OBJECTIVE:** To create the first single-cell view of AD progression in mice in order to identify alternative mechanisms of AD pathophysiology, and reveal putative molecular targets for AD drug therapy. **METHODS:** Cohorts of four mice representing both AD (using the Tg2745 APP overexpression mouse model) and control genotypes and both sexes (male and female) were humanely euthanized at six different developmental timepoints (N=24). Brains were dissociated and profiled at single-cell resolution using 10X Genomics software. *Figure 1:* Cohorts of four mice representing both AD and control genotypes (Tg2576 and wildtype) and both sexes (male and female) were humanely euthanized at six different disease progression timepoints (N=24). Brains were dissected and dissociated into a single-cell suspension. Individual cells were captured, and cellular mRNA was sequenced and profiled at a single cell resolution. Single-cell expression data was analyzed using 10X Genomics software: data was pre-processed with Cell Ranger then imported into Loupe Browser for differential expression analysis.

RESULTS: Pathway analysis of the 6- and 9-month cohorts demonstrated statistically significant enrichment in pathways related to: increased angiogenesis (p = 3.37E-02), vasculature development, (p = 3.71E-02), and amyloid-beta formation (p = 1.49E-02). *Figure 2:* (a) Cluster diagram for merged AD and wt samples. During the data analysis process, clusters are formed by grouping cells with similar transcriptomic profiles. (N=8) (b) Representative gene comparison. This representative gene, a negative regulator of angiogenesis, is upregulated in AD vs. wildtype mouse brains (N=8) (P=2.82E-08).

CONCLUSION: This study offers a unique cellular-level view of transcriptional alterations associated with AD pathology in mice. Preliminary findings support the 'vascular angiogenesis model' for AD, supporting growing evidence that neo-angiogensis-induced



disruptions to BBB integrity lead to the increase in amyloid-beta accumulation and subsequent AD pathology seen in Tg2576 mice and AD patients.

404. Stable Treatment of Infant Mice with Pompe Disease by Direct Transduction of Muscle

Kate Ekaterina Ilich[1], Benjamin D. Arnson[1], Elizabeth Brooks[1], Songtao Li[1], Matthew Weinrub[1], Troy von Beck[1], Jasson Hoggard[1], Dwight Koeberl[2]

[1]Medical Genetics-Pediatrics, Duke University, Durham, NC,[2]Medical Genetics-Pediatrics, Duke University Medical Center, Durham, NC

Early treatment is needed to reverse the symptoms of Pompe disease (PD), caused by acid alpha-glucosidase (GAA) deficiency accompanied by lysosomal glycogen in muscle. Although gene therapy with adeno-associated virus (AAV) vectors to replace GAA could treat PD early in life, its benefits are expected to be transient. We tested gene therapy and CRISPR/Cas9 mediated gene editing for PD with two AAV vectors containing: 1) a human GAA transgene with a CMV enhancer/CB-actin promoter (CB) flanked by mouse genomic DNA from the Gaa intron 1/exon 2 boundary (Donor), and 2) a CB-SaCas9 transgene and a guide RNA that targets the intron 1/exon 2 boundary in Gaa (CRISPR). Recombinant AAV9 vectors were administered at 12 of age to infant Gaa knockout mice. For gene therapy, mice received Donor only (1E+13 vg/kg). For genome editing, mice received the Donor (1E+13 vg/kg) and CRISPR (2.6E+12 vg/kg)) or high dose CRISPR (2.6E+13 vg/kg). Tissue collection at 12 and 60 weeks was performed for skeletal muscles, diaphragm, heart, and liver for GAA activity and glycogen content analyses. A transgene integration assay and next-generation evaluated genome editing. Muscle function testing revealed that mice treated with the Donor vector had improved performance, in comparison with vehicle treated mice. The GAA activity assay revealed a significant increase in the skeletal muscles of Donor and Donor + CRISPR vector groups to greater than wildtype levels in both the 12-week and 60-week groups, indicating stable expression of the Donor vector in the heart and skeletal muscle for >1 year. However, liver GAA activity was lower than wild-type levels, indicating that muscle expression was therapeutic. Donor vector DNA was quantified, revealing stable quantities of vector DNA in the heart and decreasing vector DNA in the liver. No significant differences in GAA activity were observed between the Donor and Donor+CRISPR groups. Glycogen content was significantly decreased in skeletal muscles and in the heart at 12 and 60 weeks. The integration assay revealed that CRISPR vector treated groups had a very low level of transgene integration at 12 weeks. Unexpectedly, treatment with the Donor vector alone revealed very low-level transgene integration at 60 weeks. The CRISPR vector had nuclease activity in transfected cells; however, next generation sequencing did not detect indels in treated mouse liver or heart even for the high dose CRISPR group, indicating a lack of nuclease activity in vivo. Anti-Cas9 antibodies were not increased, indicating a lack of immune responses. Thus, AAV vectors can transduce skeletal muscles, diaphragm, and heart, stably correcting GAA deficiency for greater than one year, in absence of genome editing. Transduction of non-dividing striated muscle early in life can stably treat PD, and should be considered for the treatment of infantile-onset PD.

405. Epigenomic Fingerprinting of Primary Immune Cells Defines Unique Cell Identities

Andrea L. Johnstone[1], Matthew R. Marunde[1], Danielle N. Maryanski[1], Carolina P. Lin[1], Ellen N. Weinzapfel[1], Liz Albertorio-Saez[1], Dughan J. Ahimovic[2], Michael J. Bale[2], Juliana J. Lee[3], Michael-Christopher Keogh[1], Immunological Genome Consortium (ImmGen)[3]

[1]EpiCypher, Durham, NC,[2]Weill Cornell Medicine, New York, NY,[3]Harvard Medical School, Boston, MA

Understanding immune cell differentiation is central to cell and gene therapy research. Regulation of chromatin structure drives many of these processes, leading to the widespread application of chromatin accessibility (ATAC-seq) and transcriptional (RNA-seq) profiling for immune cell characterization. However, these assays often fail to provide mechanistic insight and can lack the granular detail required to define rare and/or novel immune cells (e.g. exhausted T cells). Epigenomic features such as histone post-translational modifications (PTMs) and chromatin-associated proteins (e.g. transcription factors) mark distinct genomic compartments and regulate chromatin structure, gene expression, and cell function. Mapping these features provides a rich context to study cell fate and has great potential for discovering new biomarkers and drug targets. To better understand gene regulatory mechanisms and cell differentiation in the immune system, we aimed to build a comprehensive database consisting of reference epigenomic maps of over 100 unique primary mouse immune cells. Towards this end, we describe the generation of >2,200 epigenomic profiles from seven unique chromatin features (CTCF binding and histone PTMs associated with poised & active enhancers, active promoters, active gene bodies and repressed genes) in a limited number of FACS-sorted mouse immune cells using an automated CUT&RUN approach. By using defined nucleosome spike-in controls to confirm histone PTM antibody specificity and control for overall sample quality / assay success, the resulting datasets represent a gold-standard resource for the field. Bioinformatic analysis shows that chromatin features define unique cell identities, providing future avenues of research for applying these insights in novel cell & gene therapy approaches. Further, this high-throughput epigenomic mapping approach can be applied to address other challenges in cell & gene therapy research, including understanding gene regulation in differentiating iPSCs, mechanisms of epigenetic editors (e.g. dCas / CRISPRoff), defining the impact of chromatin states on gene editing efficiency, mechanisms of CAR T cell expansion, T cell exhaustion, and more.

406. Characterizing Insertional Oncogenic Risk of a Novel CD8-Targeted Fusosome for *In Vivo* CAR T Cell Generation

Matthew McNeill, Jeremy Kinder, Vasily Vagin, Amanda Lamoureux, Adam Johnson, Jason Lih, Nicolas Devos, Kutlu Elpek, Edward J. Rebar, Jagesh Shah, Terry J. Fry, David Shivak, Christina Chaivorapol

Sana Biotechnology, South San Francisco, CA

Introduction: *In vivo* CAR T cell therapies may offer key advantages over *ex vivo* therapies including reduction in manufacturing cost and time, broader patient access, and treatment durability. However, *in vivo* gene therapies require high on-target cell-specific delivery and sufficient transgene transduction to ensure product safety and efficacy. To overcome these challenges, Sana has tested SG299 fusosome, a self-inactivating lentiviral vector (LVV) pseudotyped with a CD8-targeting fusogen that enables CD8 T cell-specific delivery and integration of a CD19 CAR transgene *in vivo*. While SG299 uses the same LVV integration machinery as those in *ex vivo* CAR T cell therapies conventionally transduced with VSV-G pseudotyped LVV ("VSVG-LVV"), here we aim to assess insertional oncogenic risk by demonstrating that the genome-wide integration site (IS) profile of LVV in T cells from 6 donors is comparable to those observed in *ex vivo* clinical therapies. **Methods:** Activated CD8 T cells were transduced with SG299 or VSVG-LVV at 4 doses and harvested 4 days later. We evaluated vector copy number (VCN) per diploid genome (dg) and number of CAR+ cells. To gauge insertional oncogenic risk, we compared the IS profiles at 1 selected dose for preferential integration of SG299 LVV genome-wide and near or within known oncogenes. A specific dose was selected to enable a sufficient number of IS for analysis (> 10k IS per donor) while keeping VCN at < 5 copies to align with FDA guidance for CAR T therapies and companion *in vivo* studies. **Results:** At the selected dose, transduction of CD8 T cells yielded low intra-donor variability with highly correlated VCN and CAR+ cells across donors and vectors (VCN, $R^2 > 0.96$; CAR expression, $R^2 > 0.75$). Across donors, VCN was > 1.4 copies/dg and percent of CAR+ cells were > 33.8% (33.8 - 64.6% for SG299, 53.5 - 84.4% for VSVG-LVV) demonstrating sufficient transduction of CD8 T cells for IS analysis. Our assessment of insertional oncogenic risk yielded no evidence of preferential integration of SG299 LVV near or within 738 Cancer Gene Census (CGC) genes when compared with our VSVG-LVV data or Nobles et al. data from pre-infused cells collected from 58 patients across 4 *ex vivo* CAR T trials (all comparisons, $p < 0.01$). In addition, a genome-wide IS analysis did not identify *bona fide* preferential integration in any donor. While T cells from 2 donors had one nonoverlapping region on chr19 statistically enriched for SG299 LVV (FDR < 0.05), these regions were large (> 340 kbp), > 50 kbp from the nearest CGC gene, and nonrecurrent. Manual examination of the IS profile in this region showed that the enrichment may be due to artifacts and that the distributions across donors and LVVs were comparable. **Conclusions:** *In vitro* transduction of T cells with SG299 and VSGV-LVV resulted in comparable CAR transduction as measured by VCN and CAR expression, lack of recurrent evidence for preferential SG299 LVV integration across the genome, and comparable IS profiles to VSVG-LVV used in autologous therapies. These findings suggest SG299 likely carries comparable insertional oncogenic risk to *ex vivo* clinical CAR T products. While FDA recently announced an evaluation of T cell malignancy risk in patients treated with autologous therapies, Levine et al. indicate that the benefit of these CAR T therapies outweighs the risks given the low incidence of T cell malignancies (< 0.05%) and even lower numbers of CAR+ associated lymphomas. Given this, the IS profile of VSVG-LVV remains a reasonable comparator for oncogenic risk assessment. Together with prior studies demonstrating high specificity of SG299 (Shah ASGCT 2023, Chavan ASH 2023), these data demonstrate a desirable potency, specificity, and genomic safety profile that warrants continued development of the fusosome platform to generate CAR T therapies.

407. Somatic Mutation Tracking in Hematopoietic Stem Cell Gene Therapy Reveals Absence of Clonal Hematopoiesis

Francesco Gazzo[1,2], Andrea Calabria[1], Fabrizio Benedicenti[1], Maria Rosa Lidonnici[1], Samantha Scaramuzza[1], Francesca Tucci[1,3], Fabiola De Mattia[1], Sarah Marktel[1,3], Valeria Calbi[1,3], Francesca Fumagalli[1,3], Fabio Ciceri[3], Luigi M. Naldini[1,4], Alessandro Aiuti[1,3,4], Giuliana Ferrari[1,4], Eugenio Montini[1]

[1]San Raffaele Telethon Institute for Gene Therapy (SR-Tiget), IRCCS San Raffaele Scientific Institute, Milan, Italy,[2]Department of Electronics, Information and Bioengineering, Politecnico di Milano, Milan, Italy,[3]Pediatric Immunohematology and BMT, San Raffaele Hospital, Milan, Italy,[4]Vita Salute San Raffaele University, Milan, Italy

In hematopoietic stem cell Gene Therapy (GT), patients' Hematopoietic Stem and Progenitor Cells (HSPCs) are genetically corrected *ex vivo* and reinfused to reconstitute the entire hematopoietic system and provide therapeutic benefit. During this process, HSPCs are subjected to tremendous pressures to sustain high levels of proliferation until the hematopoietic reconstitution is complete. So far it is unknown if this likely stressful condition may result in the accumulation of somatic mutations which may trigger decay of the hematopoietic functions and increased risk of oncogenesis. The impact of prolonged and heightened HSPCs proliferation rates on cellular fitness and safety remains an open question in GT. Indeed, HSPCs are not comprehensively geno-protected from DNA damage accumulation in HSPCs during aging and/or in specific disease conditions as it has been observed in sickle cell disease and Fanconi Anemia.Here we performed an analysis of somatic mutations in exons of 40 genes involved in clonal hematopoiesis and myeloid cancer in 23 GT patients treated for metachromatic leukodystrophy (MLD, 15 <3 years old, 8 3-12 years old) and 9 for β-thalassemia (β-Thal, 6 pediatric and 3 adults >30 years old). We used genomic DNA from HSPCs cells prior infusion and peripheral blood mononuclear cells harvested at 2 years after GT and at the last available time point (2.5-7.5 years after GT). Sequencing reads correctly aligned on the targeted exon panel resulted in an average coverage of 4,400 and 4,300 reads/base in β-Thal and MLD patients respectively.The average mutation rate in the adult β-Thal patients was >2 fold higher than the rate measured in the pediatric patients (11.3 ± 11 vs 5.6 ± 3.5). Moreover, the average somatic mutation rates in adult and pediatric β-Thal patients were both significantly higher than in MLD patients (1.6 ± 0.72, p-value=0.0136 vs adult β-Thal, p-value=0.012 vs pediatric β-Thal, by Kruskal-Wallis test). None of the mutations were pathological or likely pathological. Most somatic mutations (85 out of 96) exhibited a Variant Allele Frequency of less than 2%. The average number of mutations in both the clinical trials remained consistent across all time points, showing no statistically significant variations. Considering that the sequenced genomic interval corresponds to 76,715 bps and that we analyzed a total of 8,100 equivalent genomes per patient, the resulting mutation rate in β-Thal patients was $1.21x10^{-8}$ mutations/bp, while MLD patients resulted in a mutation rate of $2.6x10^{-9}$ mutations/bp. Five mutations (4 in β-Thal and 1 in MLD) were found at more than one time point, but none showed a progressive increase in abundance, suggesting that these mutations did not confer a selective advantage to the mutated cell clones.Our work revealed that no somatic mutations known to drive clonal hematopoiesis or myeloid cancer, nor accumulation of somatic mutations, were found in our GT patients, indicating that the GT treatment was neutral in these conditions. However, the underlying disease in β-Thal patients resulted in a significantly higher mutation burden than MLD patients, a finding worth of deeper analysis and that supports long-term follow-up assessments of the clonal composition of the hematopoietic system in GT patients.

Vector Product Engineering, Development, and Manufacturing (excluding AAV)

408. Single and Low Dose Self-Replicating RNA Vaccine Provides Effective Immune Protection Against Rabies in Healthy Volunteers

Christian Maine[1], Shigeki Miyake-Stoner[1], Brandon Essink[2], Guillermo Somodevilla[3], Yaquelin Rodriguez[3], Andrew Geall[1], Nathaniel Wang[1], Parinaz Aliahmad[1], Zelanna Goldberg[1]

[1]Replicate Bioscience Inc, San Diego, CA,[2]Velocity Clinical Research, Omaha, NE,[3]Cordova Research Institute, Miami, FL

Despite the unprecedented success of mRNA vaccines for COVID-19, their widespread expansion to other infectious diseases is limited by unacceptable side effects at doses required for protection. Self-replicating RNA (srRNA) technology is a fully synthetic RNA modality that is able to amplify in the host cell due to the presence of a virally derived replication machinery. Thus, lower amounts of srRNA lead to exponential protein expression, which enables lower clinical dosing and better tolerated vaccines. Replicate Bioscience has developed novel, proprietary srRNA vectors with improved performance for a variety of therapeutic applications. To demonstrate the superior performance of our technology, we designed and manufactured RBI-4000, a proprietary srRNA vector encoding the rabies glycoprotein encapsulated in a lipid nanoparticle. Rabies was selected as a target for this clinical validation as the general population is exposure-naïve, in contrast to influenza or SARS-CoV-2 where pre-existing exposure may confound a clean interpretation of the vaccine-generated immune responses. Additionally, an easy to interpret immune surrogate of protection has been defined by the WHO, where titers of rabies virus neutralizing antibodies (RVNA) ≥ 0.5 IU/mL are protective. RBI-4000 was evaluated in a Phase I clinical trial (NCT06048770). Healthy adults, age 18-45 and seronegative for rabies antibodies were recruited at two clinical sites in the U.S. Sequential cohorts (n=18 subjects) were dosed IM with 0.1, 1, or 10 micrograms (mcg) of RBI-4000 in a 2-dose prime-boost schedule or prime only for the highest dose. An active control cohort of 12 subjects received RabAvert, a commercial vaccine, per the recommended schedule. Enrollment is complete, and the study is ongoing. Interim analysis demonstrated that all doses were well tolerated, with no DLTs, SAEs, or safety signals. Acute reactogenicity was limited to grade 1 or 2 events, with a single exception of a time-limited grade 3 fever reported by 1 subject in the mid dose group, at

the prime dose only. Acute reactions generally resolved within 3-4 days post-injection with no treatment or limited use of OTC oral NSAIDs. Local reactogenic events were more common than systemic and increased in a dose-dependent manner. RBI-4000 was immunogenic at all dose levels tested, with RVNA achieving WHO-defined protection levels in over 70% of subjects at the 0.1 mcg dose after two doses. At 10 mcg, protective RVNA titers were observed at close to 100% following a single dose. RBI-4000 is the first clinical demonstration of next-generation srRNA technology. The favorable safety profile combined with strong immunogenicity demonstrates an orders of magnitude advance in the therapeutic window of efficacy: tolerability over traditional mRNA vaccines. The increased therapeutic window enables broader applications of our platform to more complex infectious disease targets, oncology applications, and protein replacement therapeutics as well as being better able to address acute pandemic manufacturing requirements.

409. Kinetics-Based Assembly of Shelf-Stable PEI/DNA Particles for Viral Vector Production

Jinghan Lin[1], Yizong Hu[2], Di Yu[1], Hai-Quan Mao[1]

[1]Johns Hopkins University, Baltimore, MD,[2]Massachusetts Institute of Technology, Boston, MA

Introduction. Current methods for producing adeno-associated virus (AAV) vectors predominantly involve the transfection of plasmid DNA (pDNA) and poly(ethyleneimine) (PEI) particles into HEK293 cells. The quality of the pDNA/PEI particles plays a crucial role in achieving efficient AAV vector production, which is primarily determined by the initial mixing of pDNA and PEI solutions. However, precisely controlling the assembly of pDNA/PEI complexes in a homogenous manner has been challenging, risking the reproducibility of AAV production[1]. In this study, we developed a kinetics-based approach to assemble shelf-stable pDNA/PEI particles at controlled size ranging from 200 to 1000 nm with a high degree of uniformity. Through this approach, the assembly is extended, rendering the mixing process less time-sensitive and allowing for increased flexibility in the mixing process. **Methods.** To formulate pDNA/PEI nanoparticles, pDNA and PEI were pre-diluted into different buffers. The buffers were designed to a specific pH and ionic strength to control the assembly of pDNA/PEI nanoparticles to larger sizes. The DNA and PEI working solution were then mixed to initiate an instantaneous assembly. The size growth of the nanoparticles was stopped by adding a stabilization buffer to the total pDNA/PEI solution. The transfection efficiency of these particles was assessed by examining luciferase pDNA expression in HEK293T and HEK293F cells. **Results.** This kinetics-based method generated pDNA/PEI particles with good uniformity regardless of mixing rates from different complexation methods. The size control was achieved by tailoring pH and ionic strength of the mixture. Specifically, citrate ions were found to facilitate the growth of the pDNA/PEI particles with a lower needed concentration than phosphate buffer to induce similar growth rate. It also improved the uniformity of the particles, indicated by a much lower polydispersity (**Fig. 1A**). The assembled pDNA/PEI particles remained stable on the bench for at least 4 h at room temperature and after freeze-thaw cycles, indicated by the stable sizes of the particles as well as comparable PDI values (**Fig. 1B**). In addition, transfection efficiency of the pDNA/PEI nanoparticles prepared by this method was tested on HEK293T and HEK293F cell lines. The luciferase expression levels in both cell lines were increased with the larger size particles, with the peak transfection efficiency obtained at 600 nm (**Fig. 1C**), suggesting that the transfection efficiency of pDNA/PEI particles can be tailored in a size-dependent manner. **Conclusions.** This kinetics-based assembly method for synthesis of pDNA/PEI particles offers distinct advantages such as high DNA concentration, controllable assembly kinetics, high scalability, and high shelf stability and storage stability upon freeze-thaw cycle. The final DNA concentration in such pDNA/PEI particles can be tuned up to 200 μg/mL of pDNA. This method also eliminates the need for specific mixing equipment, as the assembly of pDNA/PEI particles was primarily controlled by assembly buffers with specific pH and ionic strength. The particles can be stabilized at different desired sizes, remaining stable both on benchtop and cryopreserved at -80 °C. These controlled-sized pDNA/PEI particles exhibit efficient transfection capabilities, indicating their great potential as an effective delivery system for viral vector production. **References.** [1] Y. Hu, *et al.*. ACS Nano, 13(9): 10161-10178 (2019).

410. Machine-Designed Synthetic 3' UTRs Significantly Increase mRNA Stability

Elise D. Flynn[1,2], Görkem Garipler[1], Emily Hoelzli[1], Uri Laserson[1], JB Michel[1], Alyssa Morrow[1], Meimei Shan[1], Ashley Thornal[1]

[1]Patch Biosciences, New York, NY,[2]Authors are displayed alphabetically, New York, NY

Using mRNA as a therapeutic has received enormous attention in the last few years, but the inherent instability of the molecule remains a

hurdle to achieving long-lasting therapeutic levels of protein expression. We have engineered synthetic 3' UTR sequences that greatly increase mRNA stability, resulting in prolonged protein expression *in vivo* for potential use in mRNA therapeutics. **Approach**: Our approach involves a massively parallel reporter assay (MPRA) that measures the half-life of tens of thousands of distinct mRNA designs in a single experiment. This data allows us to train large machine learning models, which guide the design of synthetic 3' UTR sequences predicted to enhance mRNA stability. By synthesizing and testing large pools of candidate 3' UTRs, we continuously refine our machine learning models. Through multiple design-build-test iterations, our platform identifies numerous 3' UTR sequences with improved mRNA stability. **Results**: In total, we have evaluated over 200,000 unique 3' UTRs across various cellular contexts with half-lives up to 20 hours. Several selected 3' UTR sequences were validated by formulating them as mRNA-LNPs and injecting them systemically into mice. Whole-body bioluminescence imaging at multiple timepoints over a two-week period confirmed that by four to seven days after the injection, our 3' UTRs were driving 30-100-fold higher protein output compared to the human hemoglobin beta 3' UTR sequence, a commonly used benchmark. Furthermore, our UTRs extended the threshold levels of protein expression by up to an additional 6 days. Notably, these 3' UTRs demonstrated successful translation across different species, cell types, delivery modalities, and associated coding sequences (GFP and luciferase). We believe that our 3' UTRs, along with our sequence discovery platform, have the potential to significantly enhance a wide range of mRNA therapeutics.

411. Generation of Off-the-Shelf CAR Gamma Delta T Cells Using CRISPR and AAV, a New Era in Cell Therapy

Genesis Snyder[1], Alexia Martin[1], Noushin Saljoughian Esfahani[1], Colin Maguire[1], Dean A. Lee[2], Meisam Naeimi Kararoudi[3]

[1]Nationwide Children's Hospital, Columbus, OH,[2]Nationwide Children's Hospital, Canal Winchester, OH,[3]Nationwide Children's Hospital and Ohio State University, Columbus, OH

Introduction Autologous alpha/beta (αβ) chimeric antigen receptor (CAR) T cells have been successful in treating hematologic malignancies. However, production of these cells is expensive and has led to a high rate of production failure. On the other hand, using donor αβ T cells causes lethal graft versus host disease, thus limiting their accessibility. Here we propose to genetically engineer Gamma Delta (γδ) T cells as an alternative source of T cells to increase their accessibility while providing a potent off-the-shelf CART therapy which does not cause GvHD. However, gene editing of γδT cells has been challenging and to the best of our knowledge there is no report on CRISPR/AAV gene editing of these cells. Given biological similarities between NK cells and γδT cells and our extensive experience with genome editing in NK cells, we hypothesized that growing γδT cells on feeder cells expressing mbIL21 and 41bbL enhances the DNA repair machineries. This would allow efficient CRISPR gene targeting, and site directed CAR insertion delivered by AAV vectors in γδT cells. This is particularly important since the efficacy of αβCAR-T cells generated by lentiviral transduction, has been correlated with random insertion site of the CAR DNA into the genome of T cells. Utilizing a site directed CAR gene insertion via CRISPR and AAV would minimize random insertion of the CAR. To test our hypothesis, we expanded peripheral blood primary γδT cells and electroporated them with Cas9/RNP targeting CD38 and CD70. The electroporated cells were transduced with CD38CAR and CD70CAR constructs delivered by AAV6. The CD38KO/CD38CAR γδT and CD70KO/CD70CAR γδT could overcome CAR-mediated fratricide and showed enhanced antitumor activity against hematological and solid tumors. The expanded γδCAR-T cells could be expanded and cryopreserved to clinically relevant numbers. We believe that this technology would offer an unlimited source of adaptive cell therapies for cancer and potentially other diseases such as autoimmune disorders. *Methods* Peripheral blood mononuclear cells (PBMCs) were isolated from healthy donor buffy coats (n=4). γδT cells were isolated from the PBMCs utilizing StemCells EasySep kit. Following their isolation, the cells were expanded using irradiated feeder cells (mbIL21 and mb41BBL expressing K562) and kept in culture medium that was supplemented with 100IU of IL2 every 48 hours. Expansion was repeated every 7 days. On day 21 of expansion, γδT cells were electroporated with Cas9/RNP and transduced with AAV6 (75K MOI) delivering CAR DNAs equipped with homology arms for the targeting sites. To confirm the KO and CAR expression, 2 days post transduction, flow cytometry was performed. The γδCAR-T cells were further expanded for three weeks. Calcein and InCucyte were used to measure cytotoxicity against the T-ALL, glioma and neuroblastomas. *Results* Our results showed successful proliferation of both freshly isolated and genetically modified γδT cells to clinically relevant numbers. Flow cytometry was able to confirm the loss of CD38 expression (efficiency was 99.4% ± 0.5% (mean ± SD, n=2)) CD 70 (efficiency was 97.7% ± 0.5%, n=3) and the expression of our CD38CAR construct (efficiency was 65.5% ± 10.2%, n=2) and CD70CAR (efficiency was 50.2% ± 10%, n=3). Both Calcein assay and InCycute showed enhanced killing efficiency of the CAR γδT cells. *Conclusion* We believe that our current strategy provides a method for generating novel, allogenic, off-the-shelf CART cell therapies that are accessible, economic and versatile for several cancer types.

412. Lentiviral Vector Packaging and Producer Cell Lines Yield Titres Equivalent to the Industry-Standard Four-Plasmid Process

Matthew Tridgett[1], Marie Mulet[1], Sherin Parokkaran Johny[1], Maria Ababi[1], Meenakshi Raghunath[1], Richard Parker-Manuel[1], Matthew Peckett[1], Jade Kent[1], Louise Holland[1], Robert Asatryan[1], Louise Montgomery[1], Tsz Lung Chow[1], Ryan Beveridge[1], Ieva Salkauskaite[1], Sarah Dowding[1], Heloísa Berti Gabriel[1], Maolin Li[2], Dan Yi[3], Ping Zou[4], Corinne Branciaroli[1], Weimin Valenti[1,5], David Chang[1,5], Keith Meaney[1], Maria I. Patrício[1], Qian Liu[1]

[1]OXGENE, Oxford, United Kingdom,[2]WuXi Advanced Therapies, Wuxi, China,[3]WuXi Advanced Therapies, Shanghai, China,[4]WuXi Advanced Therapies, Wuxi, United Kingdom,[5]WuXi Advanced Therapies, Philadelphia, PA

Lentiviral vectors are widely used in cell and gene therapies. However, large-scale plasmid production, testing and transfection all complicate and increase the cost of this therapeutic modality. To address this challenge, we have developed clonal lentiviral vector packaging and

producer cell lines by stable integration of lentiviral genetic constructs. This reduces or eliminates plasmid transfection during vector manufacturing. Flask-scale production testing with various therapeutic cargo genes - including anti-CD19 CAR, anti-BCMA CAR and Factor VIII - revealed consistency in the performance of the packaging and producer cell lines compared to the industry-standard four-plasmid transfection method. For example, production titres when encoding anti-CD19 CAR were 2.2 $\times 10^7$ TU/mL with the transient system, 7.2 $\times 10^7$ TU/mL with the packaging cell line, and 7.6 $\times 10^7$ TU/mL with the producer cell line. Production by clonal stable cell lines remained high for three months of continuous culture. Moreover, the producer cell lines remained free of replication-competent lentivirus throughout stability testing, highlighting the safety of this production approach. In addition, we have scaled up production with the clonal packaging cell line to ten litres and have plans to scale up further to fifty-litre bioreactor scale. Finally, we have created a GMP-grade master cell bank of the clonal packaging cell line. By decreasing the dependence on plasmid transfection, while achieving lentiviral vector production consistent with the industry-standard four-plasmid method, the cell lines developed here can reduce manufacturing costs and operational risk, thus improving manufacturability and enabling patient access to lentiviral vector-based cell and gene therapies.

413. Establishment of a Scalable Stable Lentivirus Manufacturing Process in Suspension Perfusion Mode

Holger Laux[1], Maximilian Klimpel[1], Nikki Indresh Lal[1], Marta Arrizabalagacascallana[2], Vicky Pirzas[1]

[1]CSL Behring Innovation GmbH, Marburg, Germany,[2]UCL, London, United Kingdom

Relevance to Theme Selected: Enabling lentivirus manufacturing in suspension perfusion mode for viral-based gene therapies using stable producer cell lines. **Impact/Novelty:** Implementation of a scalable lentiviral vector perfusion process using an ultrasonic cell separation system with increased perfusion rates. **Introduction:** Production of lentiviral vectors for clinical gene transfer trials is currently mainly done via transient expression. This is challenging due to the high cost of GMP-grade plasmids, the labour-intensive nature of a transient process as well as the lower reproducibility and scalability. To facilitate clinical grade lentiviral vector production, we have developed a state-of-the-art stable suspension packaging cell lines in the past. We have now significantly improved the suspension perfusion process using an ultrasonic cell separation system with optimized perfusion conditions and developed an efficient tailor-made DSP process to purify and sterile filter LVVs. **Methods/Approach:** We have established a HT small scale perfusion system (AMBR250) using an ultrasonic cell separation equipment. With this system we have performed a variety of suspension perfusion runs to identify the best conditions, which were confirmed at 2 L bioreactor scale and the LVV material was used to improve the LVV downstream process (purification, concentration and sterile filtration). **Results:** The producer cell lines are expressing high infectious titer. Conditions have been optimized to improve LVV stability, maintain high cell viability for at least 2 weeks, and increase the ratio of infectious to non-infectious particles. We have also identified more gentle culture conditions using an AMBR250 perfusion system with an ultrasonic cell retention device. **Conclusion:** Scalable production of LVVs for commercial and clinical use is a hurdle due to traditional transient production methods. We show in this work that we are capable to express and purify LVVs at high infectious titer over a period of 2 weeks using stable suspension producer cell lines and have significantly improved the process using state of the art HT perfusion systems.

414. Stable Lentiviral Producer and Packaging Cell Lines Achieve > 1E8 TU/mL

Adam Carcella, Jeremy Gam, Brianna Jayanthi, Michelle Chang, Omar El-Ghouch, Paulena Lieske, Manali Desai, Jeff McMahan, Luis Gonzalez, Kevin D. Smith, Martín Carcamo

Asimov, Boston, MA

Chimeric Antigen Receptor T-cell (CAR-T) therapy is one of the most successful types of immunotherapy to date. This success has led to ex vivo engineered cell therapies broadening to larger indications, such as solid tumors, increasing the need for scalable technologies. Lentiviral vectors have emerged as the dominant tool of choice to genetically modify immune cells due to their capacity to transduce both dividing and non-dividing cells, ensuring long-term stable transgene expression with a reliable safety profile. The current industry standard for lentiviral production relies predominantly on transient transfection of HEK293 cells which has issues with scalability, batch variability, and a high manufacturing cost largely due to the large-scale GMP plasmids required. To address these inherent shortfalls of transient transfection-based lentiviral production without sacrificing the speed to clinical and commercial stages, Asimov has developed an inducible stable packaging and producer cell line system.Asimov's LV Edge platform consists of both packaging and producer monoclonal suspension HEK293T-based, inducible cell lines encoding all the genetic elements needed for VSV-G pseudotyped lentiviral vector production. The system integrates synthetic biology with hyperactive transposase-based genomic integration to attain high copy numbers of lentiviral and transgene components under stringent inducible regulation. Both cell lines are generated through a cell line development (CLD) process with best-in-class monoclonality assurance technology, ensuring robust and reproducible performance. Our packaging cell line is a ready-to-transfer platform with stably integrated essential viral genes, permitting lentiviral production from induction of the integrated packaging components and a single-plasmid transfection encoding the transgene of interest. Generation of a producer cell line takes 4 months from transfection to research cell bank availability. Our CLD process eliminates the need for the costly GMP-grade DNA generation, and uses a novel, high-throughput clone screening approach to only progress the top performing clones. Put together, our model-guided process achieves high-E8 TU/mL titers at harvest from producer cell lines and greater than 1E8 TU/mL titers from our off-the-shelf, ready-to-transfect packaging cell line across multiple therapeutic transgenes with commercially available media and feeds. Both the packaging and producer HEK293T cell lines exhibit robust growth profiles and high viability, similar to the parental cell line, after the insertion of the lentiviral components. In addition, long-term stability studies have shown the packaging and producer cell lines to be stable without antibiotic selection. In conclusion, Asimov's LV Edge platform has the potential to shift the industry standard beyond

the current four-plasmid transient transfection system toward a more scalable and cost-effective approach, making engineered cell therapies more accessible to patients.

Targeted Gene and Cell Therapy II

415. KRAS Mutant Gene Editing Abolishes Tumor Growth *In Vivo* and Overcomes Acquired Resistance to KRAS^{G12C} and KRAS^{G12D} Small Molecule Inhibitors

Neil Desai[1], Audrey Grunenberger[2], Veronica Guzman-Gonzalez[2], Léa Cabrera[2], Elodie Czuba[2], Virginie Faure[3], Veronique Josserand[3], Gilles Di Vita[1,2]

[1]AADIGEN, Pacific Palisades, CA,[2]DIVINCELL, Nimes, France,[3]IAB, Grenoble, France

KRAS codon12 mutations are among the most commonly observed mutations in pancreatic, colorectal and lung cancers. Recently, KRAS^{G12C} inhibitors (sotorasib,adagrasib) have been approved. However, small molecule KRAS inhibitors are limited by adaptive resistance, mainly associated with the emergence of secondary KRAS mutations, activation of feedback pathway and high amplification of KRAS^{G12C} allele. KRAS^{G12D} inhibitors (MTRX-1133 and INCB161734) have recently entered clinical development. We have developed a potent strategy combining in vivo gene editing with tumor-selective peptide nanoparticles, to impair cancer cell proliferation by directly targeting mutations at codon-12 of KRAS oncogene and to overcome acquired resistance to KRAS^{G12C} and KRAS^{G12D} inhibitors. ADGN-121, ADGN-122, ADGN-123 are gene-editing complexes containing mRNACAS9 and sgRNA targeting specifically KRAS^{G12D}, KRAS^{G12V} or KRAS^{G12C} respectively, complexed with proprietary peptide-based nanoparticles to promote tumor targeted delivery upon systemic administration. We demonstrated that ADGN-121,122 and 123 selectively silenced KRAS^{G12D}, KRAS^{G12V} and KRAS^{G12C}, respectively, in colorectal, pancreatic and lung cancer cells resulting in inhibition of cell proliferation (IC50:10-30 nM) and phosphorylation of ERK and AKT. We showed that only two IV-administrations of ADGN-121 containing gRNA^{G12D} are required to abolish Panc1 tumor growth in a dose dependent manner with strong tumor regression at 1.0mg/kg. Similarly, only two IV administrations of ADGN-122 containing gRNA^{G12V} abolished SW403 tumor growth with strong tumor regression at 1.0 mg/kg. We demonstrated a synergistic combination between ADGN-121/Abraxane in pancreatic carcinoma and between ADGN-122/Capecitabine in colon Adenocarcinoma. No effect on tumor growth was observed with nonspecific gRNA. ADGN treatments were well tolerated, with no signs of clinical toxicity detected after single or repeat administration. ADGN-123 containing gRNA^{G12C} can overcome sotorasib/adagrasib acquired resistance in vitro. ADGN-123 blocks the proliferation (IC50 : 10-20 nM) of cells with secondary KRAS$^{G12C/R68M}$ and KRAS$^{G12C/Y96D}$ mutations or with KRAS in a permanent active state and effectively inhibits ERK phosphorylation. ADGN-121 containing gRNA^{G12D}/mRNACas9 can overcome MRTX1133 resistance in vitro. ADGN-121 can effectively inhibit the proliferation (IC50 : 10-15 nM) of ASPC-1 MRTX-1133R and PANC-1 MRTX-1133R cells with high level of KRAS^{G12D}-GTP active state. No resistance was detected after ADGN-123 or ADGN-121 treatments. Our study provides a proof-of-concept that ADGN can be applied to target driver mutations of cancers *in vivo* and permanently disrupt the oncogenic alleles, leading to major tumor regression. ADGN-121, and ADGN-122 were effective in invivo targeting selectively the two major KRAS mutations in G12D and G12V, which are present in 4.2% and 3.6% of all cancer patients respectively. Importantly, ADGN-123 and ADGN-121 constitute a potent alternative strategy to overcome resistance associated to small molecule inhibitors of KRAS^{G12C} and KRAS^{G12D}

416. A High-Avidity, CD8-Co-Receptor-Independent, HPV-Specific TCR Coupled with a TGF-β Chimeric Switch Receptor Enhances Polyfunctional Profiles and Anti-Tumor Activities in HPV-16/52-Associated Cancers

Susanne Wilde[1], Tao Jin[2], Nina Kallin[1], Lu Yang[2], Ying-Yin Chao[1], Alexandra Wagner[1], Luis F. Olguín-Contreras[3], Wolfgang Uckert[4], Barbara Wollenberg[5], Ulrike Protzer[3], Yi Sun[2], Jingxian Liu[2], Ke Zhang[4]

[1]SCG Cell Therapy, Planegg, Germany,[2]SCG Cell Therapy, Shanghai, China,[3]Institute of Virology, Technical University Munich, Munich, Germany,[4]SCG Cell Therapy, Singapore, Singapore,[5]Department of Otolaryngology, Head and Neck Surgery, School of Medicine, Technical University Munich, Munich, Germany

Background: Treatment of human papillomavirus (HPV)-associated cancers with TCR-T cells targeting the HPV E7 viral antigen has demonstrated promise in early clinical proof-of-principle studies but was limited by tumor-derived suppressive mechanisms. Using our proprietary GianT™ platform, we selected a natural HLA-A*02:01-restricted TCR from a donor diagnosed with an HPV-positive oropharyngeal squamous tumor via high-throughput TCR isolation and characterization processes. We further combined expression of the HPV-specific TCR with a TGF-β-receptor-4-1BB immunoswitch (HPV TCR-TB) to transform the effect of TGF-β, a key immunosuppressive cytokine, into a co-stimulatory signaling trigger to combat the tumor microenvironment. Methods: T cells were genetically modified with a lentiviral vector encoding an HPV $E7_{11-19}$-specific, HLA-A*02:01-restricted TCR and a switch receptor (TB) composed of the TGF-β receptor II exodomain fused to the endodomain of 4-1BB. HPV-TCR T cells +/- TB were produced in a fully closed and automated system, and were analyzed for TCR expression, functional avidity, TCR recognition motif, CD8-dependency, recognition of different HPV genotypes, target-dependent cytotoxicity, proliferation, cytokine secretion and long-term activity *in vitro* as well as for anti-tumor efficacy *in vivo*. Further, HPV-TCR-TB T cells were analyzed for potential alloreactivity and off-target recognition. Results: HPV-E7-specific T cells displayed a high avidity for the cognate peptide in a nanomolar range. The TCR was functional in both $CD8^+$ and $CD4^+$ T cells without adding the CD8-co-receptor, leading to secretion of inflammatory cytokines IFN-γ and TNF-α and killing of HPV^+ target cells. HPV TCR-TB T cells showed less or no upregulation of pSMAD2/3, maintained a more memory-like population, a lower exhaustion phenotype and sustained their functionality in a TGF-β rich environment. During sequential *in vitro* co-culture assays, TCR-T cells without TB eventually failed to eliminate

tumor cells, while HPV TCR-TB T cells maintained their ability to expand and kill tumor targets in the presence of TGF-β. Further, HPV TCR-TB T cells displayed no alloreactivity against the most common class I HLA molecules covering the Asian, American and European population, no reactivity against similar human self-antigen peptides presented by HLA-A*02:01, and no reactivity against primary or iPSC-derived HLA-A*02:01-positive cells. Moreover, *in vivo* studies showed efficient control of xenogeneic tumor cell growth in different tumor models, including SCC090, CaSki-E7 and HepG2-E7 xenotransplanted CDX mice. HPV TCR-TB T cells, both at low and high doses of 0.7E7 and 2E7 TCR^+ T cells/mouse were able to inhibit the growth of tumors via a single intravenous injection. Expansion of T cells could be detected in the following weeks while no side effects were observed. Conclusions: CD8 co-receptor independent, natural high affinity HPV TCR-TB T cells exhibited high specificity, potency and a favorable safety profile for the treatment of HLA-A*02:01-restricted HPV-16- and HPV-52-positive solid tumors. The TGF-β-receptor-41BB immunoswitch significantly enhanced T cell functionality upon exposure to TGF-β, driving sustained TCR anti-tumor activity. These data support the ongoing clinical investigation in HPV-associated cancers.

417. Hostile Takeover: Diagnosing Cancer from within Using a Cancer-Activated Genetic Construct as a Novel Imaging Platform for NSCLC Detection

Mohammed Goryawala[1], Hung-Yu Henry Lee[1], Ling Tong[2], Trupti Patil[1], Alex Harwig[1], Chloe Xia[1], Suthara Ramachandran[1], Xiaobin Wu[1], Dariusz Wodziak[1], Badriprasad Ananthanarayanan[1], Nadege Morisot[1], Dean W. Felsher[2], Tim Sproul[1], David Suhy[1]

[1]Earli, Inc, Redwood City, CA,[2]Stanford University, Palo Alto, CA

Early detection and localization of primary cancers has been shown to improve clinical outcomes and overall survival. While new screening techniques such as a liquid biopsy may indicate the presence of cancer and possibly provide the tissue of origin, they cannot pinpoint the exact location of cancer and its metastases. Furthermore, current imaging techniques are limited to cancers that endogenously express a certain gene product. Alternate imaging approaches using ^{18}F-FDG rely on increased metabolic rates of tumors vs. surrounding non-tumor tissue, often resulting in high background and inability to detect low-metabolic tumors. Earli is developing a highly sensitive platform that is designed to use systemically administered cancer-activated DNA construct with engineered promoter to usurp dysregulated cancer pathways and force the tumor to produce a synthetic biomarker to detect and localize the malignancy while remaining transcriptionally silent in normal adjacent tissues or benign lesions.EARLI-207 is a DNA nanoplasmid with a cancer-activated promoter to drive the selective expression of a functionally inactivated somatostatin receptor 2 (SSTR2fi) gene product as a cell surface reporter. Abrogation of internalization and signal transduction allows the safe use of SSTR2fi as an ectopically expressed PET reporter gene (PRG). Following formulation in a proprietary lipid nanoparticle (LNP) and intravenous administration, EARLI-207 is designed to preferentially transfect tumors with transcriptional activation within cancer cells resulting in selective cell-surface expression of $SSTR2_{fi}$ that can be imaged with FDA-approved and clinically validated SSTR2 PET tracers such as ^{68}Ga-DOTATATE. For preclinical development, a DNA nanoplasmid (EARLI-206) that drives the selective expression of Firefly Luciferase (FLuc) whose response can be measured using Bioluminescence Imaging (BLI) was also developed.To ascertain the sensitivity of the system, H1299 human lung cancer cells engineered to express 900 mRNA copies of the SSTR2 transgene (H1299-SSTR2) were injected into mice and revealed a discernable PET signal with as little as 31,000 cells. Mixed cell titration studies using subcutaneous (SQ) tumors with H1299-SSTR2 and non-expressing H1299-wt cells suggest tumors with transfection rates between 0.1% and 1% H1299-SSTR2 cells had a significant PET signal, compared to tumors with 100% H1299-wt. Furthermore, intratumoral (IT) dose titration of EARLI-204 (CAG-$SSTR2_{fi}$) reveals that dose levels sufficient to transfect ~1-2% of tumor cells as assessed by IHC results in the transcript production of approximately 300-400 copies of SSTR2 mRNA per cell. We continue to use these parameters as benchmarks to develop of a series of novel LNP formulations for the intravenous delivery of the EARLI-204 DNA nanoplasmid. Finally, IV dosing of EARLI-206 in SQ and intralung (orthotopic) tumor models results in cancer-activated expression of FLuc in both SQ and lung tumors with 100-fold increase ($p < 0.05$) BLI signal as compared to PBS-dosed mice. Ongoing experiments with EARLI-207 aim to show a similar response in the PET system with the expectation that tumors as small as 4 mm will be identifiable. The results demonstrate an effective molecular imaging platform for drug discovery ranging from in vivo screening to building PK-PD-efficacy relationships and enabling human dose projection for the Earli PET localization drug. The benchmarks and findings established with this preclinical imaging pipeline are currently being evaluated in large animals such as dogs and pigs, and will be translated to humans in planned clinical trials.

418. Development of Inhalable Polymeric Nanoemulsions for Delivery of Gene Silencing Therapeutics in Lung Tumors

Kasturi Siddhanta, Ling Ding, David Oupicky

Department of Pharmaceutical Sciences, University of Nebraska Medical Center, Omaha, NE

Lung cancer is one of the most common and deadliest cancers globally, accounting for the highest number of cancer-related deaths, with a 5-year survival rate of around 20%. While anti-PD-L1 monoclonal antibody immunotherapy holds promise in combating various cancers, studies suggest its efficacy may be compromised by factors such as poor lymphocyte infiltration and the emergence of an immunosuppressive microenvironment. RNA interference via siRNA/miRNA presents novel possibilities in gene silencing therapeutics, particularly lung cancer, with inhalation delivery offering a targeted, non-invasive approach to directly address specific genetic factors in the lung. We hypothesized that immune check point inhibition using siPD-L1/miR-34a cocktail delivered via inhalation route can enhance anticancer effects through miRNA's global regulatory role and minimizing systemic exposure. We have developed an emulsion polyplex (EP) as inhalable delivery system for lung cancer treatment, which can deliver si/miRNA encapsulated in PAMD-C@PFOB nanoemulsions (PAMD-C: polymeric AMD3100-Cholesterol, a copolymer for CXCR4 inhibition, PFOB: perfluorooctylbromide). PAMD-C was synthesized by Michael

addition followed by preparation of PAMD-C@PFOB oil-in-water nano emulsions (1% v/v) using ultrasonication. The formulation had a size of 170 nm and zeta potential of +20 mV which enabled successful binding of anionic si/miRNA to the nanoemulsion via electrostatic interactions. Gel retardation assay showed that at w/w ratio ≥ 2, the RNA was completely bound by the nanoemulsions. Effective CXCR4 targeting by PAMD-C@PFOB in U2OS cells (expressing GFP-tagged CXCR4) was confirmed by CXCR4 redistribution assay. Flow cytometry performed on transfected H1975 cells showed 60% double positive populations of labelled RNA and emulsion, indicating their successful uptake in the formulation. Lung metastatic breast cancer model was generated by IV injection of luciferase-tagged 4T1 breast cancer cells in Balb/c mice. Bioluminescent imaging done at 6 h and 24 h after nebulized delivery of the EPs to the mice revealed a five-fold higher lung distribution compared to other major organs (Figure 1). H&E staining confirmed that the EPs carrying anti-PD-L1 siRNA and miR-34a significantly reduced tumor burden. When compared with placebo, the EP treatment also prolonged median survival from 20 to 50 days. Immunofluorescence staining on the resected tumors showed increased CD8+ T cell infiltration, calreticulin exposure, and cytotoxic cytokine production. Flow cytometry showed reduced populations of immunosuppressive cells like Tregs and MDSCs. ELISA tests revealed lower levels of immunosuppressive cytokines like IL-10 and TGF-β upon EP administration. The inhalation platform developed here enables effective pulmonary delivery of si/miRNA to treat lung cancer by improving siRNA internalization, endosomal escape, lung penetration, and biodistribution compared to conventional polyplexes. CXCR4 antagonism and PD-L1 gene silencing was achieved, thus inhibiting important pathways involved in lung cancer pathology. EPs developed in this study remodeled the tumor microenvironment to enhance anti-tumor immune response, achieving significantly longer survival. In conclusion, this proof-of-concept study demonstrates the potential of using PAMD-C@PFOB to improve the efficacy of pulmonary siRNA therapeutics via inhalation delivery.

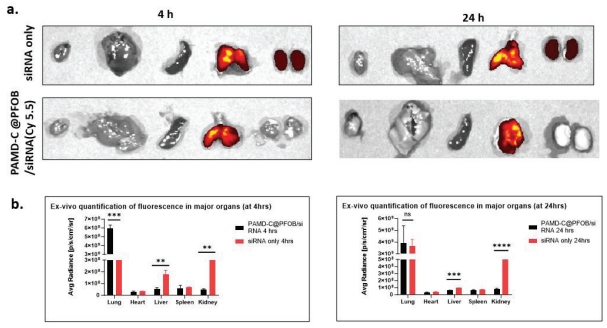

Figure 1. Biodistribution of EPs in 4T1 induced lung tumor model. (a) *Ex vivo* fluorescence imaging of major organs after nebulized administration of Cy3-PAMD-C@PFOB/Cy5.5-siRNA EPs at 4h and 24 h **(b)** *Ex vivo* quantification of fluorescence distribution in major organs at 4 h and 24 h post nebulized administration (n =3 , mean ± SD, Student's t-test). Significance was indicated as *p<0.05, **p<0.01, and ***p<0.001.

419. Discovery of Tumor Reactive TCRs and Their Cognate Antigenic Targets via High-Throughput Functional Screening

Candace Perullo, Jinyu Zhu, Yifan Wang, Kimberly M. Cirelli, Qikai Xu, Alexander Cristofaro, Amy Virbasius, Emily Miga, Rachel Lent, Shoshana M. K. Bloom, Jackson Lirette, Kenneth L. Jahan, Livio Dukaj, Jin He, Ryan Kritzer, Joel Sher, Chandan Pavuluri, Jenna LaBelle, Sida Liao, Cagan Gurer, Gavin MacBeath

TScan Therapeutics, Waltham, MA

Introduction: T cell receptor engineered T-cell therapies (TCR-T) are a promising modality for cancer treatment because unlike CAR-T cells, TCR-T cells can target both intracellular and extracellular tumor antigens. Tumor infiltrating lymphocytes (TILs) can be a source of tumor specific TCRs to fuel target discovery efforts; however, anti-tumor TCRs are rare [1] and most TILs are bystanders specific to other pathogens [2-3]. To identify targets of TILs that are cancer specific with a favorable safety profile, we developed a high-throughput reactivity screening method to identify TCRs from the TIL repertoire that target shared cancer specific antigens. The targets for these tumor reactive TCRs can then be rapidly identified using TScan's proprietary TargetScan platform. Methods: Primary CD8+ T cells were engineered to express a library of 2,439 TCRs derived from the lesions of 13 melanoma patients. The T cell pool was co-cultured with seven melanoma cell lines with patient matched HLAs and a normal cell line control. T cells expressing the activation induced markers CD69 and CD137 were sorted and sequenced to identify the TCRs of the activated T cells. Individual TCRs were selected for validation based on strong enrichment when co-cultured with multiple cell lines that express the same HLA allele. TCRs with confirmed reactivity to multiple cancer cell lines were then screened using TargetScan, wherein their cognate antigens were identified. Results and Conclusions: 95 TCRs were identified in the high-throughput melanoma screen and selected for validation. 48 of these TCRs were validated when tested individually and 24 were screened using TargetScan. 21 out of 24 were successfully deorphanized and found to target therapeutically relevant shared antigens restricted to A*02:01, including MLANA, Tyrosinase, and MAGE-C2. Using melanoma-derived TILs, we have established that the high-throughput reactivity screen to TargetScan pipeline can be used to identify tumor-reactive TCRs against shared tumor antigens and this approach will be expanded to other cancer indications to allow for the discovery of new targets of TCR-T therapy. 420. CRISPR-Cas9 Genetic Targeting of Metastatic Pancreatic Cancer

Kirsten Bowland[1], Jiaying Lai[2], Selina Shiqing K. Teh[1], Alexis Bennett[1], Alyza Skaist[3], Yan Zhang[3], Elizabeth Thompson[1], Sarah J. Wheelan[4], Ralph H. Hruban[1], Rachel Karchin[2], Christine A. Iacobuzio-Donahue[5], James R. Eshleman[1]

[1]Dept. of Pathology, Johns Hopkins University School of Medicine, Baltimore, MD,[2]Johns Hopkins University, Baltimore, MD,[3]Johns Hopkins University School of Medicine, Baltimore, MD,[4]National Institutes of Health, Bethesda, MD,[5]Memorial Sloan Kettering Cancer Center, New York, NY

Metastatic cancer affects millions of people worldwide annually and is the leading cause of cancer-related deaths. Most patients with metastatic disease are not eligible for surgical resection, and current therapeutic regimens have varying success rates, some with 5-year survival rates below 5%. Here we test the hypothesis that metastatic cancer can be genetically targeted by exploiting somatic single base substitution mutations that occur as part of normal aging prior to transformation. These passenger mutations are targetable because ~10% of them form novel tumor-specific "NGG" protospacer adjacent motif (PAM) sites targetable by CRISPR-Cas9. We studied five patients with pancreatic cancer (PC) who underwent a rapid autopsy to determine areas of evolutionary conservation that were maintained throughout all metastases in each patient's cancer. Using whole genome sequencing validated by high-depth capture sequencing, we found that that 90% of PAM targets were maintained between primary carcinomas and metastases overall. We identified rules that predict PAM loss or retention, where PAMs located in heterozygous regions in the primary tumor can be lost in metastases (private loss of heterozygosity (LOH)), but PAMs occurring in regions of LOH in the primary tumor were universally conserved in metastases. Using multitarget sgRNA which cut at a known number of sites in the human genome, we determined a relationship between the number of CRISPR-Cas9 cuts and growth inhibition in PC cells. We found that 8-10 target sites in non-coding regions were sufficient to induce >95% cancer cell death. Furthermore, only 2-3 targets were required to achieve a comparable level of cell death in the presence of a DNA double strand break inhibitor. Finally, using cocultures of PC cells transduced with sgRNA targeting multiple tumor specific PAMs, we demonstrate selective cell killing of three different PC cell lines. Importantly, deep sequencing of patient-matched normal lymphocytes lacking the tumor-specific PAMs treated with the same sgRNA array exhibited no editing at the targeted loci. This work establishes a bioinformatic platform for the discovery of tumor-specific CRISPR targets in the context of metastatic disease and demonstrates selective killing of cancer cells while sparing the patient's normal cells. These data establish the proof of principle for a gene therapy approach targeting metastatic disease.

421. CRISPR-Cas9 for Selective Targeting of Somatic Mutations in Pancreatic Cancers: A Novel Cancer Gene Therapy Approach

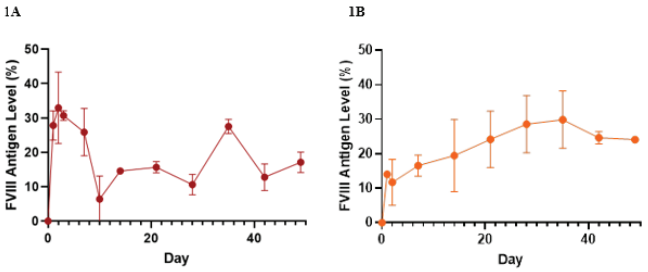
Selina Shiqing K. Teh[1], Kirsten Bowland[1], Alexis Bennett[1], Eitan Halper-Stromberg[1], Alyza Skaist[2], Jingyao Ma[3], Yining Zhu[3], Sarah Wheelan[2], Hai-Quan Mao[3], Nicholas J. Roberts[1], James R. Eshleman[1]

[1]Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, MD,[2]Department of Oncology, Johns Hopkins University School of Medicine, Baltimore, MD,[3]Institute of NanoBioTechnology, Johns Hopkins University, Baltimore, MD

Introduction Somatic mutations are desirable targets to selectively eliminate cancer, yet most are found within noncoding regions. We have adapted the CRISPR-Cas9 gene editing tool as a novel, cancer-specific killing strategy by targeting the subset of somatic mutations that create protospacer adjacent motifs (PAMs). PAMs evolutionally allow bacterial cells to distinguish between self and non-self DNA for Cas9-induced double strand breaks. We hypothesized that a large number of somatic 5'-NGG-3' PAMs that arose from single base substitutions (SBSs) existed in pancreatic cancers (PCs) and other tumor types (e.g. NCG -> NGG), and these novel PAMs could serve as CRISPR-Cas9 targets for selective cancer cell elimination. **Methods** For method development, whole genome sequencing (WGS) data of paired tumor-normal (T-N) samples from three PC patients were put through PAMfinder, a software designed for somatic PAM discovery, to identify novel PAMs. PAMs with >95% variant allele frequency (VAF) and that produced sgRNAs with minimal off-target activity (based on CRISPOR) were Sanger sequenced. To determine prevalence of somatic PAMs in different tumor types, 591 T-N subtracted variant call files from ICGC were analyzed. To investigate target selectivity and specificity of patient-specific sgRNAs designed based on novel PAMs, we set up co-cultures to detect potential selective cytotoxicity using flow cytometry, while performing deep sequencing and WGS on sgRNA-transduced clones to study on- and off-target activities. To demonstrate *in vivo* efficacy, we screened 1080 lipid nanoparticle (LNP) formulations for *in vitro* transfection efficiency using luciferase and mCherry reporter assays to identify the optimal LNPs for *in vivo* delivery. **Results** On average, 417 somatic PAMs per PC case were found (9.2% of total SBSs), >99% of them were located in non-exonic regions, and 97% of the selected subset were Sanger confirmed. Analysis of ICGC data revealed medians of 478.5 and 430.5 somatic PAMs per tumor in two PC cohorts (N=174 combined), 2790 in lung (N=29), and 3235.5 in esophageal (N=388) cancer cohorts. We demonstrated 69-99% selective cell death of three targeted PC cell lines (Panc10.05, TS0111, Panc480) using 4-9 sgRNAs designed based on their somatic PAMs. Sequencing revealed on-target activity in the targeted cell line, and no Cas9 activity in either the patient's normal cells or an irrelevant cancer transduced with a multi-sgRNA expression vector containing 7 Panc480-specific sgRNAs. Off-target analyses on sgRNA-transduced clones found no evidence of off-target events. Finally, using Panc10.05, we identified the top performing LNP formulations with distinct helper lipids, and performed subsequent screening in monolayer cell culture and organoids of human pancreatic tumor cells to further identify top performing LNP formulations for *in vivo* screening. **Conclusions** Our results showed that adult solid tumors harbor hundreds, if not thousands, of somatic PAMs, and these PAMs could serve as selective

and specific novel CRISPR-Cas9 targets to selectively kill cancer cells. This study demonstrates the potential of CRISPR-Cas9 as a novel and selective anti-cancer strategy, and supports the genetic targeting of adult cancers.

Nonviral Approaches for Therapeutic Applications



422. Optimization of Fluoroscopy Guided Ultrasound Mediated Gene Delivery in Canines for Sustained FVIII Expression

Savannah M. Lawton[1], Ting-Yen Chao[1], Feng Zhang[2], Masaki Kajimoto[1], Brian Hayes[3], Keith Loeb[3], Timothy C. Nichols[4], Carol H. Miao[5]

[1]Seattle Children's Research Institute, Seattle, WA,[2]University of Washington, Seattle, WA,[3]Fred Hutchinson Center Research Center, Seattle, WA,[4]UNC at Chapel Hill Francis Owen Blood Rsch. Lab., Chapel Hill, NC,[5]Seattle Children's Research Institute, Seattle, WA

Hemophilia A (HA) is an x-linked genetic condition that results in the faulty production of factor VIII (FVIII), a blood coagulation protein. Previously, we performed ultrasound mediated gene delivery (UMGD) of a hepatocyte specific human FVIII (hFVIII) plasmid into normal canines and generated sustained hFVIII expression between 7-15% over 60 days in 2 of 4 treated canines. In this study, we are attempting to further increase FVIII expression levels with a universal hFVIII plasmid, opposed to the previously used hepatocyte specific hFVIII plasmid in normal canines. Additionally, we will compare the difference in transfection efficiency between two liver lobes in the same canine that were each treated with a different ultrasound condition. We aim to optimize the ultrasound treatment parameters and plasmid for experiments on HA canines. A 14 mm x 20 mm balloon catheter was inserted into the hepatic vein via jugular vein access of two canines, and a mix of a high expressing hFVIII plasmid driven by the CAG promoter and RN18 microbubbles (MBs) were injected. Simultaneously, the ultrasound transducer, H114, was placed transcutaneously over the liver and was treated using a pulsed US treatment. In each dog, two lobes were treated, the left lateral lobe (LLL) and right lateral lobe (RLL) with 4 injections of the pDNA and MBs each. The individual lobe was treated for 2 minutes with the US transducer for each injection, for a total treatment time of 8 minutes. In canine 1 (C1) the LLL was treated with 1500 W and the RLL with 750 W. In canine 2 (C2) the LLL was treated with 750 W, and the RLL with 1500 W. Blood was collected on D1, 2, 3, then weekly for approximately 2 months, and subjected to ELISA to measure hFVIII activity. CBC and whole blood chemistry was also run on collected blood. C1 was sacrificed on D60, and the liver was harvested and sectioned into 1cm x 1cm sections. Copy number analysis was run on sections from both treated lobes, as well as the untreated lobes to analyze transfection with differing US conditions. Representative sections were selected from each liver lobe and subjected to H&E staining and reviewed by a certified pathologist. C2 is scheduled for sacrifice and liver collected on D90. Both canines had notable hFVIII expression over the two months followed. C1 had initially high hFVIII values of 30-42% which decreased slightly following day three but remained stable around 20% (Figure 1A). The expression for C2 continued to increase steadily for a month, and currently is stabilizing around 25-30% (Figure 1B). Copy number analysis from C1, showed significantly higher plasmid copies in the RLL. Interestingly, none of the canines developed species-specific anti-human FVIII antibodies. Both dogs had very minor elevation in the AST/ALT levels on day one, but these levels decreased to normal by day three. No other parameters from CBC and whole blood chemistry analysis showed any significant changes in either dog. This data suggests that the use of the CAG-F8X10 plasmid and differing ultrasound conditions further improved the technology of fluoroscopy guided UMGD in canines. Furthermore, these results suggest a promising therapeutic outcome if applied in HA canines.

Figure 1. Human FVIII expression levels in treated Canine 1 (1A) and Canine 2 (1B) blood plasma following UMGD

423. Intrathecal Administration of Lipid Nanoparticles to Silence Pain-Associated Genes by CRISPR Interference

Thomas J. Payne[1], Raquel Tonello[2], Jeffri S. Retamal[2], Paulina D. Ramírez-García[2], Nigel W. Bunnett[2], Colin W. Pouton[1]

[1]Monash Institute of Pharmaceutical Sciences, Parkville, Australia,[2]New York University, New York, NY

Chronic pain is inadequately treated by opioids and non-steroidal anti-inflammatory drugs, which have life threatening side effects. Lipid nanoparticle (LNP)-encapsulated mRNA can be delivered systemically to manipulate expression of disease-associated genes. However, systemically-administered LNPs do not efficiently penetrate the central nervous system due to their large size and are thus unsuitable for therapeutic targeting of the central mechanisms of pain. We investigated the therapeutic effects of intrathecally (IT) administered LNP formulations encapsulating mRNA to silence pain-associated genes using CRISPR interference (CRISPRi). LNPs were formulated comprising a lipid formulation analogous to the FDA-approved product *Onpattro*. To determine whether IT administration of LNPs can effectively control gene expression in the spinal cord, sensory ganglia and brain, LNPs were used to encapsulate nanoluciferase (NanoLuc) mRNA. LNP-NanoLuc mRNA or unencapsulated NanoLuc mRNA was injected IT into the lumbar spinal cord of mice. After 24 or 48 h, spinal cord, brain and dorsal root ganglia (DRG) were collected to measure NanoLuc protein. After administration of LNP-NanoLuc mRNA, NanoLuc expression was detected in the lumbar DRG and spinal cord, with similarly high levels of expression in the thoracic and cervical spinal cord, hind brain, mid brain and forebrain (Fig. 1). In contrast, after administration of unencapsulated NanoLuc mRNA, expression was detected only at the site of administration (lumbar spinal cord and

DRG). To determine whether LNP-mRNA formulations can be used for the treatment of pain, LNP formulations were used to down regulate the gene encoding adaptor associated kinase 1 (AAK1), a therapeutic target for chronic pain. AAK1 mediates dynamin-dependent retrieval of synaptic vesicles from the central terminals of primary sensory neurons and is thus required for sustained release of neurotransmitters in nociceptive circuits of the dorsal horn of the spinal cord. A dCas9 mRNA CRISPRi construct with either a single-guide RNA (sgRNA) targeting the promoter of the mouse AAK1 gene or a non-targeting sgRNA negative control (NC) were encapsulated into LNPs. A model of post-operative pain was studied in which an incision was made on the plantar surface of the paw of anesthetized mice. LNP-dCas9 AAK1 or LNP-dCas9 NC was administered by IT injection. Paw withdrawal responses to stimulation of the plantar surface with von Frey filaments or radiant heat were used to assess mechanical allodynia or thermal hyperalgesia, respectively. In mice treated with LNP-dCas9 NC, robust mechanical allodynia and thermal hyperalgesia were apparent for 96-168 h. LNP-dCas9 AAK1 prevented both mechanical allodynia and thermal hyperalgesia for 96 h (Fig. 2). Withdrawal responses of the unoperated contralateral paw and rotarod latency were unaffected by LNP-dCas9 NC or LNP-dCas9 AAK1, suggesting that normal motor function was unaffected. These results suggest that the IT administration of LNP encapsulating CRISPRi formulations can be used to silence pain-associated genes, offering a much-needed non-opioid therapy for the relief of chronic pain.

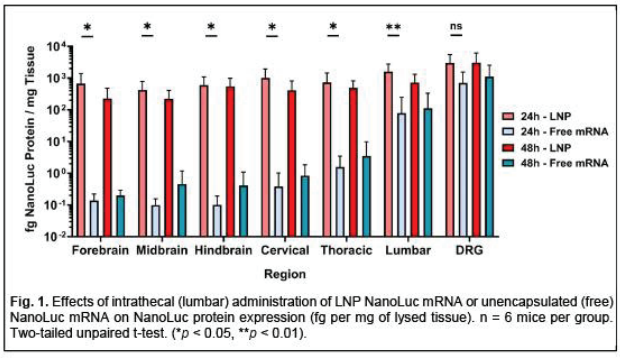


Fig. 1. Effects of intrathecal (lumbar) administration of LNP NanoLuc mRNA or unencapsulated (free) NanoLuc mRNA on NanoLuc protein expression (fg per mg of lysed tissue). n = 6 mice per group. Two-tailed unpaired t-test. (*$p < 0.05$, **$p < 0.01$).

424. Focused Ultrasound- and Long-Circulating Nanoparticle-Mediated Nucleic Acid Delivery and Genome Editing in the Brain

Gijung Kwak[1], Angad Grewal[2], Griffin Mess[2], Haolin Li[1], Hanseok Ko[3], Richard J. Price[4], Amir Manbachi[2], Justin Caplan[2], Betty Tyler[2], Jung Soo Suk[1,2]

[1]Department of Neurosurgery, University of Maryland School of Medicine, Baltimore, MD,[2]Department of Neurosurgery, Johns Hopkins University School of Medicine, Baltimore, MD,[3]Institute for Cell Engineering, Johns Hopkins University School of Medicine, Baltimore, MD,[4]University of Virginia, Charlottesville, VA

Successful translation of nanoparticles (NPs) for nucleic acid-based therapy of brain diseases, including brain cancers and neurodegenerative diseases, requires safe and efficient nucleic acid delivery to the targeted disease area within the brain. Stereotaxic convection-enhanced delivery has been explored to achieve therapeutic delivery to the target site in the brain, but the procedure of invasive intracranial injection can cause adverse effects, including infection, edema, and neuron damage. To address this limitation, systemic brain targeting has been investigated in clinical and preclinical studies. However, systemically administered NPs inevitably encounter the blood-brain barrier (BBB), which is the highly challenging barrier established throughout cerebral capillaries that limits trans-vascular NP transport into the brain. The BBB penetrable adeno-associated virus serotype 9 (AAV9)-based brain gene therapy, Zolgensma®, was approved by the FDA, but AAV9 highly accumulated in the liver, heart, and muscle as well. Here, we introduce a two-pronged strategy, comprising BBB-opening focused ultrasound (FUS) and long-circulating poly(ethylene glycol)-coated poly(beta-amino esters) (PEG-PBAE) NPs, that enables systemic nucleic acid delivery to the brain. FUS applied to a predetermined coordinate within the brain induces cavitation of systemically administered microbubbles (MBs) passing through the cerebral capillaries to open the BBB in a targeted, transient, and reversible manner. In parallel, our nucleic acid-loaded PEG-PBAE NPs stably circulate in bloodstream and efficiently penetrate the brain tissue. PEG-PBAE polymers were complexed with plasmid DNA (pDNA) or messenger RNA (mRNA) to form NPs (A and B). PEG-PBAE NPs exhibited excellent colloidal stability in relevant physiological environments, including artificial cerebrospinal fluid and whole mouse serum (C and D). Systemically administered PEG-PBAE NPs carrying pDNA or mRNA exhibited stable circulation in the bloodstream for up to 4 hours, a time window of FUS/MB-mediated BBB opening (E, F, and G). Accordingly, the combination of PEG-PBAE NPs + FUS/MB resulted in efficient NP accumulation at the FUS-applied target site within the brain while exhibiting minimal off-target accumulation (H and I). Freshly prepared and serum-incubated PEG-PBAE NPs showed comparably widespread transgene expression in the brain, underscoring that the ability of our NPs to penetrate the brain tissue was retained (J and K). FUS/MB + PEG-PBAE NPs carrying reporter pDNA or mRNA achieved efficient reporter protein production in astrocytes and neurons at the FUS-applied site (L, M, N, and O). Likewise, FUS/MB + PEG-PBAE NPs carrying mRNA encoding CRISPR-associated protein 9 (Cas9) and sgRNA targeting loxP-flanked STOP cassette in the Ai9 mice chromosome (P) resulted in efficient tdTomato expression, indicating successful gene editing, in astrocytes and neurons at the FUS-applied

site (Q, R, and S). Overall, FUS/MB + PEG-PBAE NPs provide a highly versatile means to enable efficient site-specific therapeutic nucleic acid delivery and gene editing in the brain.

FUS- and PEG-PBAE NP-mediated pDNA or mRNA delivery to and genome editing in the brain. **(A)** Representative agarose gel electrophoresis migration assay showing robust packaging of pDNA (left) or mRNA (right) in PEG-PBAE NPs. Numbers indicate the polymer-to-nucleic acid weight ratios. MK: molecular weight marker. **(B)** Representative transmission electron micrographs of PEG-PBAE NPs carrying pDNA (top) or mRNA (bottom). Scale bar = 200 nm. **(C)** Colloidal stability of PBAE and PEG-PBAE NPs carrying pDNA or mRNA incubated in aCSF at 37 °C for up to 8 hours. **(D)** Median MSD values of PBAE and PEG-PBAE NPs carrying pDNA or mRNA in PBS or whole mouse serum. MSD is a square of distance traveled by an individual particulate matter within a predetermined time interval (*i.e.*, time scale; $\tau = 1$ s) and thus is directly proportional to the particle diffusion rate. **(E)** Representative whole-body fluorescence images of live animals intravenously treated with PBAE NPs, PEG-PBAE NPs, or LNPs carrying Cy5-labeled pDNA or mRNA over time. **(F)** Representative fluorescence images of major organs harvested at 4-hour post-administration from the animals in Figure 1E. **(G)** Quantification of Cy5 fluorescence intensity of the serum collected at 4-hour post-administration of NPs from the animals intravenously treated with PBAE NPs, PEG-PBAE NPs, or LNPs carrying Cy5-labeled pDNA or mRNA. **(H)** Representative fluorescence images and **(I)** Cy5 fluorescence intensity of brains and other major organs harvested at 4-hour post-administration from the animals treated with FUS on the right striatum and intravenously received saline or PBAE or PEG-PBAE NPs carrying Cy5-labeled pDNA. **(J)** Representative fluorescence images showing reporter ZsGreen1 expression in the brain sections at the infusion site within healthy mouse brain striatum 48 hours after the intracranial CED of freshly-prepared or serum-incubated PEG-PBAE NPs carrying pDNA encoding ZsGreen1 (0.1 mg/kg pDNA). Blue: nucleus; Green: ZsGreen1. **(K)** Image-based quantification for area of ZsGreen1 expression. **(L)** Bioluminescence images of brains harvested at 48- or 24-hour post-administration from animals intravenously treated with PEG-PBAE NPs carrying pDNA or mRNA encoding luciferase or LNP carrying mRNA encoding luciferase (1.25 or 2.5 mg/kg pDNA or 0.5 mg/kg mRNA) and subsequently received a FUS treatment on right striata. **(M)** Quantification of luciferase activity in the homogenized hemispheres from the brains in Figure 1L. Representative confocal images showing reporter ZsGreen1 or mCherry production in FUS-treated areas of **(N)** GFAP- and **(O)** NeuN-stained brains harvested at 48- or 24-hour post-administration from animals intravenously treated with PEG-PBAE NPs carrying pDNA or mRNA encoding ZsGreen1 or mCherry (2.5 mg/kg pDNA or 0.5 mg/kg mRNA), respectively, and subsequently received a FUS treatment on right striata. Green: ZsGreen1 or mCherry; Red: astrocyte (GFAP) or neuron (NeuN). **(P)** Repersentative TBE gel electrophoretic analysis showing the successful packing of Cas9 mRNA and sgRNA 298 in PEG-PBAE NPs. Numbers indicate the polymer-to-nucleic acid weight ratios. MK: molecular weight marker. **(Q)** Representative confocal images of the brains harvested at 5-day post-administration of NPs from female (upper) and male (bottom) Ai9 mice intravenously treated with PEG-PBAE NPs carrying Cas9 mRNA and sgRNA 298 (0.5 mg/kg mRNA and sgRNA each) and subsequently received a FUS treatment on right striata. Blue: nucleus; Green: tdTomato. Representative confocal images showing reporter tdTomato production in untreated or FUS-treated areas of **(R)** GFAP- and **(S)** NeuN-stained brains from the animals identically treated as in Figure 1Q. Blue: nucleus; Green: tdTomato; Red: astrocyte (GFAP) or neuron (NeuN). n.s.: no significance, * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$, **** $p < 0.0001$ (one-way ANOVA).

425. Supramolecular Assembly of Polycation/mRNA Nanoparticles and *In Vivo* Monocyte Programming

Leonardo Cheng[1,2,3], Yizong Hu[1], Stephany Yi Tzeng[1,3], Jordan J. Green[1,2,3], Hai-Quan Mao[1,2,3]

[1]Johns Hopkins University, Baltimore, MD,[2]Institue for NanoBioTechnology, Baltimore, MD,[3]Translational Tissue Engineering Center, Baltimore, MD

Statement of Purpose: Circulating monocytes and their antigen-presenting cell (APC) descendants (macrophages, Mo-dendritic cells) are important therapeutic targets. Monocytes, with their great abundance, estimated to be nearly 20-fold higher than conventional dendritic cells, present an underexplored opportunity to leverage the innate immune system against target diseases. However, there is a lack of methods to controllably assemble mRNA particles of sizes that specifically target phagocytes. Exploiting the assembly kinetics of mRNA particles provides a potential route to engineer submicron (200-1000 nm) particles and explore size-dependent delivery mechanisms. Here, we develop a new kinetic assembly process for controlled assembly of submicron particles from biodegradable poly(beta-amino ester) (PBAE) and mRNA. We report preferential uptake and intracellular delivery of 400-nm particles in mouse monocytes, which differentiate into APCs and elicit potent tumor-specific immune activation. *Methods:* The PBAE was synthesized and formulated into nanoparticles (NPs) with mRNA according to our reported method.[1] Submicron particles were prepared by controlling the ionic strength and pH of the buffer with colloidal stability to obtain particles of defined size. Their *in vitro* transfection efficiencies were assessed in bone marrow-derived macrophages (BMDMs). Select particles loaded with luciferase-encoding mRNA (mLuc) were administered intravenously (*i.v.*) into Balb/c to evaluate transgene expression level *in vivo* by In Vivo Imaging System (IVIS). Cre recombinase-encoding mRNA were administered *i.v.* into Ai9 mice to assess cell type-specific transfection *in vivo*. Particles with effective monocyte transfection were loaded with control (mLuc) or ovalbumin (mOVA) encoding mRNA with/without CpG ODN1826 (ODN), a Toll-like receptor 9 agonist, and administered to C57BL/6 mice to evaluate anticancer immune activation in a melanoma model. *Results:* Submicron PBAE/mRNA particles were formulated by kinetic assembly and stabilized between 100 and 900 nm (Fig. 1A-B). Compared to conventional 100-nm NPs, 400-nm particles transfected BMDMs more effectively at high doses *in vitro* (Fig. 1C). After *i.v.* injection, larger particles achieved have higher overall transgene expression than 100-nm NPs with most expression located in the liver and spleen (Fig. 1D). 400-nm particles achieved the highest transfection in monocytes and monocyte-derived phagocytes compared to other particle sizes in the spleen and liver after *i.v.* injection (Fig. 1E-F). In an OVA-expressing B16 melanoma model, 400-nm particles elicited significantly more OVA-specific T cells in the tumor and draining lymph node than 100-nm NPs (Fig. 1G). *Conclusion:* Kinetic assembly of PBAE/mRNA particles enables the controllable and scalable production of stable submicron (200-1000 nm) particles. 400-nm submicron particles effectively delivered mRNA and adjuvant to phagocytes, particularly circulating monocytes, *in vivo*. Transfected circulating monocytes can be programmed for activation as antigen-presenting cells leading to antigen-specific T cell activation.

426. Non-Viral Targeted Laser Delivery of Multi-Characteristic Opsin Genes for Treatment of Geographic Atrophy

Samarendra K. Mohanty[1], Sanghoon Kim[2], Subrata Batabyal[2], Michael Carlson[2], Amir Singh[1], Adnan Dibas[2], Najam Sharif[1]

[1]Nanoscope Therapeutics Inc, Dallas, TX,[2]Nanoscope Technologies LLC, Bedford, TX

Purpose: Vision loss in end-stage age-related macular degeneration (AMD) patients, particularly due to geographic atrophy (GA), is linked to the loss of photoreceptors. Highly photosensitive MCO expression in higher-order retinal neurons restores light sensitivity to the retina in patients with permanent photoreceptor loss. Non-virally delivered Multi-Characteristic Opsin (MCO) optogenetic therapy may be a promising treatment strategy for retinal degenerative diseases. Optical Coherence Tomography (OCT)-guided laser-delivery of MCO plasmids achieves spatial targeting of GA lesions while avoiding healthy regions of the peripheral retina. **Method:** To achieve targeted delivery of MCO, we integrated a near-infrared (NIR) laser beam with an OCT imaging beam to locate retinal lesions. A mixture of MCO plasmids and gold nanorods (GNRs) was intravitreally injected into multiple animal models. Upon laser micro-irradiation, the GNRs cause localized enhancement of laser intensity leading to the formation of nanopores on the targeted cell membranes, thus permeabilizing the membrane to enable precise and site-specific delivery of MCO-plasmids. The efficacy of laser-delivered MCO was evaluated in retinal degeneration (*rd*) rodent models by immunohistochemistry (IHC) and electrophysiology. The safety and toxicity of this delivery method were evaluated in wild-type rodents and African green monkeys using electrophysiology, OCT, intraocular pressure (IOP) monitoring, and IHC. **Results:** Expression of MCO in the retina led to long-term expression up to 1 yr. Enhanced electroretinography (ERG) and visually evoked cortical activities in *rd* animals were observed, which correlated with MCO expression. No observed adverse effect level (NOAEL) was determined for GNR, plasmids, and laser doses. No noticeable decline in ERG, retina thickness (via OCT), increase in cell death, or increase in immune cell response (via IHC) was observed in the therapeutic dose range in wild-type rodents and monkeys. Robust MCO delivery through the internal limiting membrane (ILM) in monkeys, as visualized by fundus imaging of the reporter (mCherry) fluorescence, led to functional improvement, measured by redERG, attributed to MCO's broadband activation spectrum. **Conclusion:** The safety and efficacy of non-viral spatially targeted laser-delivery of MCO observed in multiple animal models offer an opportunity for efficient and targeted therapeutic gene expression in specific retinal cells within GA lesions. This establishes the utility of the method for translational applications while avoiding immune rejection and adverse events typical of virally delivered gene therapies.

427. Unraveling a Multifactorial Host Immune Response to Intramuscular Electrotransfer of DNA-Encoded Antibody Therapy

Debby Thomas[1], Jenny Sprooten[2], Jannes Govaerts[2], Pascal Merchiers[3], Maarten Dewilde[1], Abhishek Garg[2], Kevin Hollevoet[4], Nick Geukens[4]

[1]Laboratory for Therapeutic and Diagnostic Antibodies, KU Leuven, University of Leuven, Leuven, Belgium,[2]Laboratory of Cell Stress & Immunity, KU Leuven, University of Leuven, Leuven, Belgium,[3]Biomerpa BV, Kasterlee, Belgium,[4]PharmAbs, the KU Leuven Antibody Center, KU Leuven, University of Leuven, Leuven, Belgium

DNA-based antibody gene transfer aims to administer antibody-encoding nucleotides, rather than the antibody protein, utilizing a non-viral plasmid DNA (pDNA) vector. This strategy aims to achieve sustained *in vivo* antibody production, addressing challenges inherent to conventional antibody production and delivery. Previously, we demonstrated preclinical proof of concept for diverse DNA-encoded monoclonal antibodies (mAbs) and nanobodies delivered in muscle or tumor using electroporation (EP). We also gained insights into pDNA fate post-injection. The present pharmacokinetic (PK) profile of mAbs expressed in vivo in mice, after intramuscular (IM) EP, is typified by a gradual increase in the initial week(s), culminating in peak plasma levels after 3-4 weeks, followed by a decline of 50% after about 6 weeks, to roughly 90% after several months. Maintaining plasma levels at peak concentrations for an extended duration is highly desirable for this approach to broaden its application potential.In this study, we aim to delineate the host immune response in mouse muscle following IM pDNA EP and identify factors directly linked to expressed mAb PK. To achieve this, knockout (KO) models and immune phenotyping are employed, utilizing a validated pDNA encoding a murine 4D5 anti-HER2 mAb. Earlier experiments demonstrated that mAb PK

in athymic nude and RAG1 KO mice did not significantly differ from wild-type (WT) mice, suggesting that T and B cells, including antigen-presenting pathways, do not drive the decline in mAb expression. To assess the impact of the innate immune response, we evaluated 4D5 PK in IFNAR1 KO mice, which lack type-I interferon receptor function. After IM p4D5 EP, plasma mAb levels showed no significant difference between IFNAR1 KO and WT mice throughout the 12-week follow-up. This finding diminishes the likelihood that DNA sensing, including cGAS/STING, affects mAb PK. Concurrently, we ran flow cytometry panels on WT mice muscle, harvested one week post-IM EP. Compared to control muscle (including untreated, vehicle-injected, and EP only), infiltrated T cells showed more of the effector phenotype and dendritic cell (DC) muscle infiltration was increased. NK cell-mediated cytotoxicity was considered, but muscle NK cell infiltration was limited and did not increase after pDNA EP. This suggests that cytotoxic T-cell responses, facilitated by DC-based antigen presentation, may target mAb-producing cells. However, this does not appear to impact mAb kinetics based on earlier observations in RAG1 KO mouse model.In addition, while assessing the IM macrophage population upon treatment, we found that the percentage of pro-inflammatory macrophages (M1) increased, while the anti-inflammatory macrophages (M2) population remained unchanged. This data, supported by an increased DC infiltration, implies that phagocytic antigen-presenting cells play a role in the decreased mAb production. Potentially, cells transfected with mAb-encoding pDNA increase their "eat-me signals" due to cell stress (EP, protein overproduction, ER stress, etc.), attracting phagocytic cells. Ongoing work investigates whether modulating phagocytosis impacts mAb kinetics. In conclusion, this work started to unravel a multifactorial host immune response triggered by IM electrotransfer of a DNA-encoded mAb. As we elaborate on these observations, factors demonstrably associated with mAb kinetics will be of particular interest, as modulating these responses could allow for a more robust and prolonged *in vivo* mAb expression.

428. Sustained Endogenous FVIII Expression in Hemophilia A Mice is Achieved through *In Vivo* CRISPR/Cas9 mRNA LNP Gene Editing

Chun-Yu Chen[1], Xiaohe Cai[1], Carol H. Miao[1,2]

[1]Center for Immunity and Immunotherapies, Seattle Children's Research Institute, Seattle, WA,[2]Pediatrics, University of Washington, Seattle, WA

Small nucleotide mutations including small deletion/insertion, missense, nonsense, and splicing site mutations in the human FVIII gene result in severe hemophilia A (HA) in approximately 47% of patients. Among these, frameshift mutations contribute to around 15.2% in severe HA patients. CRISPR/Cas9-mediated indel (Insertion and deletion) mutations can facilitate the correction of frameshift-induced pre-termination codons to restore missing FVIII protein expression in affected HA patients. Moreover, advancement of lipid nanoparticle (LNP) technology provides an *in vivo* gene delivery approach. Our goal is to optimize the delivery efficiency of Cas9 mRNA-encapsulated LNPs targeting the native site of FVIII gene synthesis, liver sinusoidal endothelial cells (LSECs), for efficient correction of FVIII gene mutations. Immunodeficient HA mice (NSG HA) with a 5 bp deletion causing a frameshift mutation in FVIII exon 1 was established and served as the gene editing animal model. We encapsulated Cas9 mRNA with sgRNA into LNPs and intravenously deliver the LNPs to NSG HA mice. After treatment with Cas9 mRNA/sgRNA LNPs, average gene editing rates of 15% in LSECs and 57% in hepatocytes were observed. Among the gene-edited cells, over 60% of the frameshift mutations in FVIII gene exon 1 were corrected by CRISPR/Cas9 induced in-frame indel mutations. Additionally, NSG HA mice generated sustained expression of averagely 3% functional FVIII for 26 weeks following Cas9 mRNA/sgRNA LNPs treatment. To enhance LSEC-targeting ability, we incorporated mannose ligands on LNPs targeting mannose receptors on LSECs. We developed a novel MC3 LNP formulation, incorporating mannose-conjugated PEG for specific LSEC targeting. The efficacy of this mannose-conjugated MC3 LNP in LSEC targeting was assessed, with immunostaining and luciferase assays demonstrating a marked improvement in targeting efficiency toward LSECs. All the data suggested that our LNPs effectively delivered gene editing agents to induce indel mutations in both hepatocytes and LSECs *in vivo*. Cas9 mRNA/sgRNA LNPs specifically target and correct indel mutations in mutant FVIII exon 1, leading to the permanent correction of the mutant FVIII gene in LSECs and achieving therapeutic levels of FVIII expression in NSG HA mice. We continue to enhance the delivery and targeting efficiency of LNPs toward LSECs to to increase endogenous FVIII expression post gene editing in NSG HA mice.

Challenges to Immunological Responses to Therapeutic Interventions

429. Intricate Play Between Different Cell Types is Critical for CD8$^+$ T Cell Response Against AAV Encoded Transgene Product in Liver

Sandeep Kumar[1], Moanaro Biswas[1], Jyoti Rana[2], Di Cao[3], Barry J. Byrne[4], Ype De Jong[5], Roland W. Herzog[6]

[1]Pediatrics, Indiana University, Indianapolis, IN,[2]Pediatrics, IUPUI, Indianapolis, IN,[3]Pediatrics, Indiana University School of Medicine, Indianapolis, IN,[4]Pediatrics, University of Florida, Gainesville, FL,[5]Weill Cornell Medicine, New York, NY,[6]Pediatrics, IU School of Medicine, Indianapolis, IN

Regulatory approval for multiple adeno-associated virus (AAV) based gene therapy products highlight the scope of AAV gene therapy. Immunogenicity to the AAV capsid and its encoded transgene product remain major concerns. It is well established that the innate sensor toll like receptor (TLR) 9 and its downstream adaptor molecule, myeloid differentiation primary response 88 (MyD88) are critical for detection and initiation of immune responses against the capsid and transgene product. AAV vectors lacking unmethylated CpG motifs (TLR9 ligand) are currently used in clinical studies. Recently, in a murine model of AAV liver gene transfer we demonstrated that cellular responses to the transgene product are independent of TLR9-MyD88 sensing and instead rely on interleukin 1 receptor 1 (IL-1R1) activation by cytokines IL-1α and IL-1β. Further, we demonstrated that these cellular responses are mediated by multiple cell types including plasmacytoid dendritic cells (pDCs), Kupffer cells (KCs), and cross presenting XCR1$^+$ DCs.

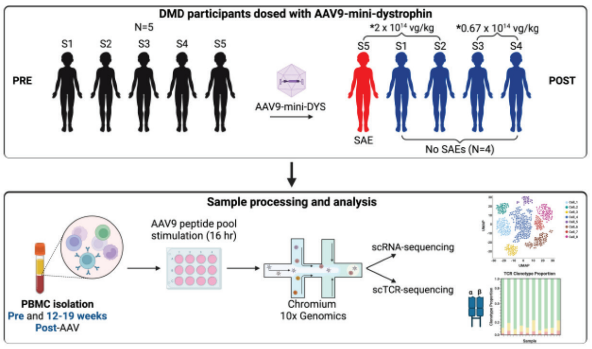
During the first 10 days, pDCs were the principal IL-1 producing cells that infiltrated AAV transduced livers. Subsequently, we noticed the emergence of IL-1 producing neutrophils, which could also be found in the co-clusters. In the present study we sought to identify potential roles of neutrophils and B cells in mediating transgene specific cellular responses following AAV liver gene transfer. We pre-treated a group of wild type (WT)-C57BL/6 mice (n=8) with neutrophil depleting antibody (α-Ly6G) and utilized μMT$^-$ mice (n=8), which lack mature B cells. Mice were intravenously injected with a previously identified immunogenic dose (1x10^{9}vg/mice) of hepatotropic AAV8 vector that encoded ovalbumin (AAV8-OVA) under the control of ubiquitous promoter elongation factor 1-α (EF1-α). Four weeks after vector administration, mice were bled to analyze peripheral blood mononuclear cells (PBMCs) by flow cytometry for OVA specific CD8$^+$ T cells using a class I MHC tetramer (H2-Kb -SIINFEKL). As expected, 50% of mice in the isotype treated group developed OVA-specific CD8$^+$ T cells. Surprisingly, none of the μMT$^-$ mice and only 25% (2/8) mice from α-Ly6G antibody treated group developed OVA-specific CD8$^+$ T cells. We hypothesized that B cell depletion may mitigate transgene product specific CD8$^+$ T cell response. We treated a group of WT-C57BL/6 mice (n=8) with two doses (3 days apart) of α-CD20 antibody (8mg/kg) intravenously prior to AAV8-OVA administration. Four weeks following vector administration PBMCs were analyzed for OVA specific CD8$^+$ T cells. Here, again 50% of control animals had circulating OVA specific CD8$^+$ T cells whereas only 12.5% (1/8) mice in α-CD20 treated group had CD8$^+$ T cells against OVA. B cell depletion with anti-CD20 has been successfully used in patients to prevent TMA that results from complement activation upon high-dose systemic AAV delivery. Previously, using the same experimental approaches, we found that B cells were not required for CD8$^+$ T cell responses against AAV capsid. It is therefore surprising that B cells may play a role in CD8$^+$ T cell responses to the transgene product that are initiated locally within the liver, the underlying mechanism of which remains to be elucidated.

430. Immune Modulation via Expansion of Treg Cells by THOR-834 Leads to Enhanced rAAV Transgene Expression

Mincheol Park, Lavesh A. Gwalani, Mona Motwani, Margaret Hennessy, Zhengyu Luo, John Bladon, Robert Jackson, Jie Bu, Christian Meuller, Sourav R. Choudhury

Genomic Medicine Unit, Sanofi, Waltham, MA

Gene therapy using recombinant adeno-associated viral (rAAV) vectors is a promising approach for treatment of variety of genetic disorders. However, despite clinical successes, challenges persist. Host adaptive immune responses can generate cytotoxic T lymphocytes (CTL) and, as has been reported in some clinical trials, loss of transgene expression over time. Immune mediated dorsal root ganglion (DRG) toxicity also poses a risk. Regulatory T cells (Tregs) play a key role in suppressing CTLs and maintaining homeostasis and self-tolerance. Our goal was to exploit this suppressive capacity of Tregs to control AAV-mediated CTL responses, avoid potential AAV toxicity, and promote the persistence of transgene expression. Interleukin-2 (IL-2) treatment activates Tregs, however, recombinant IL-2 is not specific to Tregs and is rapidly cleared. THOR-834 is a synthetic PEGylated form of IL-2 with enhanced Treg specificity and a longer half-life. We hypothesized that treatment with THOR-834 could promote expansion of Tregs, thus minimizing AAV-mediated CTL responses. To test our hypothesis, we developed a mouse model of AAV immunogenicity. We delivered rAAV via intramuscular injection and observed CD8 T cell expansion, an increase in the effector memory CD8 T cell population, capsid- and transgene-specific cytotoxic T-cell responses, and long-term loss of transgene expression. Mice that received a single subcutaneous injection of THOR-834 alongside the rAAV exhibited expansion of Tregs, reduction of CD8 T cells including effector memory CD8 T cells, and maintenance of transgene levels for at least 10 weeks. In addition, we tested THOR-834 in a rat model of DRG toxicity where we also observed suppression of CD8 T cell proliferation and of effector memory CD8 T cell responses. These results suggest that THOR-834 has the potential to address the challenge of AAV immunogenicity. Finally, to explore the clinical potential of our strategy, we extended our studies to non-human primates. In cynomolgus macaques, co-treatment with a single dose of THOR-834 led to Treg expansion and enhanced transgene levels following rAAV gene delivery thereby confirming that THOR-834 dampened rAAV-mediated immune responses in NHPs as well. These studies lay the groundwork for a new strategy which harnesses Tregs to suppress adaptive immune responses to AAV and enhance the efficacy of rAAV-based gene therapy.



431. Single-Cell and TCR Analysis from Duchenne Muscular Dystrophy Patients Treated with AAV9 Mini-Dystrophin Reveals an Expansion of Human Herpesvirus-Specific T-Cells in a Patient That Exhibited Thrombotic Microangiopathy

Micahel Emami[1], Mark A. Brimble[2], Alejandro Espinoza[3], Jane Owens[4], Thomas A. Lanz[5], Philip K. Farahat[6], Matteo Pellegrini[7], Courtney Young[8], Paul G. Thomas[2], Armando Villalta[6], Stefan A. Schattgen[2], Melissa J. Spencer[1]

[1]Department of Neurology, UCLA, Los Angeles, CA,[2]Host Microbe Interactions, St Jude Children's Research Hospital, Memphis, TN,[3]Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA,[4]Rare Disease Research Unit, Pfizer, Cambridge, MA,[5]Drug Safety Research and Development, Pfizer, Groton, CT,[6]Department of Physiology and Biophysics, University of California, Irvine, Irvine, CA,[7]Department of Molecular, Cell and Developmental Biology, University of California, Los Angeles, Los Angeles, CA,[8]MyoGene Bio, San Diego, CA

Duchenne Muscular Dystrophy is a major disease target for AAV-mediated gene therapy, with several approaches at various stages of clinical implementation. However, high systemic doses, often at, or exceeding 1x10^{14} vg/kg, are necessary to achieve sufficient skeletal muscle transduction. With this approach, there is a risk of immunogenicity leading to serious adverse events (SAEs), with thrombotic microangiopathy (TMA) being a particular clinical concern. A better understanding of the AAV-host immune response is needed before AAV-based delivery can be used to treat all patients with DMD. Here, using patient peripheral blood mononuclear cells (PBMCs) we performed single-cell RNA-sequencing of the transcriptome and T-cell receptors (TCR). Five patients had samples collected before, and after (12-19 weeks), treatment with an AAV9-microdystrophin.

Of these five patients, two received a dose of $6.7x10^{13}$ vg/kg and three received $2.x10^{14}$ vg/kg. One patient within the higher dose group experienced TMA shortly after administration. Cell frequencies remained relatively stable between the collected timepoints; however differential gene expression analysis showed upregulation of interferon response genes in several cell types. Since T-cell receptors that respond to a particular antigen in a given HLA-context also share similar, definable, features, we looked for the presence of TCR clonotype groups (TCR clumps) that were expanded after treatment. We identified two groups of related TCR sequences that appeared across two individuals with shared HLA-alleles in post-treatment samples. These same TCR sequences were not observed in the pre-treatment samples. These TCRs could be directly related to the AAV administration; however, it was not possible to determine their specificity. Interestingly, we also observed two separate clumps that were expanded in frequency in the post-treatment sample of the patient that exhibited TMA. Through literature database similarity matching, all the clonotypes within these clumps were identified as being reactive to known A02 restricted human-herpesvirus (HHV) reactive epitopes: one clump specific for an epitope within CMV pp65 (NLVPMVATV) and the other for EBV BLMF1 (GLCTLVAML). These data provide insight into the mechanistic basis of human immune-AAV interactions and lay a foundation for an improved understanding of why TMA arises in only a subset of individuals receiving high-dose systemic AAV.

432. Adeno-Associated Virus Serotype 8 Efficiently Transduces Multiple Antigen-Presenting Cells in the Liver

Di Cao[1], Sandeep Kumar[1], Moanaro Biswas[1], Maite Munoz[1], Bridget Brian[1], Junping Zhang[1], Dongsheng Duan[2], Weidong Xiao[1], Roland W. Herzog[1]

[1]Herman B Wells Center for Pediatric Research, Indiana University, Indianapolis, IN,[2]Department of Molecular Microbiology and Immunology, School of Medicine, University of Missouri, Columbia, MO

Low immunogenicity associated with AAV is one of the features that led to its development as a preferred vector for *in vivo* gene delivery. A potential reason for the low immunogenicity of AAV has been proposed to be their inefficiency in transducing professional antigen-presenting cells (APCs). A post-entry block has been proposed as an impediment to dendritic cell (DC) transduction. However, prior studies performed *in vitro* experiments or analyzed lymphoid organs such as spleen or lymph nodes. Such approaches are not without limitations. *In vitro* studies lack the complexity and physiological context of living organisms, limiting their ability to capture systemic interactions and responses observed in *in vivo* studies. Analysis of splenocytes misses events in the target organ of gene transfer. In addition, the sparse interception of time points poses challenges in identifying the optimal detection window if expression is transient. Even if certain APCs participate in immune response induced by the AAV vector, the reporter transgene (e.g., a fluorescent protein) may undergo degradation within APCs before detection, thereby eluding the capture of the fluorescent signal. In pursuit of comprehensively elucidating if AAV vectors are capable of transducing APCs, we employed the Cre reporter tool strain Ai14 mice. These mice are conditional reporter mice that harbor LoxP-Stop-LoxP-tdTomato cassette under the control of CAG promoter. In the presence of Cre recombinase, the LoxP-flanked stop codon will be excised, thereby leading to sustained and robust cytoplasmic tdTomato expression. We intravenously injected Ai14 mice with $2x10^{11}$vg/mouse of an AAV8 vector that encoded Cre recombinase under the control of cytomegalovirus (CMV) enhancer/promoter. To assess the transduction profile of AAV, tdTomato expression in different cell populations of liver and spleen was analyzed by flow cytometry on days 3, 7, 10 and 14 post vector administration (n=4/time point). To our surprise, robust tdTomato expression was observed in the liver as early as day 3 post vector administration with continual increase over time. Besides hepatocytes (up to 86% on day 14), tdTomato expression was also observed in a variety of APCs, including Kupffer cells (KCs), monocytes/neutrophils, plasmacytoid dendritic cells (pDCs), DCs (DC1 & DC2), B cells, and endothelial cells with highest expression in DC2 (78%) followed by monocytes/neutrophils (~74%) and KCs (64%). tdTomato expression in pDCs, DC1, B cells and endothelial cells ranged from 10-35%. In contrast, tdTomato expression profile in the spleen was different and much more modest. Amongst splenocytes, the highest expression of tdTomato was observed in monocytes (4.3% on day 14), followed by DC1 and DC2 (each ~1%), whereas other cell types had undetectable expression above the background. To assess vector distribution between liver and spleen, we quantified AAV genome copy number using droplet digital PCR. Vector genome copy numbers were 20-40 folds higher in the liver compared to the spleen on days 3-14. In contrast to AAV8, AAV1 vector transduced only ~6% of hepatocytes and showed much lower transduction of immune cells in the liver (2-4% of B cell, macrophages, and DC2 by day 14). In the spleen, ~1% of monocytes were transduced, with no evidence for transduction of other APCs. In conclusion, AAV vectors may efficiently transduce a variety of intrahepatic APCs in a serotype-dependent manner, which challenges traditional thinking about AAV-immune system interactions. Based on a wealth of prior studies, we suspect that transgene expression in these cells is transient and may not necessarily interfere with tolerance induction via hepatic gene transfer.

433. Artificial miRNA Delivered through AAV Induces Dorsal Root Ganglion Toxicity in Cynomolgus Macaques and C57BL6 Mice

Shih-Ching Joyce Lo, Zachary Hawley, Ingrid Pardo, Maria Zavodszky, Kyle Ferber, Denitza Raitcheva, Casey Fergal

Biogen, Cambridge, MA

Artificial miRNAs targeting superoxide dismutase 1 (SOD1) expressed from adeno-associated virus (AAV) vector have been investigated as

a therapeutic approach to treat amyotrophic lateral sclerosis (ALS) patients who carry toxic gain of function mutations within the gene. AAV-induced dorsal root ganglion (DRG) toxicity has limited the development of gene replacement approaches but has yet to be reported for RNAi AAV-based therapies. Here, we report an AAV9-based artificial miRNA that induces DRG toxicity in non-human primates (NHPs) and provide evidence that this phenomenon can be recapitulated within C57BL6 mice. Histopathological analysis showed that NHPs and mice develop AAV-induced DRG toxicity, including DRG neuron degeneration and necrosis, and nerve fiber degeneration that were associated with increases in cerebrospinal fluid (CSF) and serum phosphorylated neurofilament heavy chain (pNF-H). Furthermore, RNA-seq analysis of DRGs after AAV-treatment showed that several pathways were preserved between NHPs and mice, including increases in innate/adaptive immune responses and inflammatory pathways, and decreases in mitochondrial- and neuronal-based genes. Finally, specific endogenous miRNAs were upregulated in the DRGs of both NHPs and mice after AAV treatment. Increased expression of these endogenous miRNAs can be identified within the CSF of NHPs, and significantly correlates with pNF-H, implicating these endogenous miRNAs as a potential biomarker of AAV-induced DRG toxicity.

434. Understanding the Immune Response to Central Nervous System-Directed Adeno-Associated Virus Vectors

Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA

Immune responses to adeno-associated virus (AAV) gene therapies in human clinical trials remain a hinderance to their widespread application and have not been well predicted by preclinical studies in animals, particularly the induction of capsid-specific T cells and loss of transgene expression. Even less is known about immune responses to AAV in the central nervous system (CNS), a unique immune environment and a challenging location to study responses. In a CNS-directed AAV gene therapy clinical trial, our group observed induction of systemic capsid-specific immune responses and increases in CXCL10 in the cerebrospinal fluid suggesting an inflammatory response and potential recruitment of immune cells to the CNS. It is important that we understand the effects of direct administration of AAV to the CNS for both the peripheral and local immune responses. We sought to explore the immune response to AAV in a mouse model to measure immune responses in the CNS. We bilaterally injected the thalamus of C57BL6 mice with PBS, AAV8, or AAVrh32.33, which has previously been shown to induce capsid-specific T cells in mice. Both capsids delivered the reporter genes secreted embryonic alkaline phosphatase (SEAP), an immunogenically inert transgene, or Ovalbumin (OVA), a potent stimulator of the immune system. Animals were followed for 6- (established response) or 12-weeks (late response) post-injection. IFNγ ELISPOT assays were run to measure peripheral capsid-specific T cell responses. At 6 weeks, 2 of 3 animals in the AAVrh32.33-SEAP group were positive, indicating a capsid-specific T cell response. While we expected animals in the AAVrh32.33-OVA group to exhibit a capsid-specific response as well, it is possible that the immunogenic properties of the transgene skewed the T cell response towards a transgene-specific response. Surprisingly, at 6 weeks, 2 of 4 animals in the AAV8-SEAP group were ELISPOT positive. Hemophilia patients treated with AAV8 developed capsid-specific T cells in the peripheral blood, but AAV8 has not previously been described to elicit a T cell response in mouse models. At 12 weeks, animals in all groups were ELISPOT negative, indicating that circulating capsid-specific T cells are too few to detect at this timepoint. Despite positive ELISPOT responses at 6 weeks, AAVrh32.33 and AAV8-SEAP treated animals exhibit stable serum SEAP expression over time. Vector genomes are higher in the brain in both groups compared to the liver suggesting serum expression may come from the CNS rather than the liver. Forthcoming histology will provide insight into transgene expression in the collected tissues. Vector genomes do not decline from 6 to 12 weeks, suggesting clearance of transduced cells was not observed, even in OVA treated animals. At 6 weeks, AAVrh32.33 injected animals, regardless of transgene, exhibit significantly higher percentages of CD3+ T cells and CD8+ T cells in the brain compared to the PBS group, measured by flow cytometry of immune cells isolated from perfused brains, indicating T cell infiltration in the CNS. Additionally, both groups have noted increases of CD4+CD25+FoxP3+ T regulatory cells (Tregs) in the brain compared to PBS treated, although the OVA group had a higher percentage of Tregs. At 12 weeks, cellular infiltration in the brain is lesser compared to 6 weeks, but the Treg population remains elevated compared to PBS animals, indicating potential long lasting Treg residency after AAV injection in the brain. Upcoming work will include repeating these studies in a mouse model predisposed to neuroinflammation as many patients receiving AAV gene therapy exhibit disease-related neuroinflammation and could have exacerbated responses to direct administration. Understanding the immune response to AAV gene therapy in CNS-directed therapies will allow us to develop safer, more effective gene therapies.

435. *In Vivo* Delivery and Protection by Engineered Synthetic DNA-Encoded Influenza H1HA Head-Directed Monoclonal Antibodies in Mice

Abigail Rose R. Trachtman[1], Jacqueline D. Chu[1], Jillian Eisenhauer[1], Kaitlyn Flowers[1], David Custodio Zegarra[1], Laurent M. Humeau[2], Trevor RF Smith[2], David B. Weiner[1], John Kash[3], Ami Patel[1]

[1]The Wistar Institute, Philadelphia, PA,[2]Inovio Pharmaceuticals, San Diego, CA,[3]Viral Pathogenesis and Evolution Section, Laboratory of Infectious Diseases, NIAID, NIH, Bethesda, MD

Monoclonal antibody (MAb) therapy is revolutionizing modern medicine, for cancer, and autoimmune treatment among others with more than 200 MAbs approved for clinical use or under review worldwide. For infectious disease, monoclonal antibodies received initial emergency use authorization during the COVID-19 pandemic and the recent licensure of nirsevimab for respiratory syncytial virus prophylaxis opens a new paradigm for mAb delivery against infectious diseases. Routine mAb delivery for seasonal infections like influenza A viruses could provide a significant public health benefit. However, the global potential of MAbs remains limited due to developability limitations, manufacturing costs, delivery route challenges, and the

need for cold chain storage. In vivo gene delivery platforms, including synthetic plasmid DNA vectors can be engineered to encode antibody heavy chain and light chain genes for direct delivery. Synthetic DNA is simple to manufacture, temperature-stable, and DNA-encoded antibodies (DMAbs) are therefore a promising alternative modality for in vivo delivery of protective mAb.Influenza viruses cause acute respiratory illnesses and are a significant cause of morbidity and mortality in all age groups, particularly young children and older adults, and influenza-related illnesses have returned to pre-COVID pandemic levels. As an approach to influenza prophylaxis, we engineered 11 different synthetic DMAbs encoding human IgG1 monoclonal antibodies targeting multiple epitopes on the H1N1 influenza A virus hemagglutinin (HA) protein globular head. DMAbs were sequence optimized and then tested for their ability to express in vitro. Then, in vivo DMAb expression was evaluated following delivery of multiple doses (25-100ug) to BALB/c mice (n=5/group), with peak serum levels reaching >20ug/mL at the highest dose. Serum binding and neutralization activity against A/H1N1/pdm2009 lineage viruses was detected, identifying 2 DMAbs with potent activity comparable to a previously published DMAb, DMAb-2-12C. These top 2 DMAbs were next administered to DBA/2 mice (n=15 mice/group, 6.25-25ug doses) alone and in combination, achieving expression levels between 1-5ug/mL by day 5 post-administration. The mice were challenged intranasally on Day 6 post-administration with 10LD50 of H1N1 A/California/07/2009 X179A. Protection against weight loss and mortality was observed for all DMAb treatment groups, including at the lowest doses. Interestingly, the lungs histopathological analysis and immunohistochemistry (IHC) staining indicated dose-dependent interstitial pneumonia and presence of influenza NP antigen. Lesions and positive IHC staining were only seen in negative control groups and low dose DMAb groups, with groups receiving higher doses of DMAb not showing any lesions.Taken together, our data demonstrate that synthetic DNA H1HA head-directed monoclonal antibodies are functional and offer protection in mice against lethal H1N1 pdm2009 infection, even at low doses. Our data are supportive towards translation of this approach to larger animal models with consideration for further translational development. DMAb delivery offers important advantages for seasonal influenza prevention including long-term expression, potentially facilitating access to significant US. and global populations.

436. FastAd- A System for the Rapid Generation of Single Adenoviruses or Complex Adenoviral Vector Libraries

Shao-Chia Lu[1], Yi-Yuan Lee[2], Felix Andres[1], Daniel Moyer[3], Michael A. Barry[4,5]

[1]Division of Infectious Diseases, Department of Medicine, Mayo Clinic, Rochester, MN,[2]Department of Computational Biology, Cornell University, Ithaca, NY,[3]Immunology Track, Mayo Clinic Graduate School of Biomedical Sciences, Mayo Clinic, Rochester, MN,[4]Department of Immunology, Mayo Clinic, Rochester, Mayo Clinic, Rochester, MN,[5]Department of Molecular Medicine, Mayo Clinic, Rochester, MN

Adenovirus (Ad) vectors are highly effective gene delivery systems for *in vivo* applications. However, the standard process for constructing recombinant Ads is laborious and time-consuming, limiting rapid development, such as responding quickly to a healthcare emergency, or for high throughput applications. Here, we introduce the FastAd system, for the direct generation of recombinant Ads in living mammalian cells. In this system, recombinant DNA from plasmids or PCR products are knocked into infectious "receiver" viruses using positive and negative selections with three site-specific recombinases. This approach bypasses all traditional adenovirus cloning and rescue steps. With the FastAd system, the production time was shortened from a traditional 2-month timeline to 9-10 days for large scale production of CsCl-purified viruses. For example, we generated a replication-defective Ad expressing SARS-CoV-2 spike protein, a single-cycle Ad expressing influenza NP and a conditionally replicating Ad expressing murine OX40 ligand. Additionally, the FastAd system was also used to generate diverse barcode, gRNA and cDNA libraries. For example, following transfection of cells at a T25 flask scale, the system was able to generate a library containing over 3 million unique clones, verified by next-generation sequencing (NGS). Furthermore, the FastAd system was further used to capture a comprehensive CRISPR genome-wide sgRNA library within a 9-day production timeline. This Ad-gRNA library underwent multiple passages within cells, enabling the identification of essential host factors that effectively suppress the adenovirus life cycle. In summary, the FastAd system represents a simple and versatile tool for the rapid generation of individual recombinant adenoviruses as well as the production of complex Ad libraries.

437. An Integrase Deleted Retrovector with Persistent Payload Expression without Integration Suitable for Prophylactic and Therapeutic Applications

Bradford Steele, Jacqueline Fischer-Lougheed, Stephanie Lees, Cecilia Roh, Robert Johnson
GenVivo Inc, San Marino, CA

Integration of transferred genes into a host cell via retrovectors provides a clear advantage for duration of transgene expression over transitional or episomal vectors. However, activation and inactivation of genes by insertional mutagenesis or the deregulation of an oncogene are potential detrimental outcomes. We previously described non-integrating MLV vectors (IDRV) made by alanine mutations across three key acidic residues. All 7 mutants successfully exhibited early strong protein expression from the mRNA vector payload comparable to vectors with a functional integrase. The vector described here utilized *gagpol* (GP) with a complete deletion of the integrase gene (dINT). The particle titer of dINT vector was not affected by the deletion when compared to wildtype (WT) vector, in contrast to the report by Lai et al (2001, J Virol). Using our modified HSV-TK (v-eTK) suicide gene construct as the payload, a vector made with the deleted integrase was compared to the WT vector and several IDRV vectors. Experiments were performed to ascertain: 1) the level of v-eTK expression over time in transduced A375 melanoma cancer cells; 2) the amount of cell kill in the presence of the prodrug ganciclovir (GCV) in A375 and other cancer cell lines; and 3) the lack of integration of the v-eTK into the host genome. Flow cytometry data demonstrated stable expression of v-eTK over time in A375 transduced with the WT vector, while cells transduced with the dINT vector showed high expression at early time points followed by a steady decrease. Of note, v-eTK levels were still measurable at 14 days; thus as noted below is due to persistence of v-eTK protein rather than gene integration. Interestingly, the IDRV vectors tested exhibited lower v-eTK expression at all times despite similar transduction titers. The v-eTK/GCV cell kill activity in A375 transduced with the dINT v-eTK vector was comparable to that observed with a functional integrase for up to 7 days. Decreased yet detectable cell kill activity was measured in the dINT vector group at 14 days consistent with persistent protein expression. Other cancer lines were also tested with the dINT vector. In each cell line, there was variable but significant cell kill at day 3 (D3) and in most cases, detectable cell killing at D10. The degree of the bystander effect in some of the cancer cell lines may explain the differential in the lower percentage of cells transduced vs the high cell kill. Relative Psi copies (packaging signal of the vector) were compared with vector copy numbers (VCN) (measured from LTR sequences) from extracted DNA by ddPCR. The DNA extraction method includes all genomic DNA plus cDNA made from the reverse transcription of the vector payload. The dINT vector-transduced cells showed measurable Psi and VCN copies at D1 which decreased to near or below the limit of detection for the assays by D7, consistent with the early appearance and later disappearance of cDNA which is not integrated. This compares with the Psi and VCN copies from the WT vector transduced cells which decreased from D1 to D3 and were constant thereafter at significant levels, consistent with integration. We have constructed dINT vectors which are capable of transducing cancer cells which display protein expression comparable to the WT at early time points and in many cell lines demonstrate limited expression for over 2 weeks. This extended protein expression in the absence of integration will be useful for certain applications, while avoiding the downsides of integration and improve on the safety of the vectors. In applications requiring transient expression of a certain time period such as targeted combination immunotherapy, gene editing delivery, and therapeutic and prophylactic vaccines, and given the low natural immunity to the vector, the dINT may have future widespread applicability.

438. Engineering T4 Bacteriophage Nanoparticles: A Next-Generation Paradigm for Effective Vaccine Development

Jarin Taslem Mourosi, Ayobami Awe, Jingen Zhu, Venigalla B. Rao
Biology, Catholic University of America, Washington, DC

The T4 bacteriophage nanoparticle has emerged as a novel and promising platform for the development of vaccines against infectious diseases, as well as a large capacity vector for gene therapies. Its inherent safety, stability, and natural properties akin to adjuvants contribute to the potential for creating effective, long-lasting, and cost-efficient multivalent vaccines that are accessible to global communities. The head of the T4 bacteriophage is decorated with two non-essential proteins: the small outer capsid protein (SOC) and the highly antigenic outer capsid protein (HOC), both of which are well-positioned for displaying foreign antigens. While T4 can efficiently express and display its own proteins, foreign proteins are not expressed abundantly due to factors influencing expression, including protein size and folding kinetics. We hypothesize that modulating the transcription and translational elements in the T4 genome can enhance foreign protein expression and presentation. As a proof of concept, we incorporated an antigenic subunit, the receptor binding Domain III (DIII) of the envelop protein of Dengue viruses 1 & 2 and of Zika virus into the phage genome. Both Dengue virus (DENV) and ZIKA virus (ZIKV) pose significant global health threats because the current live attenuated DENV vaccine is not sufficiently effective, and no licensed ZIKV vaccine is yet available. The DIII gene was fused to SOC and inserted into the genome through CRISPR engineering. Further, we created a mini library of constructs by varying codon usage (T4 codon vs *E. coli* codon), promoter type (early/later promoters), riboswitch-like regulatory elements, ribosome

binding sites, and terminators. Comprehensive screening of this mini library revealed that engineered phage with a strong late promoter of the tail sheath structural gene (gp18), or deletion of a 11 bp riboswitch-like regulatory element from the upstream of SOC open reading frame, exhibited a ~10-fold increase in the vaccine antigen compared to the control construct where the SOC native promoter was utilized. This means that the engineered T4 phages are decorated with a high density of a target vaccine antigen belonging to a eukaryotic viral envelope protein and can be directly employed as a vaccine without any chemical formulation. This approach could lead to development of effective and versatile next generation vaccines, particularly for rapid generation and deployment of stable, protein-based, vaccines against emerging and pandemic pathogens.

439. Unraveling the Mystery of CAV2 Tropism: Characterization of Canine Adenovirus Type 2 Virus Infection

Payal Agarwal[1], Theresa Higgins[2], Madison D. Hogans[3], Will P. Kretzschmar[3]

[1]Scott Ritchey Research Center & Department of Pathobiology, Auburn University, Auburn University, AL,[2]Auburn University, Auburn, AL,[3]Scott Ritchey Research Center, Auburn University, Auburn University, AL

Adenoviral (Ad) vectors are the most commonly used gene therapy vectors. The expression pattern of the cell surface receptors used by Ad determines the virus tropism. The natural tropism of adenovirus can be modified to deliver genes to Ad refractory cells. Canine adenovirus 2 (CAV2) is a canine adenovirus with a known ability to infect human cells, including neurons and ovarian cancer cells. The CAV2 genome is well characterized, but the cell surface receptors involved in CAV2 transduction are unknown. The identification of these receptors and using them to alter Ad tropism will help enhance adenovirus-based vectors as augmented gene delivery tools. Identification of new cell surface receptors will also help understand the basic biological mechanism of CAV2 infection, further expanding knowledge with respect to both this virus and this class of virus. CAV2 has been erroneously grouped with Ad5 and was believed to infect cells through the CAR receptor. However, we have shown that CAV2 infects cells refractory to Ad5, such as canine lymphoma cell lines 17-71 and OSW and canine mast tumor cell line MPT1. We have also shown that CAV2 infection is not correlated with cell surface CAR expression. CAR knockdown inhibited the Ad5 infections but did not affect CAV2 infections. Using a pulldown assay, Sulfo-SBED-based affinity assay, we identified DMBT1 & DSG1 as putative CAV2 receptors. Being a non-human viral vector, CAV2 holds significant potential in translational medicine. Our work has demonstrated that receptors involved in attachment and internalization of CAV2 can be DMBT1 and DSG1.

440. Easy and Efficient Lentiviral Transduction with a Macroporous Transduction Sponge

Thomas P. Quinn, Mei Fong, Lily Lee, Adrian Martin, Myn Uddin, Michael Haugwitz, Andrew Farmer

Takara Bio USA, San Jose, CA

The advancement and approval of engineered cellular therapies using lentiviral vectors are revolutionizing the treatment landscape for diseases resistant to traditional therapeutics. To optimize lentiviral transductions and mitigate inefficiencies, various strategies have been employed, such as "spinoculation" and the use of reagents (polybrene, Retronectin) to enhance cell-virus contact or modify cellular responses during transduction (rapamycin, prostaglandin E2). Despite their efficacy, many enhancers have limitations due to their bioreactivity impacting cell behavior. Moreover, lentiviral transductions in standard cell culture vessels face challenges as the virus must traverse considerable distances before reaching cells, leading to significant viral wastage due to insufficient transport and virus degradation. Microfluidic systems, by spatially constraining cells and virus to small volumes, address these biotransport issues inherent in standard cell culture systems. However, previous applications of microfluidics for lentiviral transduction necessitated special chips and hardware to facilitate the flow of cells and virus through microfluidic channels. To overcome these requirements, we developed a macroporous 3D alginate sponge, eliminating the need for additional hardware. The microfluidic sponge is made from calcium-crosslinked alginate, a GMP-compliant, FDA-approved biomaterial with high biocompatibility and low toxicity. The crosslinked alginate undergoes a gentle cryogelation process, yielding a sponge (5mm radius) with uniform pore sizes ranging from 20 to 300nm. The simple workflow involves a mixture of cells and virus applied to the sponge for absorption, followed by a short incubation of 1hr, media addition, and harvesting 24 hours later. The release of transduced cells is facilitated by adding a chelating release buffer that depolymerizes the sponge, ensuring the efficient release of transduced cells. Sponge-based transductions demonstrate flexibility and can accommodate a wide range of cell numbers (from 1e5 to 1e7) and types, transduction volumes (50-150 µl), and incubation times (4 hours to overnight). This straightforward workflow is designed to maximize transduction efficiency across a diverse array of cell targets, including both suspension and adherent cell types. Our alginate sponge demonstrated efficient transduction of over 15 cell targets, including human primary T cells, CD34+ HSCs, NK cells, and adherent cell lines, with high viability. Sponge-based transductions are consistent, with a coefficient of variation (%CV) of less than 15%. The innovative ex-vivo lentiviral transduction sponge is user-friendly, scalable, and compatible with diverse cell types, providing efficiencies equal to or surpassing conventional protocols.

441. Refined Expression of 3' End Long-Noncoding RNA Using Lentiviral Vectors

Liping Zhang, Jiali Yang, Hua Gao, Jia Xu, Wei Mao, Guodong Jia, Weiran Shen, Yang Xinglin

R&D, OBiO Technology (Shanghai) Corp., Ltd., Shanghai, China

Lentiviral Vectors (LVs) have proven effective for delivering genes of interest to target cells, but the delivery of long non-coding RNA (lncRNA) poses challenges. Many lncRNAs terminate with polyadenylation (polyA) signals, leading to disruptions in LV genome integrity during vector production. The conventional LV genome includes expression regulatory sequences, such as WPRE, which may interfere with lncRNA if termination is imprecise, introducing unnecessary and disruptive sequences. Additionally, certain lncRNAs undergo auto-processing during maturation, resulting in the truncation of the LV genome. To address these challenges, we implemented a reverse genome setting combined with the V-Pac system for lncRNA expression via LV. The V-Pac system incorporates a short CuO

regulatory element inserted upstream of the lncRNA coding region and the expression of CymR protein in the packaging cell line. CymR binds to CuO, inhibiting lncRNA expression. Once the LV vector is used for transduction in target cells without CymR, efficient lncRNA expression is achieved. Our study compared various polyadenylation signals for vector yield, revealing that SV40 polyA V2 yielded the best performance. Different LVs expressing various lncRNAs were produced and tested, demonstrating that our system could generate significantly higher LV yields. Notably, vectors constructed with a reverse expression cassette exhibited enhanced potency in terms of lncRNA functions related to inhibiting or promoting cell migration. These findings highlight the advantages of the V-Pac system combined with a reverse expression genome design for packaging lncRNAs using LVs.

442. Chimeric Ad5/3 and Ad5/21 for Improved Tropism of Human Airway Epithelial Cells

Lei Lei, Patrick L. Sinn
University of Iowa, Iowa City, IA

Background: Adenoviral (Ad)-based vectors are extensively used gene therapy tools. To date, human Ad type 5 has been the predominant choice for preclinical and clinical trials using Ad-based viral vectors in the airways. The fiber's C-terminal globular domain node (knob) binds to host cell receptors that mediate adenovirus infection. Human Coxsackie and Adenovirus Receptor (CXADR) is the principle receptor for most species C adenoviruses, including Ad5; whereas, Ad3 and Ad21 are species B adenoviruses that reportedly use DSG2 and CD46 as cellular receptors. Here we generated chimeric Ad5-based vectors that have its fiber/knob replaced with the corresponding region from Ad3 or Ad21. We ask if the chimeric vectors have altered receptor usage and determine the impact on cell-type specific transduction of primary human airway epithelial cells. **Methods**: Ad5, Ad5/3, and Ad5/21 (each expressing an mClover reporter gene) were used to transduce primary human airway basal cells, as well as fully differentiated primary human airway cultures. Transduction efficacy was determined by microscopy and flow cytometry. To confirm the cellular receptors of the chimeric Ad vectors, we constructed three CHO-tet-on stable cell lines expressing hCXADR, hCD46, or desmoglein-2 (hDSG2), respectively. Receptor cDNAs were cloned into a piggyBac transposon, and transfected CHO-tet on cells alongside a transposase expression plasmid. Puromycin was used to select positive cells. Doxycycline induces receptor gene expression. The receptor usage of Ad5, Ad5/3, Ad5/21was then determined by microscopy and flow cytometry. **Results**: Ad5/3 and Ad5/21 showed enhanced transduction of human airway basal cells as compared to Ad5. Over the course of 3 weeks following transduction, the basal cells grew into a well-differentiated, pseudostrified epithelial layer suggesting that transduction didn't impact cell differentiation. For each vector, secretory cells were the main cell type transduced, followed by ciliated cells, then basal cell. Transduction of fully differentiated airway cell cultures with Ad5/3, Ad5/21 and Ad5, were overall similar; however, a trend toward increased basal cell transduction was observed with Ad5/3 or Ad5/21 (over Ad5) which is consistent with higher basal cell expression of DSG2 and CD46 as determined by scRNA-seq.As expected, Ad5 used CXADR as its cellular receptor. Ad5/3 primarily used DSG2 as its receptor however some affinity for CD46 was observed. Ad5/21 primarily used CD46 as its receptor and showed little affinity for DSG2 or CXADR. **Conclusion**: This study suggests that Ad5/3 and Ad5/21 use DSG2 and CD46 receptors, respectively. The use of chimeric Ad5/ species B vectors may be a strategy to alter cell tropism and improve delivery of gene editing tools to airway progenitor cells for life-long correction of lung disease. **Acknowledgements**: This study is supported by NIH R01 HL-133089 funding.

443. Engineering of a Nucleic Acid Platform to Augment RNA Mediated Therapy

Debora Mazzetti, Marco Mineo, Ludovica Gaiaschi, Michal Nowicki, Pierpaolo Peruzzi
Brigham and Women's Hospital, Boston, MA

Background: RNA-mediated interference has been proven over the years to be biologically effective, yet its translational benefits in oncology have been lagging. This is mainly due to the fact that its efficiency is generally not at par with that of small molecules, nor is its ease of use. However, RNA constructs, in particular non coding transcripts, have the potential to offer a high degree of customization that make them superior to drugs in terms of achieving focused oncogene multitargeting, a progressively recognized necessity in cancer treatment. Methods: Taking advantage of the genetic structure of microRNA genes, we have engineered artificial RNA sequences which are recognized by the cell microprocessor as bona fide microRNA transcripts, but are cleaved into smaller components. The design allows to retrofit each sequence with multiple microRNAs, microRNA sponges and RNA aptamers, each with specific targeting functions. The net result is a relevant expansion of their interference capacity. Results: Three sequences of progressive structural complexity were designed and biologically validated in HEK293 cells as a proof of principle. Each showed retained ability to be processed by the cells into desired clusters of microRNAs (CL3 sequence), an additional sponge sequence against oncogenic miR-21 (CL3a21 sequence), and an aptamer directed against NFkB (CL3a21ap65). The targeting specificity of each sub-component of the sequence was confirmed by RTqPCRT, Western blotting and a luciferase reporter assay. A functional analysis of the biological effects of the three different sequences was performed in primary , patient-derived, glioblastoma cell lines after lentiviral mediated expression of each sequence. Adding the antimiR21 function to CL3 significantly reduced growth (clonal ability, migration potential and tumorigenicity) in vivo. Cell proliferation demonstrates a substantial decrease of nearly 50%. CL3a21 displayed a reduction of 60% in comparison to CL3 and 80% in comparison to the negative control in regards to migration and invasion properties. Similarly the clonal potential was significantly reduced in CL3a21 cells. Conclusion: Our study provides proof of principle and feasibility for designing artificial RNA constructs based on the genetic scaffolds of microRNAs. This strategy offers a significantly augmented capacity for tumor multitargeting by RNA-based interference. References: Bhaskaran V, et al. The functional synergism of microRNA clustering provides therapeutically relevant epigenetic interference in glioblastoma. Nat Commun; 10(1):442. doi: 10.1038/s41467-019-08390-z (2019). 444. Anellovector Derived from Human Retinal Pigment Epithelium Delivers and Expresses a Therapeutically Relevant DNA Payload in the Retina of Nonhuman Primates

Parmi Thakker, Alexander Auld, Vimal Vaidya, Nolan D. Sutherland, Maciej Nogalski, Isabella Gold, Hyun Jung Jun, Geoffrey Parsons, Tuyen Ong, Ashley Mackey, Chris Wright

Ring Therapeutics, Cambridge, MA

Anelloviruses are a highly diverse family of commensal ssDNA viruses that are a principal constituent of the human virome. These viruses have been found across many vertebrates and demonstrate broad tropism to multiple organs and tissues in humans. Moreover, they naturally evade the immune system, can persist for many years, and importantly do not appear to cause any known pathology in humans making anelloviruses an attractive tool for the delivery of genetic medicine. An anellovirus originally discovered and sequenced from the retinal pigment epithelium (RPE) of a human patient was vectorized to contain a CMV-eGFP or CMV-Aflibercept payload. In the first nonhuman primate (NHP) study of an anellovector (ANV.X.CMV-eGFP), we observed DNA delivery to the eye and mRNA expression that was comparable to AAV2 via IVT administration. In additional NHP studies, we administered an ANV.X-eGFP vector at higher doses as well as a vectorized therapeutic payload (ANV.X.CMV-Aflibercept). We are also evaluating the impact of redosing ANV.X.CMV-Aflibercept via the IVT route. These studies are the first demonstration of therapeutic payload delivery with an ANV vector and represent an initial investigation into the potential use of this novel platform to treat eye diseases such as wet AMD. This ANV platform could have several advantages compared to current gene therapies. A substantial proportion (up to 50%) of patients on gene therapies in development have failed injections (e.g., lack of Aflibercept expression) or require rescue medications due to loss of efficacy. Therefore, in addition to a high tissue specific and potency, a gene therapy vector such as ANV that has the potential to be re-dosed, could be a more effective, longer lasting, and tolerable treatment option than current standard of care.

445. Engineering Gene Therapy Vector Properties in the Baculovirus

Tanya Jain, Lucas Brown, Gang Bao

Rice University, Houston, TX

The CRISPR-Cas9 gene editing system has been widely researched over the last two decades, and viral methods are commonly used for the delivery of gene therapies such as CRISPR. Current common viral delivery methods include lentivirus and adeno-associated virus. These can efficiently deliver DNA into living systems, but have relatively small packaging capacities-5 and 8 kilobases, respectively. However, much larger gene circuits than this must be developed to create editing systems that afford more control over their induction and function. This research aims to use baculovirus, an insect-virus with a comparatively large carrying capacity, to deliver inducible, targeted gene therapies. As an insect virus, baculovirus poses unique challenges when used within mammalian systems, namely low transduction, inactivation by the complement system, and transient gene expression. This work focuses on the process of producing pseudotyped baculovirus containing proteins to enhance transduction, immune protection, and targeting. Genes for the pseudotyped proteins were placed downstream of the p10 insect promoter in the engineered baculovirus genome using standard molecular cloning techniques. Baculovirus was then produced, purified, and tested *in vitro* on various cell lines-including HEK293T cells, HEPA-1,6 cells, C2C12 muscle cells, and Jurkats-using GFP as a reporter for transduction, as well as *in vivo* in C57BI6 mice using a firefly luciferase reporter. Both *in vitro* and *in vivo*, vesicular stomatitis virus protein-G (VSV-G) has been determined to improve transduction efficiency. With VSV-G, a three-fold increase in transduction was observed in HEK293T and C2C12 cells, and a 30-fold increase was seen in HEPA-1,6 cells. Decay accelerating factor (DAF) also appears to provide protection from the complement portion of the immune system in experiments performed with mouse serum containing the complement system. *In vivo*, while pseudotyping with VSV-G and DAF each independently increased baculovirus transduction, adding both proteins to baculovirus together led to the highest transduction-approximately a 10-fold increase as compared to wild type-and expression that persisted for a month. Ongoing efforts are focused on the engineering and production of pseudotyped baculovirus containing proteins to enhance targeting and transduction in primary T-cells. The level of control afforded to clinicians and researchers by the large DNA capacity of baculovirus can be used to implement small-molecule inducible systems for temporal control of therapeutic gene expression, or autonomous cell-state sensing mechanisms to monitor and respond to CAR T-cell activity *in vivo*.

446. Papillomavirus as a Novel Viral Vector for Gene Therapy of Olmsted Syndrome

Francesco Diversi, Elisa Mazza, Fernanda de Castro Reis, Paul Heppenstall

SISSA, Trieste, Italy

Olmsted syndrome is a rare dominant genetic skin disease caused by a gain of function point mutation in the Transient receptor potential vanilloid-3 (Trpv3) gene. TRPV3 is a non-selective cation channel sensitive to non-noxious warm temperatures (31-39°C) mainly expressed in keratinocytes and sensory neurons. The mutation renders the channel hyperactive, thus increasing intracellular calcium levels; this leads to hyperproliferation and defects in the maturation of basal keratinocytes, invasion of immune cells, and chronic itch and pain. Olmsted syndrome, given its well-defined etiology, stands out as a promising target for gene therapy. Here we have asked whether we can reverse the disease phenotype of Olmsted syndrome by disrupting gene expression in a cell type-specific manner. In vivo gene therapy of the epidermis is particularly challenging: AAVs, the most common viral vectors, are not efficient in targeting keratinocytes, meanwhile, lentiviruses have been exclusively employed ex-vivo on reconstructed skin equivalents due to their capability to integrate into the host genome. We reasoned that we could employ papillomavirus (PV) as a viral vector: it has a natural tropism towards keratinocytes, its double-

stranded DNA cargo remains episomal, and it can package up to 8 kilobases - a much larger capacity than AAVs. We used papillomavirus to encapsidate SaCas9 with a gRNA to disrupt Trpv3 locus. A disrupted Trpv3 should be preferable over the mutated gene since genetic ablation of Trpv3 in mice leads to only mild phenotypes such as a thinner stratum corneum and an altered wavy fur. We transduced both a keratinocyte cell line and mouse primary keratinocytes with PV-SaCas9; nearly 60% of the alleles showed indel formation ten days after transduction. Next, we evaluated the functionality of the disrupted gene via FURA-2 calcium imaging. One week after the transduction of PV-SaCas9, keratinocytes showed a significant reduction in their response to carvacrol, a TRPV3 agonist. Furthermore, we reconstructed skin equivalents starting from PV-treated primary keratinocyte to prove its applicability to autologous transgenic skin transplants. Hence, we have demonstrated that papillomavirus can be engineered to efficiently deliver a gene of interest to keratinocytes, resulting in a promising new candidate for skin gene therapy.

447. Development of Adenoviral Vectors That Transduce Purkinje Cells and Other Cerebellar Cell Types in the Cerebellum of a Humanized Mouse Model

Emre Kul, Uchechi Grace Okoroafor, Amanda Dougherty, Lauren Palkovic, Hao Li, Paula Valino-Ramos, Leah Aberman, Samuel Young

University of Iowa, Iowa City, IA

Hereditary cerebellar ataxias are a group of monogenetic conditions due to gain or loss of function of genetic mutations resulting in debilitating impairments in movements, cognition, behavior and premature deaths. Cerebellar Purkinje Cell (PC) dysfunction and degeneration have been identified as a hallmark of these ataxias. Although much is known about causative mutations and their link to PC degeneration, no therapy exists to address the root cause of hereditary cerebellar ataxias. Viral vector mediated gene therapy is an attractive strategy to treat hereditary cerebellar ataxias as it has the potential to treat the root cause of the disease by restoring gene function. However, many of the associated gene encode large cDNAs that exceed the packaging limit of adeno-associated viral vectors (AAV) and lentiviral vectors. Helper-dependent adenoviral vectors (HdAd) with a large packaging capacity of around 36kb has the potential to deliver these large genes, making it a promising viral vector for hereditary cerebellar ataxia gene therapy. However, the commonly used 1st generation Ad vector to make HdAds are a Group C adenovirus which use the Coxsackie-adenovirus receptor and do not transduce PCs. To overcome this roadblock, we created chimeric 1st generation Ad vectors that utilize the human CD46 receptor (hCD46) to infect and transduce cells. Using a "humanized" hCD46 mouse model, we demonstrate these Ad vectors transduce PCs and other cerebellar cell types. Since the tropism and transduction properties of Ad vectors are dependent of the Ad capsid proteins, these chimeric 1st generation Ad vectors open new avenues for HdAd gene therapy approaches for cerebellar disorders and for multiple neurological disorders.

448. Paramyxovirus-Like Particles for Therapeutic Delivery of Proteins to Cells

Srijana Adhikari, Santosh Panthi, Phuong Tieu Schmitt, Anthony P. Schmitt

Veterinary and Biomedical Sciences, The Pennsylvania State University, State College, PA

Virus-like particles (VLPs) have the potential to safely deliver functional proteins to cells for therapeutic purposes. However, foreign proteins do not naturally package into VLPs. We previously discovered that paramyxovirus NP proteins contain short packaging sequences near their C-terminal ends that can be fused with foreign proteins, allowing the foreign proteins to participate in viral assembly and package efficiently into VLPs. These VLPs in turn are naturally capable of delivering the cargo to the target cell interiors. Using this approach, we have generated paramyxovirus VLPs loaded with different cargos, including Cre recombinase. These VLPs can deliver biologically active cargo to target cell cytoplasm and nuclei. We tested multiple paramyxoviruses as VLP production platforms, including parainfluenza virus 5 (PIV5) and Nipah virus (NiV), and successfully achieved efficient cargo packaging and delivery in each case. We also tested a series of altered PIV5 M mutant proteins that have enhanced virus assembly capacity. These resulted in significantly improved VLP production and a corresponding increase in the delivery of functional Cre into target cell nuclei. Together, these findings lay the groundwork for the use of paramyxovirus-like particles as safe and effective tools for delivering therapeutic proteins to cells and tissues.

449. Advancing Gamma Retroviral Vector Production: A Streamlined Process with One-Step Purification and Concentration Approach

Soodeh Baghaee Ravari, Josh Moore

Genezen, Technical Review, IN

Retroviral vectors (RVV), particularly Gamma retroviral vectors, are potent tools extensively utilized in cell therapy applications, offering the advantage of transferring larger transgenes for stable integration. The current manufacturing approach for RVV involves stable producer cell lines during upstream production, with minimal downstream processing due to the inherent instability of RVV envelopes. However, the development of producer cell lines adds a significant 3-4-month timeframe to the client's journey to IND/clinic. At Genezen, we have explored an alternative method for RVV production involving transient transfection, comparing three commercially available packaging cell lines that can produce higher transducing unit titers. Additionally, we implemented a high-speed centrifugation method for RVV concentration, addressing the prolonged duration and potential loss of vector titers associated with the traditional Tangential Flow Filtration (TFF) step. This study introduces a streamlined, one-step concentration method using high-speed centrifugation for RVV. Our findings demonstrate not only enhanced RVV stability but also scalability for late-stage and commercial vector productions. High-speed centrifugation allows for the concentration of viral titers in the range of 1e7-1e8 Transducing Units per milliliter (TU/mL) with a remarkable >60% overall recovery. Moreover, this purification method for RVV contributes to a reduction in overall production costs by eliminating the need for Anion Exchange Chromatography (AEX)

and TFF materials in the production process. The presented approach marks a significant advancement in RVV manufacturing, offering improved stability, scalability, and cost-effectiveness for applications in the gene therapy field.

450. Anellovectors: Expanding the Payload Capacity of Anellovirus-Based Vectors Beyond the Wild-Type Genome Capacity

Cato Prince, Nicole Boisvert, Silin Liu, Simeon Springer, Lovepreet Chahal, Rajendra Boggavarapu, Waseem Raja, Chris Reardon, Emily Stead, Yong Chang, Tuyen Ong, Geoffrey Parsons, Joseph Cabral
Ring Therapeutics, Cambridge, MA

We recently reported the development of the Self-Amplifying Trans-complementation of a Universal Recombinant Anellovector (SATURN) production system for producing a functional novel gene therapy class, termed Anellovectors, based on the vectorization of human commensal anelloviruses. Anelloviruses are a highly diverse family of non-enveloped negative-sense single-stranded DNA (ssDNA) viruses that are a ubiquitous component of the human virome. Despite their ubiquitous presence in human populations, anelloviruses are apathogenic and evade induction of robust humoral responses, making them attractive candidates for the next generation of genetic medicines. Here, we report the development of an Anellovector cargo that is significantly larger than the wild-type anellovirus genome. Anelloviruses are the only truly negative-sense ssDNA viruses that infect eukaryotes. Notably, anelloviruses also lack the Rep proteins produced by other ssDNA viruses, pointing to a unique replication and packaging mechanism that may allow for the encapsidation of larger genomes. The Anellovector presented here is based on the Beta genera of human anelloviruses which have genome sizes of ~2.8-3.0 kb. Using vector genomes of increasing size for encapsidation, we have demonstrated that Anellovectors are capable of packaging vector genomes ranging from 2.0kb - 5.0kb, representing up to 65% beyond the wild-type genome capacity. A combination of qPCR and next-generation sequencing was used to verify that the encapsidated expanded cargo DNA is intact, circular, and single-stranded. Electron microscopy was used to verify that vectors containing expanded genomes were capable of forming the expected 30nm particles. The overall potential for Anellovector cargo capacity appears to be similar to or even exceed the ~4.7 kb cargo capacity of AAV. The payload capacity of viral vectors often drives their therapeutic potential. Expanding the payload capacity of the Anellovector builds upon its intrinsic characteristics of immune favorability and tropism in efforts to reach the broadest possible patient population in need of gene therapies.

451. Improvements in AAV and Lenti-Viral Vector Production Using the Mirus RevIt AAV Enhancer and VirusGen LV Transfection Reagent and Kit

Ngan Trinh, Kelly Geosits, Khan Umaer, Srivanya Tummala, Marguerite Campbell, Brian Tomkowicz
Viral Vector Research & Development, SK pharmteco - US, King of Prussia, PA

Transient transfection of three plasmids (rep, cap, and helper) in HEK293 cells facilitated by a transfection reagent is the most widely used method for AAV and other viral vector production. It has, in fact, been shown effective for all viral production platforms and is a regulatory-validated approach. Mirus Bio, a leader in transfection reagent technology, recently developed the TransIT-VirusGEN® Transfection Reagent in conjunction with two enhancers: RevIT™ for AAV and VirusGEN® LV Enhancer for lentiviruses. We sought to investigate the performance of these AAV and LV systems in comparison to other commonly used transfection reagents, as well as address how the addition of enhancers improves performance, regardless of the transfection reagent used. Our results indicate that both enhancers, when added at the appropriate time in the transfection workflow, greatly improve overall titers of virus, when compared to transfection conditions without enhancer. Not only was there an improvement in overall titers, but when using the RevIT Enhancer, we also noticed an increase in full particles across a panel of AAV serotypes. With both TransIT-VirusGEN® and the LV Enhancer currently available in GMP grade and the RevIT AAV Enhancer available for GMP use later in 2024, these reagents will undoubtedly provide an overall improvement for viral vector manufacturing.

452. Development of a Universal, GMP Ready, Clonal HEK293 Cell Line for the Manufacturing of Adeno Associated, Lenti, and Adenoviral Vectors

Marguerite Campbell[1], Kelly Geosits[1], Ngan Trinh[1], Khan Umaer[1], Srivanya Tummala[1], Thomas J. Burton[2], Kaitlyn Krewson[2], Ryann Russell[2], Brian Tomkowicz[1]
[1]Viral Vector Research & Development, SK pharmteco - US, King of Prussia, PA,[2]Process Development, SK pharmteco - US, King of Prussia, PA

Utilizing the well-established, adherent, Frank Graham HEK293 cell line as a starting point, we have successfully adapted cells, from a qualified master cell bank, to grow in animal component-free, suspension conditions, in shake flasks and bioreactors. In head-to-head studies comparing our CBM-HEK suspension-adapted versus 3 commercially available suspension HEK293 cell lines, we demonstrate comparable yields of AAV vectors, following plasmid triple transfection method for virus production. In order to establish a cell line amenable for use in GMP-grade manufacturing, we clonally printed CBM-HEK293 pool cells using the Cytena f.sight cell printing and CloneSelect imaging platform. Herein, we show full-traceability of clonal outgrowth from single-cell through scale-up and have identified select clones that perform equally well in head-to-head comparison studies versus other HEK293 cell lines for virus production. The lead clone 4G9, supports the robust production of all viral platform

tested: AAV, LVV, and Adenovirus. Importantly, the 4G9 clone can support the production across a diverse panel of all natural AAV serotypes evaluated (AAV1, 2, 5, 6, 8, 9) as well as Lenti-viral CAR-Ts. Establishment of a GMP master cell banks for use in large scale AAV manufacturing is underway with expected availability in 2024. The advancement of this production-ready clone represents a significant cost saving for viral vector manufacturing. With integrated process and analytical development as well as commercial scale manufacturing, SK pharmteco can streamline the entire manufacturing process.

Wednesday Posters: AAV Vectors - Virology and Vectorology

453. CRISPR Screen for rAAV Production Implicates Genes Associated with Infection

Sakshi Arora[1], Emily O'Driscoll[2], John Lang[1], Beverly L. Davidson[1], Ophir Shalem[1]

[1]Children's Hospital of Philadelphia, Philadelphia, PA,[2]Department of Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA

Recombinant adeno-associated virus (rAAV) vectors are an effective and well-established tool in the growing gene therapy field, with five approved AAV-mediated gene therapies already on the market and numerous more in clinical trials. However, manufacturing rAAV vectors is an expensive, timely, and labor-intensive process that limits the commercial use of AAV-mediated gene therapies. To address this limitation, we screened producer cells for genes that could be targeted to increase rAAV yield. Specifically, we performed a CRISPR-based genome-wide knockout screen in HEK 293 cells using an antibody specific to intracellular, intact AAV2 capsids coupled with flow cytometry to identify genes that modulate rAAV production. We discovered that the knockout of a group of heparan-sulfate biosynthesis genes previously implicated in rAAV infectivity decreased rAAV production. These findings were validated in a secondary screen performed in producer cells that lack AAV receptor (AAVR). Additionally, we identified several vesicular trafficking proteins for which knockout in HEK 293 cells increased rAAV yields that were further validated using RNP based approach. This approach yielded higher knockout efficiency and avoided the selection effect on cell growth and viability. In summary, our work presents new pathways that can be co-opted to improve rAAV production, with practical applications to the adoption of AAV-gene therapies more broadly. (S.A. and E.O. contributed equally to the work)

454. Towards rAAV Genome Delivery with Lipid Nanoparticles and *In Vitro* Assembled AAV Capsids

Marco T. Radukic[1], Dinh T. Le[2], Lucas Krause[1], Timo Krassuski[1], Kristian M. Müller[1]

[1]Cellular and Molecular Biotechnology, Bielefeld University, Bielefeld, Germany,[2]III. Department of Medicine, Medical Center Hamburg-Eppendorf (UKE), Hamburg, Germany

Production of recombinant AAV in cell culture is inflexible, expensive, and hard to scale. We demonstrate methods to disentangle AAV genome production from packaging, which maintain the function of ITR flanked transgenes while allowing for low cost and flexible manufacturing. First, we established the *in vitro* production of rAAV-mimetic DNA with ITRs but without bacterial remnants and without the AAV length limit. Such DNA was packaged in lipid nanoparticles (LNPs) with proven redosing option. To demonstrate the versatility of the approach, we additionally added *in-vitro* produced mRNA of Rep78 to the LNPs, which should drive transient expression of the integrase. Cas9 guided nanopore sequencing of genomes of respectively transduced cells indeed revealed AAV wild-type like genome integration. For certain applications, the scalability of this approach might democratize gene therapy. In a second line of experiments, we established recombinant VP capsid protein expression in *E. coli* and obtained capsids directly with AAV5 VP3 or from inclusion body purification and refolding with AAV2 VP3. We also recombinantly produced the four Rep proteins and tested their helicase and nickase activity. The components together with the ITR-DNA provide an excellent basis to study factors of a mix and match strategy for AAV encapsidation.

455. Factors Influencing the Level of Plasmid Backbone Impurities in Self-Complementary AAV Products

Holly Appleton[1], Mike Boyd[2], Dmitriy Lukashev[3], Ralf Schmid[4], Ge Tan[5], Edward Oakeley[5], Joel Jenzer[5], Samantha Baker[6], Jasmin Haegele[5], Huang Hon-Ren[6], Lisa D'costa[1], Taylor Pleines[1], Sophie Marshall[1], Binod Pandey[1], Mukund Patel[1], Fangfang Liu[7], Quyen Truong-Royce[7], Marianne E. [1]Technical Research and Development, Novartis Gene Therapies, Durham, NC,[2]Novartis Gene Therapies, Quincy, MA,[3]Novartis, Cambridge, MA,[4]Novartis, Norfolk, MA,[5]Novartis Gene Therapies, Basel, Switzerland,[6]Novartis Gene Therapies, Cambridge, MA,[7]Novartis Gene Therapies, Durham, NC,[8]Novartis Gene Therapy, Raleigh, NC

Recombinant adeno-associated viral vectors (AAV) have demonstrated tremendous potential as an effective gene delivery vehicle for treating a wide range of human diseases. However, current AAV production methods have certain limitations including the presence of capsid associated nucleotide impurities, which originate from plasmid backbones or host cell DNA raising valid safety concerns. Previous studies have reported that the incorporation of short-hairpin DNA sequences into the backbone of the AAV gene of interest (GOI) plasmid leads to a decrease in the occurrence of reverse-packaged genomes. In this study, we aimed to evaluate whether the inclusion of a hairpin structure adjacent to the wild-type (wt-ITR) within the backbone could decrease the level of plasmid backbone impurities in self-complementary AAV using AAV2 and AAV8 serotypes. A total of four AAV2 and three AAV8 self-complementary (sc) vectors were produced using AMBR250 bioreactors via triple plasmid transfection. The vectors were harvested 72 hours post transfection and subjected to AAVX purification. Neutralized AAVX eluates were submitted for ddPCR titer, ddPCR plasmid backbone impurity quantification, and

PacBio NGS. While some of the assays are still ongoing, our preliminary data indicates: 1. The presence of backbone impurities within sc-AAV was found to be associated with wild-type (wt)-inverted terminal repeats (ITR); namely, the quantity of backbone impurities detected on PacBio NGS increased as the distance to the wt-ITR decreased. 2. The presence of a hairpin structure on the sc-AAV GOI plasmid backbone did not result in a significant decrease in the amount of backbone packaging impurities via ddPCR assay. 3. There was also a significant disparity in the percentage of backbone impurities between sc-AAV derived from AAV2 and AAV8. Specifically, AAV2 exhibited a higher percentage of backbone impurities, approximately 2.6 times higher than that of observed in AAV8. This study will offer valuable insights into the production of safer and more efficient recombinant AAV vectors for clinical applications.

456. Tuning AAV Transgene Expression with Autogenous, Chemical-Based Control Systems

Sara R. Wasserman, Matthew L. Hirsch, Nathaniel A. Hathaway

University of North Carolina, Chapel Hill, NC

A common challenge for pre-clinical AAV gene therapies is insufficient transgene expression. However, high or repeated AAV dosing regimens increase immunogenic risk. Thus, an auxiliary method of activating AAV expression at the transcriptional level could be valuable to the development of more effective gene therapies. To chemically activate the expression of AAV, we have developed a proximity-based technology that uses heterobifunctional small molecule recruiters of endogenous transcriptional regulators. When combined with a small, synthetic zinc-finger based molecular scaffold, this bioorthogonal approach facilitates targeted recruitment of the transcriptional upregulator bromodomain-containing protein 4 (BRD4) directly to AAV genomes. We first identify a series of minimal, autogenous cassettes that can effectively regulate AAV expression while preserving ~3 kb for single-stranded therapeutic payloads. The lead regulatory cassette efficiently induces AAV expression, increasing transgene production over 30-fold in vitro. CUT&RUN-Sequencing reveals that AAV genomes in cells treated with the heterobifunctional recruiter are significantly enriched for BRD4 occupancy. Chemical control of AAV expression is shown to be effective across multiple human cell lines and transgene cassette configurations. Activation of AAV expression by this method is dose-dependent, resistant to washout, and can be chemically reversed within 72h. Future steps for the application of this technology in translational models of dose-sensitive diseases are discussed. This chemical method of tuning AAV expression may help circumnavigate the immunogenic risk of repeated AAV treatments by providing a controlled and reversable chemical strategy to increase the expression of single-dose AAV therapies.

457. The Impact of rAAV Genome Size on Vector Production in the Sf9-Baculovirus System

Zhaohui Yang[1], Clarissa Tjoanda[1], XuShan Wang[2], Shreya Ahuja[1], Brandon Zhuang[1], Andrew Pla[1], Mary Ng[1], Nicole Nasta[1], Jessica Cheng[1], Stuart Nelson[3], Garrett Daniels[1]

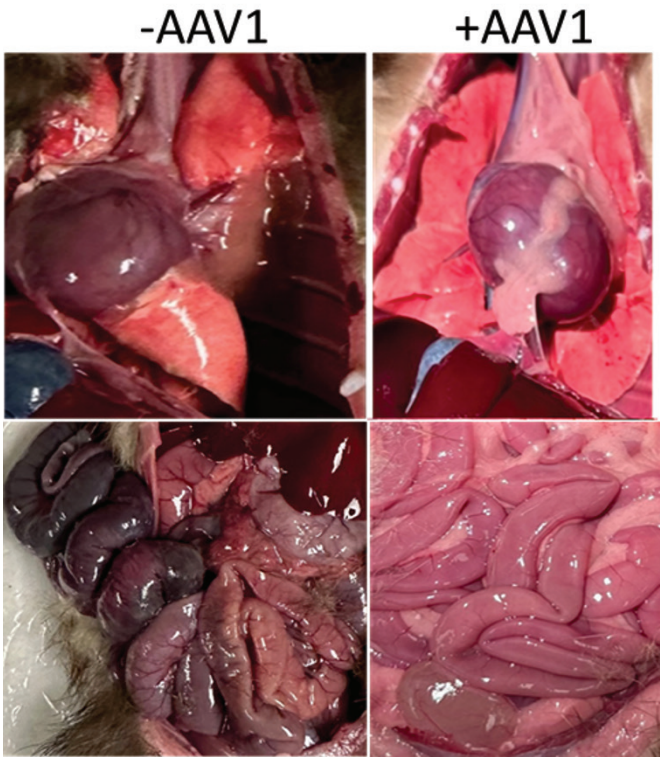
[1]Prevail Therapeutics, a Wholly Owned Subsidiary of Eli Lilly and Company, New York, NY,[2]Eli Lilly and Company, Indianapolis, IN,[3]Eli Lilly, New York, NY

Recombinant adeno-associated virus (rAAV) is an effective vector for gene delivery currently being used in multiple FDA-approved gene therapies and over 100 clinical trials for the treatment of genetic diseases. The increasing demand for high-quality rAAV vectors requires improved manufacturing. The Sf9-Baculovirus production system has great potential to meet such needs with its high yield, packaging efficiency, and scalability. Wild-type AAV has a single-stranded DNA genome of approximately 4.7 kb. Previous studies have shown that the packaged genome size can impact the characteristics of rAAVs produced from mammalian cell lines. In Sf9-produced AAVs, packaged genomes that are slightly bigger than wild-type length have been reported, which likely leads to increased vector heterogeneity. In order to systemically investigate the impact of genome size on the production of rAAVs in Sf9 cells, we evaluated the yield and quality of a series of vectors with a wide range of genome sizes. The transgene cassettes were designed to have identical components (promoter, reporter, polyadenylation signal, backbone) and only differ by the length of stuffer sequences, resulting in undersized, close to wild-type, and oversized AAV genomes. Using a panel of characterization assays including gel electrophoresis, next generation sequencing (NGS), analytical ultracentrifugation (AUC), and expression-based analyses, we observed heterogeneous vector populations that encapsidated undersized genomes in both self-complimentary (dimer) and single-stranded (monomer) forms of DNA, whereas close to wild-type and oversized genomes only exhibit single-stranded DNA. Interestingly, there was a remarkable decrease in vector potency *in vitro* as genome size gets bigger, whereas the empty vector ratio as well as the purity of packaged DNA were similar across all the vectors tested. The production yield measured by physical titer using droplet digital PCR (ddPCR) was not significantly affected by genome size. To further interrogate whether the decreased potency of vectors with larger genomes was due to decreased infectivity, additional assays will be carried out. Since the viral capsid protein VP1 is known to play a critical role in the infectivity of the virus, the relative ratio of VP1 will also be analyzed. Taken together, this work demonstrated that the genome size has great impact on Sf9-produced rAAV product quality. Our findings can help further optimize the design of transgene cassette to improve the production of fully functional and high-quality rAAVs.

458. Co-Packaged Genomic DNA in AAV Particles is Not Detected in Animal Tissues After Systemic Administration

Matthew Fuller, Lorelei Stoica, James Maratt, Zachary Sykes, Emily Agro, Elliott Wilion, Nicholas J. Richards, K. Reed Clark, Samuel C. Wadsworth

Ultragenyx, Somerville, MA



An adeno-associated virus (AAV) vector with a hu.37 capsid was developed for the treatment of hemophilia A. This AAVhu.37 vector, termed DTX201, carries a genome that encodes for expression of B-domain deleted human Factor(F)VIII. Preclinical characterization studies in hemophilia A mouse models and nonhuman primates with DTX201 have been published. The results of these studies, along with formal GLP safety studies, formed the basis for a clinical trial using DTX201 in subjects with severe hemophilia A. Because of the size of the hemophilia A population, and the likely requirement for high vector doses to achieve therapeutic benefit, a readily scalable, suspension, serum-free system was chosen for manufacturing of the DTX201 product. This system utilized a stable producer cell line (Pinnacle PCL) based on the HeLa S3 cell substrate. Advantages of the PCL platform for vector production include ease of scalable manufacturing, high vector yield and higher proportion of full length vector genome containing particles, as compared to other platforms. For the PCL platform, a potential perceived disadvantage is that the HeLa cell line was derived from a cervical carcinoma transformed by the genome of human papilloma virus type 18 (HPV18). To address this potential disadvantage, we characterized the presence of HPV18 sequences in DTX201 product via sensitive and quantifiable methods. We further examined whether transfer of HPV18 sequences could be observed in tissues of animals exposed to the DTX201 product. We demonstrate that HPV18 contaminants were detectable but not quantifiable in highly purified virus preparations. Importantly, HPV18 sequences were undetectable *in vivo* from mouse tissues extracted from multiple organs following intravenous delivery of DTX201. Taken together, these data support the safety of manufacturing high-quality gene therapy products such as DTX201 in PCLs derived from HeLa S3 cells.

459. AAV Gene Therapy Successfully Ameliorated Clinical Symptoms in Cystic Fibrosis G551D Ferrets

Cristian Ciobanu[1], William B. Guggino[2], Liudmila Cebotaru[1]

[1]Medicine and Physiology, Johns Hopkins University, Baltimore, MD,[2]Johns Hopkins University School of Medicine, Baltimore, MD

Cystic fibrosis (CF) is caused by mutations in the cystic fibrosis conductance regulator (CFTR). Developing a gene therapy for CF is still a critical need especially for patients who either are not approved for corrector therapy or do not tolerate it. One way to show definitively that gene therapy can be therapeutic is to rescue defective CFTR function in a relevant animal model that recapitulates, as closely as possible, human disease. To accomplish this, we used the ferret model bearing the G551D mutation which responds to the potentiator, VX-770, similar to humans. The goal was to assess whether dosing of AAV1/6-Δ27-264-CFTR vectors administered to G551D ferrets in the absence of proteasome inhibitors leads to widespread gene transfer, expression and phenotypic rescue. Most studies on CF gene therapy have targeted the lung. Here, we have taken a different approach targeted to treat several organs in a G551D ferret model of CF. We have chosen to use this model to study a distinctly different route of delivery whereby vector was both sprayed into the airway and injected systemically, testing the hypothesis that this dual route of delivery can transduce airways, lung, liver, pancreas, and ileumThe G551D ferrets were removed from VX-770 treatment 7 days before AAV treatment. 1 dose of 10^{11} vg of AAV1-Δ27-264-CFTR or AAV6-Δ27-264-CFTR was sprayed into the airways and injected intravenously into eight, 3-month-old male and female ferrets. 2-G551D and 2-wild-type ferrets were kept as controls. Animals were necropsied at 35 days post-instillation. AAV1-Δ27-264-CFTR or AAV6-Δ27-264-CFTR were detectable at $\geq 10^6$ vg/ug-genomic-DNA in trachea, bronchi, lung, ileum, liver and pancreas. mRNA expression was detected at $\geq 10^6$ copies/ug-genomic-DNA in trachea, bronchus, lung, pancreas and ileum and $\geq 10^5$ copies/ug-genomic-DNA in liver. Widespread CFTR protein expression was seen in the tissues of all the treated animals above levels measured in untreated wild-type and G511D ferrets. CFTR protein expression above untreated animal levels following a single dose of AAV1-Δ27-264-CFTR or AAV6-Δ27-264-CFTR suggests that transduction by AAV1 or 6 based vectors occurs in airways, liver ileum and pancreas of AAV treated G551D ferrets. The gross morphology of the treated ferrets resembled that of the normal ferrets compared to the untreated G551D ferrets. Minor amounts of mucous was present compared to untreated animals. The results are important in that we were able to transduce trachea, lung liver, pancreas and ileum despite the barriers associated with mucous plugging, AAV degradation and potential inhibitory factors in the sputum. Successful transduction of G551D ferrets suggests that systemic delivery of AAV may be the preferred route of delivery for a gene therapy for CF to reduce multiorgan disease. Transduction of the G551D ferrets in the organs affected in CF provide promise for rescue of multiorgan disease in CF.

460. Comprehensive Characterization of AAV Vectors' Genome Integrity Through Long-Read Sequencing

Ting Chen[1], Kirk Elliott[1], Amanda Zhang[2], Ayda Mayer[2], Lan Jin[1], Mi Shi[1], Olivier Danos[1], Ye Liu[1]

[1]Research and Early Development, REGENXIBO Inc., Rockville, MD,[2]Technical Operations, REGENXIBO Inc., Rockville, MD

Recombinant adeno-associated virus (AAV) is a promising *in vivo* gene delivery vector due to its safety and efficacy evaluated in current approved AAV products. It is of utmost importance to characterize the genome integrity of AAV vectors since defective vectors could compromise the effectiveness and safety of AAV gene therapy. In this study, we present a comprehensive methodology for the quantitative and visual assessment of packaged AAV genomes using the long-read sequencing technology. Our methodology utilizes the single-molecule real-time (SMRT) sequencing from PacBio for its high accuracy in analyzing AAV genomes. It accommodates sequencing data from both single-stranded AAV (ssAAV) and self-complementary AAV (scAAV). It is designed to facilitate accurate quantification of single molecules mapped to either vector sequence (i.e., transgene and ITR) or non-vector sequences (i.e., cis-plasmid backbone, trans plasmid, helper plasmid and host genome sequences). The entire analysis comprises several distinct features. 1. Long sequencing reads are aligned to a unified version of vector and non-vector sequences for each AAV sample, followed by graphic presentation of the AAV genome integrity using the Integrative Genomics Viewer (IGV) software. We further evaluate the ITR integrity and AAV genome truncation hotspots through graphical representation of read counts in each starting and ending alignment position throughout the AAV transgene region spanning from 5' ITR to 3' ITR. 2. A plot is generated to depict the distribution of lengths of reads that are aligned to the AAV transgene region. This enables us to assess whether the AAV genomes are primarily distributed at their expected full length or instead exhibit a specific concentration at other lengths (i.e., truncation or duplication). 3. We characterize full length AAV genomes as well as partial genomes that may consist of, for instance, 5' ITR and a partial transgene region or a partial transgene region followed by 3' ITR. We also calculate the compositions of non-vector sequences and chimeric reads arising from the recombination of vector and non-vector sequences. 4. Abundances of snapback genomes related to cis plasmid, trans plasmid, helper plasmid and host DNA sequences in the AAV population are quantified. 5. The ITR integrity is assessed by analyzing the composition of reads that contain both ITRs, 5' ITR only, 3' ITR only or no ITRs. Furthermore, we quantify ITR flip and flop configurations. We present the analysis of two ssAAV vectors expressing either a microRNA or an antibody fragment under the control of the CAG promoter. They exhibited 73%-83% full length genomes with 0.08%-0.14% non-vector sequence contamination. We also analyzed multiple scAAV vectors that were packaged into AAV8 or AAV9-variant capsids and expressed three antisense sequences fused with modified U7 small-nuclear RNA scaffold under the control of mouse U7 promoters. Our data showed 84%-85% full length genomes with 0.04%-0.16% non-vector sequence contamination in these scAAV vectors. The ssAAV vectors demonstrated flip and flop configurations (i.e., flip/flip, flip/flop, flop/flip, flop/flop) with ratios of approximately 1:1:1:1 and 1:1.5:1.5:1, whereas all the scAAV vectors presented a consistent ratio of approximately 4:1:1:4. This comprehensive analysis offers us a useful perspective on the quality of our AAV products, presenting valuable insights for further research and applications.

461. An Artificial Exonic Barcode System for AAV Capsid Selection

Matthew J. Burke[1], Xiufang Pan[1], Yongping Yue[1], Jin Han[1], Chady H. Hakim[1], Jun Li[2,3,4], Lei Jin[2,3,4], Shi-Jie Chen[2,3,4], Dongsheng Duan[1,5,6,7]

[1]Department of Molecular Microbiology and Immunology, University of Missouri, Columbia, MO,[2]Department of Physics, University of Missouri, Columbia, MO,[3]Department of Biochemistry, University of Missouri, Columbia, MO,[4]Institute for Data Science and Informatics, University of Missouri, Columbia, MO,[5]Department of Biomedical, Biological & Chemical Engineering, University of Missouri, Columbia, MO,[6]Department of Neurology, University of Missouri, Columbia, MO,[7]Department of Biomedical Sciences, University of Missouri, Columbia, MO

Capsid selection is a major determining factor for the efficacy and safety of adeno-associated virus (AAV) gene therapy. The short nucleotide (3 to 15 nucleotides) barcode system has been used to compare the transduction and expression of various AAV capsids using high-throughput sequencing and bioinformatic analysis. However, the short barcode system has some limitations. For example, the results cannot be validated by a different method. The system is unsuitable for *in situ* evaluation of transduction and expression at the single-cell level in tissues. Since the cDNA sequence and the gene sequence are identical, it is also impossible to rule out DNA contamination in the cDNA preparation completely. Further, different bioinformatic algorithms

may yield different outcomes. To overcome these limitations, we developed an artificial exonic barcode system. Specifically, we designed a set of artificial exons distinctive from the genomic sequences of commonly studied species, including humans, non-human primates, dogs, pigs, mice, rats, and rabbits. To accurately quantify the vector genome and the transcript copy number of the candidate AAV capsids, we designed and validated a series of exonic barcode-specific TaqMan qPCR assays. Using this system, we screened 11 AAV capsids in a mouse model of Duchenne muscular dystrophy and normal canines. Our results are highly consistent with the literature. The artificial exonic barcode system is a promising approach to identifying the best capsids for AAV gene therapy (Supported by NIH).

462. AAV Cell Surface Target Profiling Using Binding and Functional Cell Microarray Screening Technology

Claire Tebbutt[1], Beth Walker[1], Lucy Hanley[1], Clare Halliday[1], Elli Tudge[1], Lucinda Branton[1], Louis Sykes[1], Ruofan Wang[2], Giovanna Gayoso[2], Ashley Przygocki[2], Mark Aspinall O'Dea[1]

[1]Charles River Laboratories, High Peak, United Kingdom,[2]Charles River Laboratories, Rockville, MD

AAV (Adeno-Associated Viruses) vectors have emerged as a promising gene therapy. In 2019 > 200 clinical trials accounted for 24% of viral vector studies worldwide (1), however challenges remain in overcoming organ specificity, innate immunity, and dose-dependent toxicity (2). Here we describe a novel dual screening capability for AAV's, using the Charles River Retrogenix Cell Microarray technology, to enable identification of novel cell surface receptor interactions involved in virus sequestration and functional payload delivery. The Retrogenix Cell Microarray consists of over 6,500 full length human cell surface, secreted and heterodimeric proteins, over-expressed in HEK293 cells. Now expanded to include non-human plasma membrane proteins with ≤ 90% human homology in the extracellular domain, the array can be used to identify novel primary receptors, potential off-targets and assess in vitro / in vivo efficacy (3) and safety profiling (4) for gene therapeutics. Additionally, a functional screening method has been developed enabling AAV binding to specific cell surface receptors (5) and internalization (transduction) observed via reporter gene expression. WT AAV9 controls presented over X cell surface interactions when tested, allowing distinction between sequestration and transduction activity upon cell surface binding. Examples include KIAA0319L, a protein receptor required for AAV endocytosis, together with AAV attachment factors and co-receptors, such as fibroblast growth factor receptors (FGFR), heparan based molecules, solute carrier proteins, interleukins and neuropeptides. Functional and binding studies can facilitate candidate selection, demonstrate therapeutic specificity and de-risk future in vivo studies. This technology presents surface proteins in their natural environment, affording several advantages over conventional array technologies, including low false positive rates and high target specificity. AAV screening against Human and Non-Human arrays for potential off-target binding presents a unique strategy to help de-risk therapeutic candidates and provide supporting data for IND submissions. 1. An Essential Receptor for Adeno-Associated Virus Infection. Nature. 2016. 530; 7588.

463. CBN-1100: A New and Differentiated Non-AAV Parvovirus Vector Designed to Overcome Current Gene Therapy Limitations

Sebastian Aguirre[1], Yoshifumi Hashimoto[1], Carolyn Pelletier[1], Melvys Valledor[1], Michael Rak[1], Yousuf Aqeel[2], Gillian Payne[2], Richard Matters[3], Shu-hao Liou[3], Joshua Merritt[3], Marc Abrams[4]

[1]Platform Development Team, Carbon Biosciences, Waltham, MA,[2]Analytical Development Team, Carbon Biosciences, Waltham, MA,[3]Process Development Team, Carbon Biosciences, Waltham, MA,[4]Carbon Biosciences, Waltham, MA

CBN-1100 is a new recombinant non-AAV parvovirus vector which overcomes many of the challenges associated with AAV parvovirus vectors: it offers ~1 kb more cargo capacity, minimal seroprevalence in humans, compelling systemic biodistribution and natural liver de-targeting. CBN-1100 leverages a wild type autonomous parvovirus capsid which is >80% divergent from all AAV capsids at the amino acid level. Among its advantages, the larger capacity offers the ability to deliver therapeutic transgenes and tissue-specific promoters which are out-of-reach for AAV. In this work, we demonstrate that CBN-1100 can efficiently encapsidate functional AAV2 ITR-flanked cassettes with an insert size of at least 5.5 kb, including large reporter genes and editing cassettes containing spCas9 and sgRNAs. CBN-1100 also demonstrates robust manufacturability; vector cell culture yields using our plasmid-based mammalian cell process are comparable to AAV industry standards at 40 liter bioreactor scale. Chromatography-free purification resulted in vector product with ~90% filled capsid by analytical ultracentrifugation and cryo-electron microscopy. Finally, we observed robust gene expression in several diverse human cell types, achieving transduction efficiencies of up to 90% with predictable kinetics and dose proportionality. The attributes of CBN-1100 suggest that viral vectors powered by non-AAV parvovirus capsids offer a path forward for numerous targets and indications that are undruggable using current gene therapy technology.

464. Chimeric and Rationally Designed Compact Promoters for Cardiomyocyte-Specific Gene Expression

Prasad R. Konkalmatt[1], Chris A. Reid[2], Melissa Van Pell[1], Samantha Jones[1], Ze Cheng[1], Joe Woods[1], Anastasiia Budan[1], Alex Aycinena[1], Mo Mandegar[2], Kathy Ivey[1]

[1]Tenaya Therapeutics, South San Francisco, CA,[2]Ascend GCTx, San Francisco, CA

Adeno-associated virus (AAVs) vectors have become among the preferred gene delivery vehicles for a broad range of human gene

therapy applications. AAVs have proven ability to transduce and provide durable gene expression in various organs and cell types, including cardiomyocytes (CMs), making them well suited for the treatment of genetic cardiomyopathies and other prevalent forms of heart diseases via gene replacement therapy as well as gene editing. The broad tissue tropism of AAV serotypes and their smaller packaging capacity calls for the development of shorter tissue-specific promoters to increase specificity in tissue targeting while maintaining a therapeutic levels of expression, potentially improve the safety profile, and enable AAV gene therapies for larger genes or sizeable genome editing constructs without exceeding the ideal packaging capacity of ~4.7 kb. As a novel strategy to develop a shorter CM-specific promoter, we created a library (n = ~1000) of 250 bp chimeric promoters and screened them for cardiac-specific gene expression. These chimeric promoters were constructed using the natural 500 bp proximal promoter regions of five genes that are preferentially expressed in the adult CM. The promoter chimeras fused to EGFP were independently screened for their magnitude of gene expression in human induced pluripotent stem cell-derived CMs (iPSC-CMs). The top twelve chimeric promoters were then packaged in AAV9 capsids and evaluated in mice and non-human primates for cardiac-specific expression versus a 400 bp cardiac specific promoter, hTNNT2. Sequence analysis of the top-performing chimeric promoter revealed enriched CM-specific transcription factor (TF) binding sites within the proximal region. Further trimming and introduction of additional CM-enriched TF binding-sites and known cis-regulatory elements resulted in expression comparable to the TNNT2 promoter when evaluated in mice, but with a much smaller footprint. As an alternative approach, we also used rational design starting with the proximal portion of the TNNT2 promoter to create short promoters with strong and CM specific expression. We began by identifying regions enriched for CM-specific TF binding in the TNNT2 proximal promoter from human, mouse, and chicken. Fusing the TF-enriched sequences with known TATAA box and transcription start site (TSS) elements resulted in <220 bp promoters that produced 0.57 ±0.08, 0.45 ±0.16, and 1.02 ±0.21-fold gene expression in the human iPSC-CMs compared to 400 bp hTNNT2 promoter. Overall, this strategic approach resulted in successful development of a suite of novel, shorter CM-selective promoters that produced varying degrees of gene expression in the mouse heart. These novel short promoters have the potential to facilitate creation of AAV cardiac gene therapies for larger genes of interest, as well as cardiac gene editing where extra space is needed for genome editing machinery, while maintaining CM specificity and without exceeding the packaging capacity of AAV vectors.

465. AAV9, AAVrh.10, and AAVrh.74 Exhibit Different Cell Type Tropisms in the Heart Following Systemic Delivery and AAV9 Mediates Superior Cardiomyocyte Transgene Expression in Murine and Non-Human Primate Models

Ze Cheng, Emilee Easter, Lindsey M. Rollosson, Emma Xu, Huanyu Zhou, Karl Doerner, JianMin Lin, Kathryn N. Ivey, Timothy Hoey, Laura M. Lombardi

Tenaya Therapeutics, South San Francisco, CA

Gene therapy is an emerging treatment option for both acquired and inherited cardiac disorders and targeting cardiomyocytes following systemic delivery is critical to enable gene therapy treatments for many cardiac conditions. Several natural AAV serotypes, including AAV9, AAVrh.10, and AAVrh.74, have been hypothesized to efficiently transduce cardiomyocytes *in vivo* and are being advanced in cardiac gene therapy programs. We, for the first time to our knowledge, studied heart transduction and transgene expression properties of AAV9, AAVrh.10, and AAVrh.74 head-to-head using cell type specific RNA reporters in both murine and NHP models. In mice, all three serotypes show similar transduction to the heart as measured by viral genome DNA load, however, AAV9 generates higher expression level of cardiomyocyte-specific RNA reporter transcripts than the other two serotypes manufactured in parallel on the same platform. We also performed a similar study with fibroblast-specific RNA reporter transgenes and the results show that, in contrast to cardiomyocyte transgene expression, all three serotypes mediate transgene expression in fibroblasts with similar efficiency in mice, highlighting the difference in their cell type tropisms. We further investigated the relationship between cell type specific transgene expression level and cardiac gene therapy efficacy by treating a cardiomyocyte-autonomous cardiomyopathy mouse model with the same gene editing based therapeutic cassette delivered by AAV9, AAVrh.10, and AAVrh.74 at the same dose. The degree of efficacy, which was highest with AAV9, correlated with *in vivo* cardiomyocyte transgene expression level and not with viral genome DNA load in the heart. Finally, we measured heart transduction and cardiomyocyte transgene expression of all three serotypes in Cynomolgus monkeys and observed similar trends as those achieved in mice, namely that AAV9 mediates the highest level of cardiomyocyte gene expression. Together, our work demonstrates that AAV9 more efficiently expresses transgene in cardiomyocytes following systemic administration compared to AAVrh.10 and AAVrh.74. Our results also highlight that it is crucial to use cell type specific reporter cassettes while performing comparison studies to support capsid selection for cardiac and other categories of gene therapy programs, as failing to do so could lead to the risk of misguided selection.

466. Designing Therapeutic Recombinant AAV Vectors Using *In Silico* Vector Modeling

Ethan Waple[1], Jennifer C. Gifford[1], Sarath Mandava[1], Nicholas Ketz[2], Alpha Diallo[2], Amicia D. Elliott[2], Adam S. Cockrell[1]

[1]Solid Biosciences, Charlestown, MA,[2]Form Bio, Austin, TX

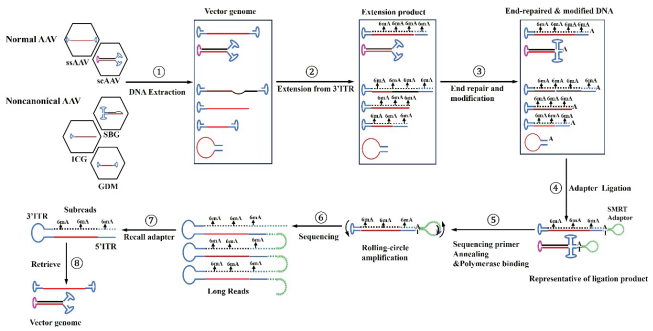
When designing safe, efficacious, and cost-effective AAV gene therapies, early R&D seeks to determine the best vector configuration with the intended full-length genetic payload from thousands or even millions of possibilities. Genetic cargo packaged within a single production lot can be a heterogenous population of recombinant AAV vector particles comprising a combination of different molecular species. *In silico* vector modeling may support early identification of *cis* elements in genetic cargos that may shift vector productions to the desired homogenous population of therapeutic molecules. We used long read sequencing to profile the molecular species in early discovery research grade rAAV therapeutic vector productions which revealed the presence of intended full-length vector species as well as varying amounts of unintended molecular species including

vector truncations, chimeric molecules, molecules containing plasmid backbone sequences, and a variety of double-stranded vector molecules (i.e. snap-back genomes). *In silico* modeling of the rAAV vector using the FORMsight[AI] artificial intelligence platform revealed specific *cis* nucleotide elements in promoter and intron regions that exhibit high propensities for truncations to occur. Further, some *cis* nucleotide elements align with predicted secondary structures in the single-stranded rAAV DNA molecules. Modifying the promoters and introns resulted in decreased truncation propensity and decreased secondary structures. We hypothesize that long-read sequencing analysis of the modified rAAV vectors will validate a shift to a higher proportion of full-length single-stranded rAAV molecules packaged into vector particles, thereby resulting in a shift to a more homogenous population of vector particles containing therapeutic transgenes. Overall, utilizing *in silico* vector modeling to assess thousands and potentially millions of vector configurations prior to *in vitro* and *in vivo* testing could dramatically improve workflow efficiency resulting in a more cost-effective therapeutic for gene therapy applications.

467. Rational Engineering of the AAV P5 Promoter Improves Vector Purity

Stephen M. Winston[1], Mark A. Brimble[2], Isaiah Reeves[2], Yunyu Spence[1], Pei-Hsin Cheng[2], Christopher L. Morton[1], Andrew M. Davidoff[2]

[1]Department of Surgery, St. Jude Children's Research Hospital, Memphis, TN,[2]St. Jude Children's Research Hospital, Memphis, TN



Previous work has demonstrated that both P5- and ITR-associated nucleic acid contaminants from plasmids used to produce recombinant adeno-associated virus (rAAV) vectors can be expressed *in vivo*, highlighting a need to further characterize their implications and develop strategies to increase vector purity. These sequences are encapsidated within fully functional virions, resulting in transcription and translation of undesired plasmid-derived sequences. We hypothesized the packaging of contaminant plasmid sequences is related to the P5 promoter structure and Rep gene expression during production, and that by manipulating critical elements of the P5 promoter and modulating Rep expression, we can reduce the encapsidation of these contaminant sequences. To prevent this encapsidation, we mutated the Terminal Resolution Sequence (TRS) loop mimic on the AAV2 P5 promoter. We have previously shown that placing a spacer between the P5 TRS loop and Rep protein Binding Elements (RBE) reduces its encapsidation three fold, however, it is still present at a relatively high quantity. By directly mutating this site we can reduce encapsidation of nearby DNA by an additional ten-fold. This improvement in purity coincides with a modest reduction in overall viral titer. Rep westerns and fluorescent reporter assays highlight changes in promoter activity correlated with changes to vector titer and purity. These assays were used to identify the implications of promoter modifications on promoter function. Modifications which improved purity and had the most detrimental effect on viral titer, had the strongest impact on promoter activity. Specifically, we observed decreased large Rep expression and increased small Rep expression. We then found that additional modifications to compensate for altered promoter activity rescued viral titer, suggesting these assays may be relevant in establishing and optimizing conditions for rAAV production. These modified promoters may prove to be viable alternatives to the canonical AAV2 P5 routinely used in rAAV production. Large scale production, vector characterization and *in vivo* assays with these new AAV promoters are currently underway. In conclusion, rAAV contamination can be reduced by rationally engineering the P5 promoter. Our findings have implications for making safer, purer products for rAAV gene therapy.

468. Thorough Molecular Configuration Analysis of Non-Canonical AAV Genomes in AAV Vector Preparations

Junping Zhang[1], Xiangping Yu[2], Matthew Chrzanowski[2], Jiahe Tian[3], Derek Pouchnik[4], Ping Guo[5], Roland W Herzog[1], Weidong Xiao[1]

[1]Herman B Wells Center for Pediatric Research, Indiana University School of Medicine, Indianapolis, IN,[2]Nikegen LLC, Wynnewood, PA,[3]Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY,[4]School of Molecular Biosciences, Washington State University, Pullman, WA,[5]Lewis Katz School of Medicine, Temple University, Philadelphia, PA

The unique palindromic inverted terminal repeats (ITRs) and single-stranded nature of adeno-associated virus (AAV) DNA are major hurdles to current sequencing technologies. Due to these characteristics, sequencing non-canonical AAV genomes present in AAV vector preparations remains challenging. To address this limitation, we developed Thorough Molecule Configuration Analysis of non-canonical AAV genomes (TMCA-AAVseq). TMCA-AAVseq takes advantage of the documented AAV packaging mechanism, in which encapsidation initiates from its 3'-ITR, for AAV sequencing library construction. Any AAV genome with a 3'-ITR is converted to a template suitable to adapter addition by Bst DNA polymerase mediated extension reaction. This extension reaction helps fixing ITR heterogeneity in AAV population and allows efficient adapter addition to even noncanonical AAV genomes. Additionally, during the second strand extension, dATP is replaced with N6-methyladenine (6mA), this can efficiently distinguish from the new synthesized strand and original sequence. A flowchart of the library preparation and subsequent sequencing by TMCA-AAVseq is depicted in Figure 1. The resulting library maintains the original AAV genome configurations without introducing undesired changes. Subsequently, long-read sequencing can be performed by the Pacific Biosciences (PacBio) single molecule, real-time (SMRT) sequencing technology platform. Finally, through comprehensive data analysis, we can recover canonical, non-canonical AAV DNA, and non-AAV vector DNA sequences, along with their molecular configurations. The method is a robust tool for profiling thorough AAV-population genome. TMCA-AAVSeq can be further expanded and applied to all parvoviruses and their derivative vectors.

469. Engineering of AAV Replication Protein

Jixin Liu[1,2], Conradin Baumgartl[1,2], Dirk Grimm[1,2,3]

[1]BioQuant, Heidelberg University, Heidelberg, Germany,[2]Department of Infectious Diseases/Virology, Section Viral Vector Technologies, Medical Faculty, Heidelberg University, Heidelberg, Germany,[3]German Center for Infection Research (DZIF) and German Center for Cardiovascular Research (DZHK), Heidelberg University, Heidelberg, Germany

Adeno-associated virus (AAV) has become the most popular viral vector for therapeutic gene transfer in humans. However, numerous questions surrounding the biology of the wild-type virus persist, restricting the streamlining and upscaling of AAV vector manufacturing. A particularly enigmatic step is the replication and packaging of the recombinant AAV DNA genome, in which the four pleiotropic Rep(lication) proteins play pivotal roles that are only partially understood. Previous research including work from us showed that the Rep proteins of the most studied AAV serotype 2 (AAV2) are compatible with the inverted terminal repeats (ITRs) of several other serotypes. Hence, they can support the replication and encapsidation of an embedded genome, with the notable exception of the AAV5 ITRs that differ significantly in sequence and structure. Nonetheless, it is possible that wild-type Rep proteins, while adapted evolutionarily for the processing of wild-type viral genomes, may only function suboptimally during replication and/or packaging of recombinant AAV DNA. Moreover, they might also perform subpar in combination with synthetic ITRs that have been engineered or evolved independently, and that may ultimately replace the wild-type AAV2 ITRs which are used in most of the current vectors. Likewise, with the growing number and diversity of AAV capsid variants that were designed or enriched for certain properties, the likelihood concurrently increases that wild-type Rep proteins will no longer mediate an optimal capsid-genome interaction and DNA packaging. Altogether, these considerations have motivated us to adapt our previously established pipeline for DNA family shuffling of AAV capsid proteins to the Rep proteins as well, with the aims to: 1) improve the production yield of wild-type and novel AAV capsids, 2) reduce the proportion of empty capsids during the production process, 3) enhance the replication and/or packaging of recombinant genomes based on different AAV ITRs, and 4) decode the mechanisms, sequences and structures that underlie Rep-capsid and Rep-ITR interactions. To this end, we have shuffled *rep* genes from a wide variety of naturally occurring AAV isolates, resulting in complex libraries for subsequent interrogation through iterative *in vitro* screening for the aforementioned enhanced properties, using a collection of AAV genomes carrying wild-type or synthetic ITRs as templates for viral DNA replication and packaging. The enrichment of shuffled Rep variants with desired properties is comprehensively monitored at high quality and quantity using next-generation sequencing pipelines, comprising PacBio and Nanopore sequencing, which we have adapted and optimized in parallel for this purpose.The results of this work are expected to benefit our understanding of natural AAV biology including genome replication and packaging, while also enabling the improvement of the components and processes required for large-scale AAV manufacturing.

470. Advancing Recombinant AAV Manufacturing: TESSA® Platform for Scalable and Efficient Gene Therapy Production

Weiheng Su[1], Chloe Fustinoni[1], Marek Kucej[1], Pablo Monje[1], Cristina Araujo-Cuevas[1], Michael White[1], Louise Montgomery[1], Daniel Chow[1], Matthew Peckett[1], Qian Liu[1], Yi-Hsin Fan[2], Yu-Pin Su[2], Bibek Ghosh[2], Man-shiow Jiang[2], Ryan Cawood[1], Weimin Valenti[2]

[1]OXGENE, Oxford, United Kingdom,[2]WuXi Advanced Therapies, Philadelphia, PA

Recombinant adeno-associated virus (rAAV) vectors hold significant promise for gene therapy; however, challenges persist in achieving efficient and scalable production. This study investigates the 'Tetracycline-Enabled Self-Silencing Adenovirus' (TESSA®) platform, offering a robust solution for rAAV manufacturing devoid of adenovirus contamination. TESSA® provides a versatile approach to rAAV production, utilizing either the TESSA® Duo, which involves two vectors for AAV rep/cap and the rAAV transfer genome, or the TESSA® Pro method, which employs co-infection with existing rAAVs for propagation. These approaches empower researchers to produce cost-effective, scalable, and rapid rAAV vectors. The TESSA® Duo method, requiring the construction of two TESSA® vectors, proves highly effective, yielding over 30 times more rAAV compared to the triple transfection process across various serotypes, including AAV1-9 & rh10, with productivities exceeding 1E+6 vector genome copies (GC) per cell. Scaling up production in 50 L and 200 L bioreactors using TESSA® achieves impressive yields of >7E+11 GC per mL of cell culture and >1E+17 GC of Drug Substances for rAAV6 and rAAV2. In contrast, the TESSA® Pro approach streamlines rAAV propagation by eliminating the need to encode the rAAV transfer genome within a second TESSA® vector. Co-infection with HEK293 cells using rAAV seed stocks and TESSA® RepCap enables >5,000-fold amplification of input rAAV materials, yielding up to 4E+11 - 2E+12 vector genome copies (GC) per mL of cell culture. TESSA® Pro proves particularly efficient for propagating AAV serotypes that exhibit high-transduction efficiency in HEK293 cells, including AAV2 and AAV6, enabling high rAAV productivity from a relatively low AAV vector input of 50-250 GC per cell. Critical observations indicate that the TESSA® Pro process exhibits high efficiency in rAAV genome packaging, generating up to 90% full capsids before purification. This process is presumed to expedite the replication and packaging of the single-stranded rAAV genome post-nuclear entry, bypassing the conventional requirement for rescuing the AAV ITR embedded within the double-stranded DNA structure associated with other rAAV manufacturing systems. To ensure the production of clinically viable rAAV gene therapy drugs

and facilitate product approval, the TESSA® technology integrates in-depth in-house testing capabilities, including biosafety assessments, viral clearance, and product release testing.

471. A Novel Dual-Isotope Labeling Method for Quantification of AAV Tissue Biodistribution and Cellular Internalization Following Systemic Injection

Hongzhi Wang, Ran Li, Shraddha S. Sadekar, Amrita Kamath, Ben-Quan Shen

Preclinical and Translational Pharmacokinetics and Pharmacodynamics (PTPK), Genentech Inc., South San Francisco, CA

Introduction: An understanding of the biodistribution profile of different components of Gene therapy products following in vivo administration is an important element of the nonclinical development program. Current biodistribution studies emphasize vector genome as the surrogate for PK analysis of AAVs. However, the AAV capsid as an essential component involved in cell binding, internalization, and trafficking within the targeted cell cannot be overlooked. Radioisotopes are ideal tracers with high sensitivity for in vivo imaging and have been applied to AAV capsid modification. Limitations remain as the tracer could not provide detailed distribution on tissue level. The quantification method falls short on distinguishing the AAV been transduced into the cell from the vectors remaining in extracellular matrix. Such limitations may lead to inaccurate PK/PD prediction.Methods/Results: We developed a dual isotope labeling strategy combining iodine-125 (non-residualizing) and indium-111 (residualizing) radionuclides to the capsid to obtain the information regarding both capsid distribution and cellular uptake of AAV vectors. Each capsid was covalently conjugated with around ten 125I or four 111In with high radiochemical purity (>98%). Size measurement by DLS and SEC-HPLC verified AAV capsid's structural integrity and physical property remain intact by the conjugation chemistry. In vitro studies demonstrated the isotope conjugation didn't alter the biological activity of the labeled AAV vectors. The labeling method has been successfully applied to most of wild type and engineered AAV capsids. Dual isotope labeled AAV9 and AAV-PHP.eB as tool molecules has been systematically injected to C57BL/6 mice, followed by tissue collection and counting 125I and 111In individually. Based on the mechanism, 125I represented the intact AAV vectors mainly located in extracellular matrix, while 111In reveal the location of both intact and dissociated AAV vectors in both interstitial spaces and cells. The difference of 125I and 111In radioactivity elucidated the cellular uptake of AAV vectors. From the results, AAV capsid biodistribution profile provided by 111In was consistent with previous reports. Similar tissue biodistribution patterns were observed in major organs, where both AAV serotypes showed accumulation at early time point in highly perfused organs such as liver and spleen, and AAV-PHP.eB exhibited a remarkable elevated brain penetration. Analyzing the cellular uptake result derived by 125I/111In together further reveal detail spatial distribution information in collected organs and tissues. While Liver and spleen have highest capsid accumulation (~40% at day 1), the internalized capsid is relatively low (~12% at day 1), indicating AAVs was mainly located in extracellular matrix of high perfused organs at early time point without entering into the cells. qPCR result also shown a better correlation with cellular uptake corrected result than with total capsid distribution. Conclusion: The dual-isotope labeling method not only trace capsid biodistribution but also provides valuable insights into AAV vector spatial distribution in the context of tissue microenvironments. The results demonstrated dual-isotope labeling method as an efficient tool to elucidate a complete AAV distribution profile, thus facilitating lead candidate selection, capsid optimization and providing guidance on the administration route selection and human dose prediction. Utilizing two SPECT isotopes, this labeling strategy holds promise for integration with SPECT/CT imaging, providing a noninvasive imaging method for preclinical pharmacokinetic studies.

472. Single-Nuclei RNA Sequencing Enables High Resolution Quantification of Transgene Expression in the CNS After AAV Delivery

Kyle Ford[1], Diogo Pessoa[1], Yian Khai Lau[1], Brian Fochtman[1], Zoe Zhaostein[1], Mei Zhu[1], Jessica Willen[1], Zikun Wang[1], Ellen P. S. C. Furber[2], Audrey Lee-Gosselin[2], Fares Bassil[2], Tao Yang[1], Edmund C. Schwartz[1], Ben Shykind[1], Anindya Sen[1], Mansuo Shannon[1], Sitharthan Kamalakaran[1]

[1]Prevail Therapeutics, New York, NY,[2]Prevail Therapeutics, Indianapolis, IN

Efficient delivery of genetic cargo to disease relevant cell types is a ubiquitous challenge in gene therapy. Adeno-associated virus vectors (AAVs) have been used to deliver therapeutic cargos to the central nervous system (CNS), but their efficacy is often limited by poor biodistribution or expression in the target cell types. Consequently, there is a pressing need for methods which can quantify AAV transgene expression with cell-type level resolution. Here, we developed a single nuclei RNA-seq (snRNA-seq) methodology for tracking AAV tropism *in vivo.* We isolated nuclei and generated single nuclei transcriptomes using commercially available reagents, enabling flexible processing of flash-frozen tissue samples. To improve transgene detection, we developed a custom transgene amplification protocol. By amplifying the transgene from the 10x cDNA pool, we can detect orders of magnitude more transgene molecules compared to the unamplified control. We modified the standard bioinformatics pipeline to address unique challenges in AAV transgene quantification. Our pipeline retains high quality nuclei by adopting strict quality filtering measures and doublet removal. To avoid bias due to RNA content difference between cell types, we chose to normalize the transgene expression using a set of stably expressed genes across cell types. We also estimated the noise level due to the ambient RNA and adaptively remove background in a cell type-specific manner. Comparing to standard sequencing and analysis protocols, our in-house methodology demonstrated higher sensitivity and allowed more confident quantification of transgene expression rates across cell types and treatment groups, enabling stratification of capsids/promoters by neural specificity. We then used this methodology to profile transgene expression in the mouse CNS, post injection of various serotypes/promoters via intracerebroventricular (ICV), intravenous (IV), or intracisterna magna (ICM) route of administration. By generating 100,966 single-nuclei transcriptomes, our data showed that ICV delivered AAV9 transduced various cell types in the mouse brain, including neurons, microglia, astrocytes, and oligodendrocytes, while an IV delivered engineered capsid transduced various cell types in the spine cord. All

tested promoters drive robust expression in neurons. Expanding the snRNA-seq methodology to non-human primate, we profiled 4,709 nuclei after ICM delivery of AAV9, quantifying the transduction and expression for various cell types in the spinal cord. We compared the differences in cell-type abundances between NHP and mice, showing a reduced neuron/non-neuron ratio in the NHP spinal cord. In conclusion, we established an efficient single-nuclei RNA sequencing method and collected initial mouse and NHP datasets in the CNS post AAV administration. Looking ahead, we are exploring methods to improve capture of rare cell types and to quantify genome editing with cell-type level resolution. We anticipate cell-type resolved assays will be key to evaluating novel capsids, promoters, and regulatory elements for next generation AAV therapies.

473. Optimization of AAV Production Using New Statistical Design of Experiment: Space Filling Designs

Nida Sayed-Zubairy

Boston Institute of Biotechnology, LLC, Southborough, MA

Applications of adeno-associated virus (AAV) in gene therapy has increased significantly over the past two decades due to its remarkable safety profiles and efficiency of gene delivery into various tissues. Demand for the supply of recombinant AAV vectors has also increased to fulfill pre-clinical and clinical needs. Low titer and process scalability remain two key issues in AAV manufacturing. Productivity of AAV vectors is often affected by the AAV serotype, cell culture type, the size of Gene of Interest (GOI), cell density, transfection method, plasmid DNA concentration/ratio and other factors. Based on risk assessment of factors that may impact AAV production, we have evaluated process parameters using a 24-run Space Filling Design generated by the JMP Statistical Software. Space-Filling Designs (SFDs) are a class of experimental designs created with the objective of covering the entire design space as completely as possible; this in turn allows more accurate modelling of complex response surface behavior typically found in bioprocesses. SFDs are very flexible in structure, do not require any prior assumptions about response surface shape and typically require fewer runs for larger numbers of factors than the commonly used response surface designs. The commonly used classical and optimal response surface designs primarily distribute the design points near the boundary of the experimental region such that little or no data is collected in the interior. As a result, the experimenters have no direct knowledge of the kinetic behavior inside the design region. Without data describing the interior kinetic behavior it is not possible to build accurate response surface models. In this study, we will describe the value of SFDs and how to establish critical process parameters (CPP) and operating ranges for optimum and robust AAV production in suspended HEK293 cells in Ambr® 15 Microbioreactor System.

474. Comparison of Common Methods for Cell Transfection and rAAV2 Purification with Commercially Available Options

Mariana Santana Dias, Gabriela S. Almeida, Rafael F. Azevedo, Hilda Petrs-Silva

Federal University of Rio de Janeiro, Rio de Janeiro, Brazil

Adeno-associated viral vectors have emerged as a powerful tool for human gene therapy. Nowadays, they represent the most common viral vectors for in vivo gene therapy applications. They are safe, with low toxicity and immunogenicity, and promote stable expression with high transduction efficiency for several tissues, especially due to its diversity of serotypes. Since the first cloning of the AAV genome, the production process of rAAV vectors has been developed and optimized over time. However, it is still laborious, costly, and vector titers need to be improved, especially for clinical applications. Apart from traditional, firstly applied, methods of cell transfection and vector purification for rAAV production, nowadays there are several commercially available options that require less laboratory apparatus. In the process of establishing bench-scale rAAV production in our laboratory in Brazil, we have compared two different methods of cell transfection and three methods of vector purification. Transfection was examined with calcium phosphate and a commercially available transfection kit for rAAV production (Gibco #A51217), which has been adapted from cell suspension to a cell factory. Furthermore, we compared purification with iodixanol gradient followed by anion exchange FPLC with commercial kits (Takara #6232 and Norgen #63250), using calcium phosphate as the transfection method. Each rAAV2 production was carried out in a 4-layers cell factory. Results indicated a higher transfection efficiency of the calcium phosphate method (with the transduced area of 27.5 %) as compared to the commercial option (8.0 % of transduced area) at 24 hours after transfection, which led to higher rAAV titers after a similar purification method and analysis by qPCR (5.97E+07 vs. 2.52E+06 vg/mL). When comparing purification strategies, Norgen kit (2.96E+08 vg/mL) reached the highest particle titer by qPRC analysis, followed by iodixanol gradient + FPLC (5.97E+07 vg/mL) and then the other commercial kit, by Takara (1.26E+07 vg/mL). Overall, among all tested methods, transfection with calcium phosphate and rAAV purification with Norgen kit or iodixanol gradient + FPLC provided higher rAAV2 titers, indicating that the classical non-commercial is still very efficient for rAAV production when compared to expensive commercially available options.

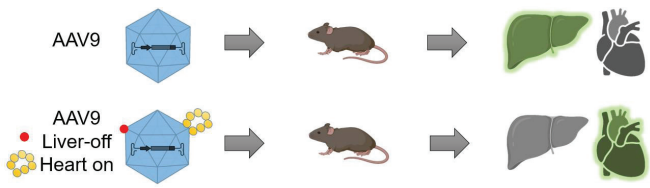
475. Targeting Gene Activation to Specific Cell Populations Using Convolutional Neural Networks

Michael Leone[1], BaDoi Phan[1], Jing He[2], William R. Stauffer[2], Leah C. Byrne[3], Rebecca P. Seal[2], Andreas Robert Pfenning[1]

[1]Computational Biology, Carnegie Mellon University, Pittsburgh, PA,[2]Neurobiology Department, University of Pittsburgh Medical Center, Pittsburgh, PA,[3]University of Pittsburgh, Pittsburgh, PA

Gene therapies have the potential to transform healthcare, but are often hampered by a lack of specificity. These limitations are especially problematic in the central nervous system, where even a single tissue

can be composed of dozens of distinct neuron subtypes with different functions. Although systematic screening of candidate cell type-specific enhancers has yielded useful tools, the low success rate and time consuming nature of the experiments prevents these techniques from being applied more broadly. To improve the specificity of gene activation to a population of interest, we have developed the SNAIL approach (specific nuclear-anchored independent labeling). SNAIL uses an ensemble of convolutional neural networks trained on open chromatin data to prioritize the cell type-specificity of candidate enhancers. We have applied our approach to successfully label a variety of rare or subtle neuron subtypes in the cortex, the striatum, and spinal cord in a combination of rodent and non-human primate experiments. In parallel to the development of computational approaches, we paired massively parallel reporter assays with AAVs to measure the specificity of hundreds of enhancers in vivo in a single experiment. As a proof of concept, we have applied SNAIL to attenuate features of chronic pain without influencing baseline responses to touch.



Wednesday Posters: AAV Vectors - Capsid Engineering

476. Liver-Off and Heart-On Tropism with Engineered AAV9 Capsid

Huachun Liu[1,2], Reynette Estelien[1], Julio Sanmiguel[1], Kevin Bersell[3,4,5], Hiroko Wakimoto[4], Christine Seidman[4,5,6], Nerea Zabaleta[1,2]

[1]Schepens Eye Research Institute, Mass Eye & Ear, Boston, MA,[2]Department of Ophthalmology, Harvard Medical School, Boston, MA,[3]Department of Medicine, Brigham and Women's Hospital, Boston, MA,[4]Department of Genetics, Harvard Medical School, Boston, MA,[5]Cardiovascular Division, Brigham and Women's Hospital, Boston, MA,[6]Howard Hughes Medical Institute, Chevy Chase, MD

Adeno-associated viruses (AAVs) are indispensable in gene therapy, providing a safe and precise means to deliver therapeutic genes and treat a variety of genetic disorders. However, when used for heart gene therapy, natural serotype AAV9 has limited effectiveness in transducing cardiac tissues and exhibits substantial off-target transduction in the liver, which would introduce potential liver toxicity during AAV9-based gene therapy. Thus, generating a cardiac tissue-specific variant serotype would tremendously boost the efficiency and safety of AAV9-mediated heart repair. To address this challenge, we engineered the AAV9 capsid by integrating a lab-developed liver-off mutant (GGSS to GAST at VP1 from 266 to 269) with muscle-targeting peptides (MyoAAV4E and 2A) developed by another group. In the variable region VIII of AAV9, the MyoAAV4E and 2A peptides, which include RGD domains, are specifically inserted to improve muscle targeting, with 2A developed in mice and 4E in non-human primates. When delivered systemically, our GAST+2A and GAST+4E variants significantly reduce liver transduction by 0.14- and 0.04-fold, increasing heart-targeting efficiency by 49- and 61-fold at transgene mRNA expression level, respectively. The modified capsid holds great promise for heart gene therapy, allowing for significantly reduced dosage and alleviating liver toxicity.

477. Approaches for Developing an AAV Gene Therapy Candidate: A Hemophilia A Case Study

Hui Wang

Genevoyager, Philadelphia, PA

Currently, commercially available AAV products can cost millions of dollars per patient. Due to high prices and limited production capabilities, only a few hundred patients can receive treatments each year, leaving a considerable number without access to medication. In the pursuit of developing safe, effective, affordable, and accessible AAV gene therapies, Genevoyager offers one-stop services for gene therapy product development. Using Hemophilia A (HA) as a case study, we highlight various approaches: 1) Optimization of liver-specific promoter: We engineered a liver-specific promoter, ATH2, demonstrating higher FVIII activity *in vitro* as compared to traditional HLP promoters (approximately 1.2 and 2.2-fold increase in HepG2 and HUH7). In mouse studies, the hFVIII expressed under ATH2 promoter exhibited approximately 9-fold and 2.5-fold increase at 2 weeks, while displaying approximately 1.7-fold and 1.3-fold increase at 10 weeks, as compared to HLP and TTRm promoters, respectively. 2) FVIII gene modification for improved secretion and activity: We inserted an additional segment between the A2 and A3 domains, resulting in a 2 to 3-fold increase in FVIII secretion and activity levels *in vivo*. 3) Capsid engineering for enhanced yield: We mutated key sites of the AAV capsid, leading to a 2 to 3-fold increase in yield. 4) Optimization of production system: We utilized our proprietary Bac/Sf9 system for AAV production. In comparison to the traditional Sf9 system, there is a significant 4 to 30-fold increase in yield and 2 to 5-fold increase in FVIII activity. By leveraging the exclusive liver-specific promoter, optimized processes, and the innovative Bac/Sf9 system, Genevoyager introduces comprehensive approaches for developing a promising and affordable gene therapy product for Hemophilia A. These highlights also demonstrate our capability to provide one-stop services for the development of gene therapy products.

478. Engineered Enhancer Bolsters AAV Tropism to the Heart

Lauren E. Switala[1], Lin Di[1], Daria Fedyukina[2], Andrei Maiseyeu[1]

[1]Case Western Reserve University, Cleveland, OH,[2]BioHeights, Cleveland, OH

Several adeno-associated viral (AAV) vector strategies for cardiac muscle targeting have been developed to enable disease-modifying treatments for heart failure and genetic cardiomyopathies. However, significant off-target accumulation of intravenously (i.v.)-delivered AAV has led to the high effective dose requirement even for novel cardiac-specific AAV serotypes. We engineered cargo-less polymeric

nanoparticles that drastically improve heart delivery of AAVs when administered prior to AAV i.v. injection. Our lead formulation (referred to as ePL, enhancer polymer) increases selectivity of AAVs to the heart and de-targets them from the liver. Serotypes known to have high (AAVrh.74) and low (AAV1) heart tissue tropisms were tested with and without ePL. We demonstrated up to an order of magnitude increase in heart-to-liver accumulation ratios in ePL-injected C57BL/6 mice. Key advantages of ePL include its excellent safety profile and complementarity to serotype engineering strategies. ePL does not need to be co-formulated with an AAV product, thus simplifying IND CMC requirements. Our study introduces an exciting possibility to direct a variety of AAV vectors to the heart at significantly reduced i.v. doses.

479. Novel Engineered Cardiac-Specific AAV Vectors via Directed Molecular-Evolution in Human-Relevant Model Systems Outperform Current Benchmark Vectors for Clinical Cardiac Gene Therapy

Gregor Habeck[1], Joerg Schweiggert[1], Michael Smuglov[1], Johanna Ferdinand[1], Dorothea Kehr[1], Kristin Cimen[1], Xenia Kramp[1], Hugo A. Katus[1], Marc Johannes Lerchenmueller[1], Matthias Mietsch[2], Lena Erffmeier[2], Rabea Hinkel[2], Patrick Most[1], Martin Busch[1]

[1]AaviGen GmbH, Heidelberg, Germany,[2]German Primate Center, Goettingen, Germany

Introduction and Objective: Recombinant adeno-associated viral (rAAV) vectors currently used in gene therapy (GT) clinical trials for hereditary and acquired heart failure (HF) have a high potential for clinical toxicity due to a lack of cardiac transduction specificity. For example, despite numerous cases of fatal liver failure by rAAV9-based gene therapy medicinal products (GTMPs) in patients due to the predominant hepatic tropism of rAAV9, the capsid continues to be a vector of choice due to its high in vivo myocardial transduction efficiency. Against this background, we have developed an integrative experimental-bioinformatic next-generation Cardiac AAV Platform (next-CAP) to engineer synthetic rAAV capsids that meet the clinical demand of high-performant in vivo cardiac transduction specificity as a foundation for safe and precise cardiac GTMPs against various HF forms. *Approach and Results:* Feeding novel mammalian heart-derived AAV capsid sequences into a genetically-engineering platform that leverages DNA-shuffling and peptide-display methodologies, we generated a highly diverse AAV capsid library with over 200 million variants. This library was subjected to an iterative cross-species in vivo evolution procedure by intravenous injections in mice, farm pigs and non-human primates (NHP) to identify synthetic AAV capsids with optimal in vivo cardiac transduction specificity and efficacy. In order to ensure reliable AAV capsid identification, we employed unique molecular identifier to combine long- and short-read sequencing of AAV genomes to ultimately select a top-100 cardiac-enriched AAV capsid portfolio against a variety of clinically relevant off-target organs, including the liver, central and peripheral nervous system or organs of the immune system (n=3 individual library injections in mice, pigs and NHPs). Subsequent co-injection of this top-100 vector portfolio in mice, pigs and NHPs (n=3 each) with current clinical and pre-clinical vector benchmarks for cardiac GT (e.g., rAAV9, rAAV2i8, rAAVrh74, rAAV2-THGTPAD and myo-AAV) yielded a top-10 portfolio of novel heart-specific AAV capsids that outperformed these benchmarks in terms of tissue-specificity in the human-relevant farm pig and NHP model systems. Our novel cardiac-specific AAV capsids displayed a homogeneous distribution pattern of the left and right ventricle of pigs and NHPs with an up to 20-fold higher heart/liver vector genome copy (vgc) ratio compared to all benchmarks as well as optimal de-targeting of other clinically relevant tissues, such as dorsal root ganglions, brain or spleen in NHPs. In addition to the clinically desirable on- and off-target biodistribution profile, our technical workflow concurrently enriched HEK293 cell high-titer producing cardiac-specific rAAV capsids to eventually enable scalable large-batch manufacturing to meet the demand for rare and common cardiac diseases alike. *Conclusion:* Our versatile next-CAP pipeline enabled the development of novel synthetic cardiac-specific rAAV capsids characterized by a high-performant transduction specificity and efficacy of human-sized pig and NHP hearts, respectively, that clearly outperformed available AAV benchmark vectors yet proposed for cardiac GT. In light of their inherent good producibility, our vector portfolio puts us into the ideal position to effectively assess the best therapeutic hear-specific rAAV-promoter/target systems for subsequent assessment of dose-expression, -efficacy, and -toxicity relationships to move our therapeutic HF GTMP pipeline towards clinical trials.

480. Engineered Cardioskeletal-Directed AAV Capsids That Detarget the Liver

Widler Casy[1], Tiffany Willacy[2], Jen Gifford[2], Jenny Marlowe[1], Cockrell Adam[1]

[1]R&D, Solid Biosciences, Charlestown, MA,[2]Solid Biosciences, Charlestown, MA

Gene therapy remains a promising therapeutic path for treating various monogenic diseases. Currently, AAV-mediated therapeutic treatments for musculoskeletal and cardiac indications require high doses to transduce the large quantities of affected muscle and to achieve widespread therapeutic benefit. However, the use of large vector doses has been associated with liver damage, acute liver failure and even death, as reported in some clinical trials. AAV capsid engineering, aimed at detargeting the liver, offers a solution to address these issues by developing more precise and efficacious vectors. Numerous strategies exist to engineer novel AAV capsids, and our group is continuing to employ an iterative rational design approach, using naturally occurring capsids. Previously, we described these engineered capsids as capable of targeting cardiac and musculoskeletal tissues. Among them, AAV-SLB101 has a 2-4x increase in muscle transduction and ~0.5x decrease in liver tropism in comparison to AAV9 in mice, both DMDmdx and wild type, and non-human primates. This capsid is being used in Solid Biosciences' SGT-003 program for the treatment of DMD that recently had an IND cleared by the US FDA. When designing newly engineered capsids, we followed a stepwise approach to globally detarget tissues, including the brain, liver, and other peripheral organs, while introducing cardiac and musculoskeletal tissue targeting modifications to the AAV capsids. The newly engineered capsids underwent assessment for production, transgene delivery efficiency, and efficacy in vitro and in vivo. Quantitative evaluation included assays for in vivo imaging, protein expression, and vector copy number. Through the combination of liver detargeting and muscle targeting

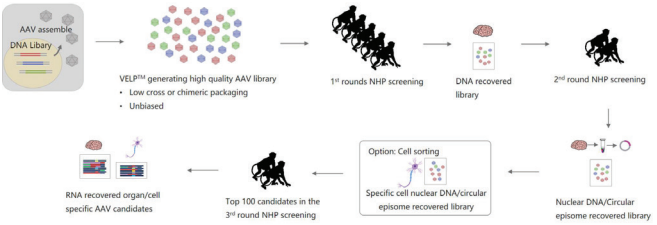
modifications in wild type capsids the resulting capsids maintained or improved cardiac and musculoskeletal transduction while detargeting the liver. These precisely engineered capsids could lead to gene therapy vectors with high efficiency, efficacy, and safety profiles for treating cardiac and musculoskeletal indications, which require a systemic delivery approach.

481. Novel AAV Capsids with Favorable Pre-Existing Immunity, Biodistribution, and *In Vivo* Potency

Silvia Ramirez, Justin Ishida, Darlene Chen, Kahsay Gebretsadik, Vincent Leonard, Hassibullah Akeefe, Peter Colosi, Sripriya Ravindra Kumar, Pooja Agarwal
BioMarin Pharmaceutical Inc, San Rafael, CA

Adeno-associated viral (AAV) vectors have emerged as effective delivery vectors for gene therapy applications. However, pre-existing immunity and off-target tissue uptake and resulting dose-limiting toxicities including dorsal root ganglia (DRG) and liver toxicity remain critical challenges. According to epidemiological analyses, between 40%-80% of the human population is seropositive for antibodies against common AAV serotypes leading to potential patient exclusion from AAV clinical trials and limiting the number of patients that can potentially benefit from these therapies (Wang et al, 2019). There is also significant interest in identifying capsids with superior in vivo potency, as evidenced by enriched RNA/protein- to-DNA profiles or cell type selectivity (Kondratov et al, 2021). In an effort to find novel AAV capsids with low pre-existing immunity, favorable biodistribution, and strong in vivo potency, we have invested in AAV capsid discovery and engineering efforts and generated a large library of proprietary natural and engineered AAV capsids. Systematic characterization of these capsids for safety, biodistribution, potency, and manufacturability is being evaluated, but early studies reported here have identified several novel capsid clades with favorable pre-existing immunity and distinct tissue tropism profiles. Pre-existing immunity screening was conducted using a pooled human immunoglobulin G (IgG) neutralization assay and identified several novel capsids with up to a 10-fold reduction in pre-existing immunity relative to benchmark capsids with clinical precedence. To determine the in vivo biodistribution of these novel capsids following intravenous (IV) administration, single capsid chemiluminescent screens were conducted in rodents. Interestingly, distinct clade-specific profiles were observed, with some capsids selectively enriched in the liver while others showing liver-detargeting and cardiac or skeletal muscle tropism. Translatability of this biodistribution in larger mammals was explored for a subset of clades through a 9-capsid multiplexed barcoded rAAV distribution study in cynomolgus macaques. Next generation sequencing (NGS) based DNA and RNA barcode analysis of 20+ tissues, collected six-weeks post IV administration, was conducted to inform transduction and transcription profiles of each capsid. This multiplex analysis identified several key differences in biodistribution as well as RNA/DNA profiles across different tissues, suggesting that the capsid's influence may extend beyond delivery, as predicted, to additionally impact potency and/or durability. Follow-up analysis of the same multiplex in rodents yielded similar trends, demonstrating translatability across species. Notably, the NHP multiplex study identified a novel capsid clade with preferential targeting of the heart muscle (38% relative barcode enrichment in the ventricles) and significant liver detargeting (0.6% barcode enrichment). These results were also confirmed in a single capsid NHP study and additional characterization of this novel clade is ongoing. In summary, we report here the identification of novel clades of natural and engineered AAV capsids with low pre-existing immunity and desirable tissue distribution profiles, warranting further investigation of their suitability for gene therapy applications. Manufacturability, stability, and potency evaluation in relevant healthy and disease models has been initiated and will be reported in future meetings.

482. AAV DNA Shuffle Library of GH Loop Variable Regions for Directed Evolution of Cardiotropic Capsids



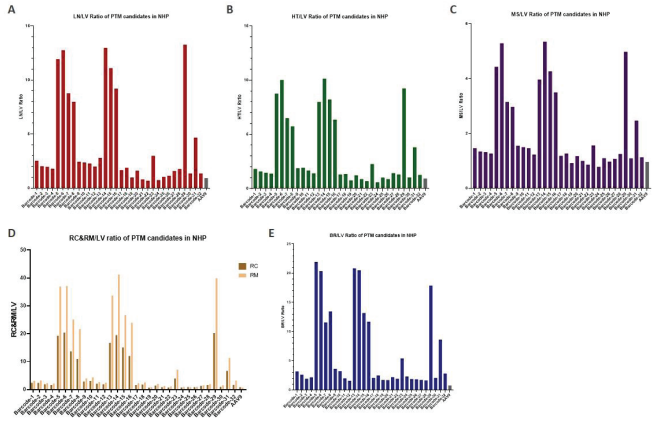
Prasad R. Konkalmatt, Reva Shenwai, Kathy Ivey
Tenaya Therapeutics, South San Francisco, CA

Gene therapies targeting cardiomyocytes (CMs) for treating disorders such as genetic cardiomyopathies require a relatively high vector dose when treated systemically to achieve broad distribution across nearly 100% of the CMs. While AAV9 serotype offers effective transduction of CMs at systemic doses ≥ 3E13 vg/kg body weight, lowering doses may reduce the potential for off-target toxicities and decrease the cost of goods. Therefore, the development of novel AAV capsids with improved tropism to CMs is critical to enable the next generation of therapeutically relevant cardiac gene expression at lower doses with the potential for use in more prevalent forms of heart disease. Strategies involving directed evolution of Adeno-associated virus (AAV) capsid libraries created by random DNA shuffle or rational design to modify receptor binding sites have been employed with limited success. As an alternative approach, we have developed a novel AAV capsid library, the GHVR shuffle library, by randomly shuffling the five variable regions (VRs; VR-IV to -VIII) located between the G and H beta sheets of the capsid protein from the 16 natural AAV serotypes on the AAV9 capsid backbone. We targeted the GH loop since it is present on the exterior of the AAV particle and play a key role in the receptor binding and internalization of the AAV virus particle, and thus drive tropism. This strategy allows us to evaluate a genetically diverse molecular space that is known to determine infectivity, while still limiting the theoretical capsid pool to a manageable size of 1.05E6 capsid variants. To our knowledge, this is the first example of this approach being used for identification of novel capsids with improved tropism for a specific organ or tissue. Using a CM-specific promoter to drive expression following systemic administration, we employed RNA-based recovery of the CM-tropic variants, as determined by next-generation sequencing. The GHVR library was subjected to two rounds of screening, first in mice and then in non-human primates (NHPs), which identified shuffled variants with CM tropism in both species. After the second round of screening in the NHPs the size of the capsids recovered from hearts was reduced to a total of 1.3E4 variants, enriched with the AAV13 at position VR-IV; bat AAV at VR-V; AAV5 at VR-VI; AAV11 at VR-VII; and AAV9 at VR-VIII. Our data indicate tolerance of capsid assembly to VR sequences from the other serotypes at their respective positions in the AAV9 capsid backbone and reveal patterns of VR sequence enrichment from non-AAV9 capsids. Further analysis of these enriched variants is expected to reveal chimeric AAV capsids that can offer enhanced transduction to CMs compared to AAV9.

483. VELP™: An Efficient AAV Capsid Evolution Platform Based on Novel Viral Library Production Strategy

Lei Zhao, Tongxin Liu, Fengkuan Shi, Xingrong Luo
Cure Genetics, SuZhou, China

Introduction: Adeno-associated virus (AAV) is one of the best viral-delivery cargo in many gene therapies because of the different organ/tissue tropism for each wtAAV. However, the specificity of organ/cell targeting efficiency is still required as an ideal delivery vector to reduce the dose-dependent toxicity. Thus, novel AAV serotypes with specific organ/cell tropism plays important roles in development of innovated gene therapies. Directed evolution is a normal way to generate the organ-directed property. However, extensive problems would be existed in directed evolution which are 1) bias, chimeric and cross-package of viral particle library, especially in RNA recovery strategies which requires high amount of library DNA in recombinant AAV packaging; 2) false positive data by DNA recovery strategy which does not correlated to GOI expression; 3) limited RNA recovered data due to the low efficient of tissue specific promoters. Those problems may cause the loss of the valuable candidate since non-significant predominant sequences and the poor population of recovered data for validation. Therefore, we used VELP (Vector Evolution by Library Production) platform to generate unbiased plasmid library and minimize the cross-package in the initial round of selection by reduce and balanced MOI of ITR-Rep-Cap-ITR plasmid during the packaging of natural AAV library. Our plasmid library was then packaged by HEK293T cell with optimized process to generate high transduction activity library. Then we recovered nuclear DNA/circular episomal DNA in the 1st round. The compact and organ specific AAV library will be generated after 1st round followed by the routine RNA recovery strategy for 1-2 rounds selections. Our high qualified AAV starting library with well-established data recovery strategy can generate more reliable candidates with organ/cell-specific tropism, which could be the ideal capsid in the further trials of gene therapies. Results and Discussion: The low redundancy of VELP library was test by NGS after 1st round NHP screening. In liver for instance, our NGS data showed that 7-mer peptide insertion library is 85.6%-91.3%, imply that only a small part of redundant sequences in the library including the other length of peptide insertion (6, 8, 9-mer and any other length of inserted peptide). Moreover, in the 7-mer peptide insertion library, the data without stop-codon is 99.93%-99.96%. The transduction activity after selection of VELP library was monitored by in vitro HEK293T cell assay. The VELP library was generated from 107 random AAV capsid plasmids resulting 19 viral sequences while the conventional packaging generated 88 viral sequences. After VELP packaging, almost all viral sequence represented high transduction activity but very low activity by conventional packaging. The DNA data recovered from cell nuclei are more accurate than the information from tissue DNA while are also larger amount of data recovery than RNA recovered data. This strategy can be good back-up for RNA recovery strategy. Based on our approach, the heart, kidney and muscle targeted screening had been generated in NHPs. Conclusion: The VELP platform generates non-redundant, low cross packaged and high transduction efficiency AAV starting libraries and recovered different information within particular screening cycle. The unique nuclear DNA/circular episomal DNA recovery in VELP platform generate a backup before RNA recovery which might loss lots of candidates. This strategy significantly increases the amount of reliable organ/cell-specific sequences.



484. Studies of Biodistibution Regulated by the Combinations of Glycosylation Profile on AAV9

Lei Zhao, Tongxin Liu
Cure Genetics, SuZhou, China

Introduction: Adeno-associated virus (AAV) is one of the best viral vector in gene therapy. However, several biological properties such as post-translational modifications (PTMs) of particular AAV serotype still remains unknown. Glycosylation is one the most important PTMs during the protein expression in eukaryotic cell lines. Different cell line such as mammalian HEK293 and insect Sf9, represent different glycan-profiles. For instance, HEK293 cells, which confer mostly complex- and high-mannose-type glycans, while Sf9 cells, which impart mainly paucimannose-type glycans. The different glycans may induce different immunogenicity and biodistributions of protein or assembled nanoparticle. Although previous studies have identified glycosylation site on most of wild-type serotypes (AAV2-AAVrh10) by LC/MS, it is still lack of study of structure-function relationship. Here, we selected 5 N-glycosylation sites (253, 462, 497, 552, 706, based on AAV9 VP1 numbering) and designed the full combination of those site with/without N-glycans based on AAV9 according to the most frequency of detected in AAV2-AAVrh10. The titer during AAV packaging and the biodistribution in vivo (rat and NHP) have been studied based on qPCR and NGS-barcode technology. Some particular site of N-glycans or combinations play important role in AAV production and liver de-targeting. Results and Discussion: The 32 combinations of 5 N-glycosylation sites have been introduced to AAV9. After triple-plasmid packaging by HEK293T cell, the titers were monitored by qPCR. As showed in Fig. A-E, the barcode-1-16 represents comparable titer with wtAAV9 while barcode 17-32 showed significant reduced titer. The different between the two groups is barcode 1-16 have N253 glycosylated motif but barcode 17-32 carried Q253 non-glycosylated amino acid. This result indicated that the N-glycosylation site 253 originally from AAV2 also effect the titer in AAV9. The biodistribution studies of the 32 variants were then preformed in rat and NHP. Barcode 1-16 behaved strong liver de-targeting effect in rat while only barcode 5-8 and 13-16 represented strong liver de-targeting effect in NHP. Interestingly, barcode 5-8 and 13-16 have very high non-liver/liver ratio in NHP indicating that those N-glycan combinations strongly reduce the liver accumulation by particular pattern of PTMs. This potential liver de-targeting property could help the design of AAV capsid engineering to reduce the liver toxicity in systematic administration of AAV vector. Conclusions: Glycosylation might play an important role in AAV capsid potency by

effecting the productivity and biodistribution. Our work generated the full combinations of 5 N-glycosylation sites which reported before to study the biodistribution. To balance the titer and liver de-targeting properties, we find a motif with NXQXX (based on 5 N-glycosylation sites 253, 462, 497, 552, 706) are potentially reduce the liver target effect which might be used in combine with other novel AAV serotypes.

485. Extending ML Toolbox for AAV Design: AAV-RoBERTa

Oleksandr Kondratov[1], Arunava Banerjee[2], Sergei Zolotukhin[1]

[1]College of Medicine, Pediatrics, University of Florida, Gainesville, FL,[2]Department of Computer & Information Science & Engineering, University of Florida, Gainesville, FL

Multiple machine learning approaches have been extensively explored in recent years to predict AAV library fitness: feedforward artificial neural networks (ANN), convolutional neural networks (CNN), variational autoencoders (VAE), recurrent neural networks (RNN) etc. The most remarkable characteristic of the aforementioned models is their original purpose - analysis of plain data, images or video, respectively. Therefore, adapting AAV sequence to these models required techniques such as one-hot encoding and sometimes extra null dimensions to match dedicated data dimensionality of each model. At the same time, AAV shell protein sequences represent a set of amino acid strings with nonlinear interactions arising from complex structural organization. Such protein organization of AAV has conceptual similarities with human languages, presenting an opportunity to leverage robust natural language processing (NLP) approaches. Recent advances in language-to-language translation in the domain of NLP have been based on deep feed forward networks incorporating attention nodes. These networks, known as transformers, have demonstrated great improvements in accuracy. By abandoning the serial sequence to sequence approach as well as the recurrent network, not only does the transformer circumvent the vanishing gradient problem, but it can also learn from orders of magnitude more data due to its inherent parallelism. Possibility to feed to the model plain sequences (text) makes it friendly to users with biological background. In our initial exploration, we compared packaging prediction efficiency of already published feedforward ANN, modified CNN and NLP based approach on the same raw AAV2 mutant dataset. As an NLP model we selected Robustly Optimized BERT Pre-training Approach (RoBERTa) trained from scratch (AAV-RoBERTa) with subsequent fine-tuning on packager/non-packager dataset. As anticipated, the NLP approach showed its superiority over simpler models in accuracy. Further, we generated NGS datasets for five distinct AAV libraries representing four different serotypes with approximately 400M packaged variants. This dataset was used to train a multiserotype version of RoBERTa (aka XLM-AAV). We tested XLM-AAV vs single AAV-RoBERTa models in their perplexity, prediction accuracy and potential of sequence representation. All models demonstrated size dependence in perplexity improvement but for XLM-AAV model this effect was more pronounced.Our future research is directed on investigation of AAV structural relations captured by XLM-AAV and its usage for acceleration of directed evolution.

486. Efficient Transduction of Nasal Epithelial Cells Achieved through the Intranasal Administration of a Newly Developed Adeno-Associated Virus, AAV-GC09

Cenfeng Chu

OBiO Technology (Shanghai) Corp., Ltd., Shanghai, China

Rhinologic diseases pose a significant health concern, leading to systemic symptoms that impact mood, cognition, and sleep. Among these, atopic rhinitis (AR) stands out as one of the most prevalent disorders, affecting 10-20% of the global population. Unfortunately, effective treatments for AR remain elusive. The adeno-associated virus (AAV) has emerged as a highly efficient gene delivery tool, holding therapeutic promise for common diseases like AR. In the realm of respiratory diseases, intranasal administration is a widely adopted drug delivery method. This study devised a 7-peptide insertion AAV library, based on the natural serotype AAV1 at amino acid sites 590-591. Mice were infected through intranasal administration, and multiple *in vivo* screening rounds were conducted. Through sequencing data validation, a novel AAV vector, AAV-GC09, emerged as the top candidate, efficiently infecting nasal epithelial cells. Importantly, intranasal administration in mice demonstrated the vector's specificity and safety by not infecting lung cells. In the clinical landscape, monoclonal antibody AR drugs targeting critical pathways, such as the interleukin-4 receptor alpha antibody, are currently undergoing clinical testing. Leveraging the AAV delivery tool holds the potential for sustained antibody expression, significantly enhancing the overall patient experience. Our findings underscore the substantial potential of AAV-GC09 as a vector for rhinologic gene therapy, offering a promising avenue for addressing the challenges associated with atopic rhinitis and other rhinologic conditions.

487. A Comparative Analysis of Engineered Liver Tropic Capsids Across Different Species: Towards Cross-Species Translation

Joy Wang, Shiliang Hu, June Deng, Yinxing Chen, Nannan Jia, Kirsten Lapoint, Neil Huang, Gregory Preston, Jay Wang, Nupur Kale, Noel Walsh, Lauren M. Drouin, Matthew Chiocco, Matthias Hebben, Mariana Nacht, Jing Liao

Alexion Genomic Medicine, AstraZeneca Rare Disease, Lexington, MA

Rapid advancements in genomic medicine, particularly in viral vector-based delivery systems, underscore the necessity for AAV capsids suitable for translation from rodent models to humans. Therefore, there is a high need for a robust platform to assess the tropism and potency of engineered capsids. In our study, we focused on liver-tropic capsids and conducted a comprehensive analysis across diverse models, including *ex-vivo* primary human hepatocytes, *in vivo* wild-type (WT) mice, different liver humanized mouse models, and non-human primates (NHP), to evaluate the transduction efficiency of different liver-specific capsids designed for genomic medicine applications. In primary human hepatocytes, WT mice, and humanized mouse models, we employed reporter genes GFP and human FIX to evaluate transduction efficiency in different models. Droplet digital PCR measured GFP RNA expression levels, GFP protein was quantified by IHC staining, and ELISA was used to measure human FIX protein levels. In the NHP study, we barcoded different capsids and validated transgene RNA levels quantified by next-generation sequencing (NGS). Consistent results were observed for capsid ranking in two different liver humanized mouse models, FRG and PXB mice, aligning with the outcomes in human primary hepatocytes. Notably, the top capsid from human models also demonstrated excellent transduction efficiency in the WT mouse liver, suggesting its potential use in preclinical, primate, and human studies. Importantly, the lead capsid identified in the WT mouse study, humanized mice, and primary human hepatocytes remained the top performer in the NHP study, the most relevant model to humans for liver-tropic capsids. The results of this comparative analysis not only deepen our understanding of capsid behavior but also lay the groundwork for a standardized screening platform for capsids, streamlining preclinical testing across diverse species. The identification of a common capsid with tropism and transduction capabilities across various species represents a significant advance in the field of genomic medicine.

488. A Rationally Designed AAV Capsid Variant of sL65 Can Achieve Efficient Cross-Species Liver Transduction

sL65 is the first human liver tropic AAV capsid developed using LogicBio's sAAVy platform. sL65 is a synthetic capsid through DNA shuffling of cap proteins from 12 natural serotypes, demonstrating superior non-human primate (NHP) liver tropism compared to well-known liver tropic capsids like AAV8 and LK03. However, sL65 exhibits lower mouse liver tropism than AAV8. We addressed this by engineering sL65 to ensure consistent transduction across species, enhancing preclinical data reliability for both mouse and NHP livers. For the AAV capsid engineering, we employed a rational design strategy, modifying the variable region I (VR-I) of sL65. GFP served as the transgene reporter in WT mice studies, while hFIX was the reporter gene in cynomolgus macaque (NHP) experiments. Quantification of cell entry and transgene expression for new sL65 variants was performed using ddPCR and NGS sequencing. Of the 6 sL65 variants produced, our new capsids demonstrated excellent AAV manufacturability. Some sL65 variants exhibited increased mouse liver tropism compared to the original sL65 capsid and natural serotype AAV8. Notably, new variant sL65-V6 showed about 2 and 10-fold transgene delivery compared to AAV8 and sL65, respectively, in mouse liver. In NHP studies, sL65-V6 showed about 2 and 6-fold transgene liver delivery compared to sL65 and LK03, respectively. Addressing the variability in transduction capabilities among different AAV capsids in mice and NHPs, our engineered sL65-V6 variant demonstrated efficient transgene expression across mice, NHPs, and human primary hepatocytes. In summary, considering manufacturability, high transduction efficiency in NHP livers, and cross-species capability, our new AAV capsid, sL65-V6 emerges as a strong preclinical and clinical candidate for liver targeted gene therapies.

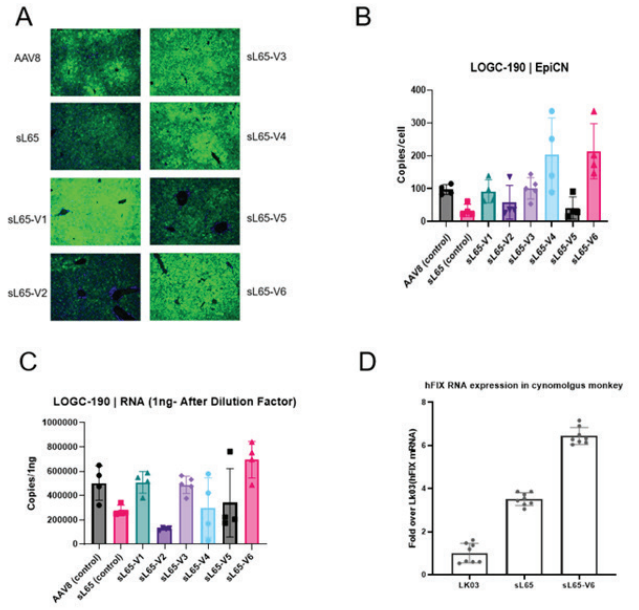

Fig1. A, WT Mouse liver transgene expression by different capsids. B, episomal copies number to check AAV capsid variants entry to WT mouse hepatocyte. C, transgene mRNA expression by different capsid in WT mice. D transgene mRNA expression comparison by different capsids in cynomolgus macaque.

489. Identification of AAV2-13 Hypervariable Regions Mediating Liver Transduction and Detargeting in Rodents and Non-Human Primates

[1]GENETHON, Evry, France,[2]Université Paris-Saclay, Univ Evry, Inserm, Genethon, Integrare Research Unit UMR_S951, Evry, France

Adeno-associated viral (AAV) vectors are widely used in gene replacement strategies in preclinical and clinical contexts. Along the years gene therapy with AAV vectors showed efficacy for the targeting of different organs and sustained expression over time (Mendell JR,

2017; Nathwani AC, 2014; D'Antiga L, 2023). The excellent safety profile and the proven efficacy resulted in the multiplication of clinical trials to address unmet medical needs that eventually led to achieve marketing authorization for some of the AAV-based products. Despite these enormous successes, limitations in their use still exist, and a better understanding of the mechanisms mediating liver targeting and detargeting is required. In this work, we conducted a shuffling study of the hypervariable regions (HVRs) of AAV8 with homologous regions from AAV2-13 capsids isolated from human liver (La Bella T, 2020) to pinpoint regions involved in liver tropism. HVRs were shuffled in AAV8, a capsid with a robust liver tropism, by substituting them individually or as combinations. Shuffled capsids were combined with a ubiquitous or a hepato-specific promoter to evaluate the *in vivo* and *in vitro* transduction efficiency in mouse. Our results highlighted the HVR5 as a region of the AAV capsid able to improve the specificity of liver targeting. Noteworthy, HVR5 shuffled capsids combined with ubiquitous promoter led to a modest improvement in liver transduction. On the contrary, when combined with the hepatic promoter, shuffled capsids outperformed AAV8 transduction efficiency, suggesting that modifications of the HVR5 may increase the selectivity of AAV vectors for hepatocytes. We then tried to combine other HVRs with the HVR5 to evaluate whether a synergic effect was observed. The combination of HVRs 1, 7, 8 and 10 with HVR5 led to a dramatic decrease of liver targeting suggesting that the simultaneous replacement of multiple HVRs of AAV8 with the corresponding regions of wild type AAV impaired the liver tropism regardless of the promoter used. On the contrary, individual HVRs 1, 5, 7, 8 and 10 substitutions did not independently impact liver transduction. Validation of the association of certain HVR regions with liver targeting and detargeting was performed in non-human primates. Importantly, we found that shuffled AAV capsids containing regions that mediated liver detargeting in mice had a similar profile in primates pointing to an inter-species conservation of the detargeting characteristics associated to these regions. To conclude, in this study, rational shuffling of regions derived from wild-type AAV2-13 capsids isolated in human livers into homologous regions of the AAV8 capsid, allowed to identify determinants of liver transduction and detargeting across species. This knowledge is fundamental to develop AAV capsids for diseases where concomitant muscle and liver gene transfer maybe required to reduce the impact of the immune response by achieving sufficient transgene expression to induce liver-mediated peripheral tolerance without liver overloading (Sellier P, 2023). When validated in appropriate preclinical models and with clinically relevant transgenes, the use of capsids derived from shuffling of HVRs may thus provide safer AAV vectors tailored to the specificities of the disease.

490. A Novel AAV9 Mutant with a Remarkably Short Circulation Half Life Leads to Exclusive Liver Transduction Following Systemic Administration

Pratheppa Rajagopal[1], Teruyuki Nishi[2], Kei Adachi[1], Jessica Dillon[1], Anusha Sairavi[1], Hiroyuki Nakai[1]

[1]Molecular and Medical Genetics, Oregon Health and Science University, Portland, OR,[2]KANEKA Corporation, Takasago, Japan

Introduction: AAV capsid engineering has emerged as a promising strategy to overcome challenges. To explore novel phenotypes of AAV capsids attractive for clinical translation, we adopted an NXT/S scanning mutagenesis approach to introduce the NXT/S motif into AAV9 capsid protein. **Methods and Results:** We introduced the NXT/S motif into AAV9 capsid in a systematic manner to create potentially N-glycosylated amino acid residues at non-native site. Total 258 AAV9 mutants were created and their biological phenotypes were determined in vitro and in mice using the AAV Barcode-Seq technology. Briefly, the mutant vectors and the wild-type AAV9 vector were packaged in HEK293 cells using the barcoded double-stranded (ds) AAV-U6-VBC vector genome as the transgene. The dsAAV-U6-VBC vector genomes harbor a human U6 small nuclear (sn) RNA promoter-driven non-functional noncoding RNA expression cassette containing a pair of 12 nucleotide-long viral DNA barcodes (VBCs). From AAV Barcode-Seq analysis using tissue culture cells and samples from mice treated with this library, we identified an AAV9NXTmutx that can transduce HepG2 cells at least an order of magnitude better than AAV9 and show exclusive liver transduction with a modest enhancement compared to AAV9 and minimal off-target effects in mice. For further evaluation, we injected C57BL/6J mice intravenously with ssAAV-CAG-nlsGFP-VBC vector packaged with the wild-type AAV9 or the AAV9NXTmutx mutant capsid. Three weeks post injection, the protein quantification (ELISA) and histopathological analysis of the liver and non-hepatic organs revealed the preferred liver tropism of the AAVNXTmutx as opposed to the systemic transduction with AAV9. To understand potential mechanisms of liver exclusivity of this mutant, we determined pharmacokinetic profile in the blood following administration and computationally determined capsid surface electrostatic charges by Adaptive Poisson-Boltzmann Solver (APBS). The pharmacokinetic study revealed an interesting characteristic of the mutant being cleared extremely rapidly, cleared within minutes, as opposed to AAV9 showing prolonged persistence in the circulation. APBS analysis highlighted the presence of a newly created basic amino acid patch on the surface of the AAV9 capsid that is not present in the wild-type AAV9. To assess the effect of this NXT mutant on other serotypes, we engrafted a similar mutation on other AAV serotypes to evaluate enhanced liver transduction. The AAVxNXT library containing AAV3, 5, 7, 8, 9, 10, DJ, KP1, KP3, Anc80, LK03, NP59, rh10 and its mutant was packaged with different barcodes. The in vivo analysis of AAVxNXT mutant library exhibited a slightly elevated liver transduction in AAV10, 8, 9, and rh10 in the mutant group, whereas the mutant in AAV DJ, KP1, KP3, Anc80 had a deteriorative effect. Considering the difference in efficacy of AAV transduction between animal models and humans, the chimeric xenograft mouse model with human hepatocytes was used to further understand the mutant behavior. The humanized chimera mice were administered with AAVxNXTmutant library, and the human hepatocytes were subjected to NGS analysis, revealing that the mutation had the similar effect as in C57BL/6J mice. In addition to the minimum beneficial properties in AAV8, 10, and 9 serotypes, a deteriorative effect was observed for other serotypes. **Conclusion:** Since the enhanced liver transduction and restricted biodistribution may lead to the usage of a lower vector dose which in turn minimizes the dose-dependent host immune responses, this mutant may represent a novel attractive candidate for liver-directed gene therapy with minimum off-target effects.

491. BI-GT101 Enhances Adeno-Associated Virus Uptake and Overall Transduction Efficiency in a Serotype-Independent Manner

Olaniyi Olarewaju, Franziska Held, Christian Schoen, Udo Maier, Francois du Plessis

AAV Gene Therapy Group, Research Beyond Borders, Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach an der Riß, Germany

The need for high AAV doses to achieve clinical efficacy remains a key challenge to AAV utility in the clinic. High vector dose increases cost and has been majorly implicated in the activation of immune responses directed against the AAV capsid, as well as the therapeutic payload. Hence, numerous efforts are currently directed at improving AAV transduction efficiency in order to overcome these challenges. In this study, we demonstrate the potency and efficiency of BI-GT101, a small peptide, which, upon pre-incubation with AAVs, effectively enhances transduction efficiency by two- to four-fold in multiple cell lines of epithelial and fibroblastic origins *in vitro*. Additionally, BI-GT101 outperforms other commonly used cell penetrating peptides such as TAT, BIP2 and ARF which have been previously used to enhance AAV transduction. Moreover, we show similar enhancement of transduction for multiple AAV serotypes, suggesting that the mechanism of action for BI-GT101 is serotype-independent. Mechanistically, BI-GT101 increased vector DNA-uptake by two-fold, resulting in a corresponding increase in the uncoated vector genomes. Our data reveals BI-GT101 primarily influences cellular uptake of AAV particles in a HSPG-dependent manner, as we observed no differences in the vector genome uncoating efficiencies between WT-AAV and BI-GT101-supplemented-AAVs. Next, BI-GT101 was genetically incorporated in the GH2/GH3 loop of the VP1 of a transduction-incompetent AAV2 (HSPG-motif ablated AAV2), this led to the restoration of the transduction efficiency of the modified AAV2 displaying BI-GT101 to levels comparable or approximately 2-fold higher than WT-AAV2 in HEK293T cells and HT1080 cells, respectively. Therefore, showing that BI-GT101 facilitates HSPG receptor binding and subsequent uptake of the modified AAVs. In conclusion, we demonstrate that combining/supplementing AAVs with BI-GT101 robustly enhances AAV transduction efficiency, thereby opening new opportunities to reduce vector doses by a factor of two to four. This could be significant in gene therapy applications in compartmentalized environments such as the knee, eye, CNS, and in the inner ear.

492. A Novel AAV2 Mutant SonuAAV™ Expressing mGjb2 Can Improve Hearing in Adult Gjb2-Deficient Mice by Cochlear Perilymph Administration

Yoshinori Tanaka[1], Kazusaku Kamiya[2,3], Toshiyuki Miura[1], Sachiko Okamoto[1], Tatsuji Enoki[1]

[1]Takara Bio Inc., Kusatsu, Shiga, Japan,[2]Department of Otorhinolaryngology, Juntendo University Faculty of Medicine, Tokyo, Japan,[3]Gap Junction Therapeutics, Inc., Tokyo, Japan

Hearing loss is one of the most common sensory disorders. Current therapies for hearing loss involves the use of hearing devices to amplify sound, but this treatment still has limitations in terms of hearing sensitivity. Recently, AAV gene therapy has emerged as a promising strategy for the treatment of genetic diseases and has demonstrated clinical efficacy in several organs, such as retina, central nervous system, and muscle. Mutations in the gap junction protein beta 2 (GJB2), which encodes Connexin 26 (CX26), have been reported as a major cause of inherited hearing loss. Several studies targeting the GJB2 gene using AAV vectors have shown successful hearing correction in neonatal rodent model. However, there are currently no effective AAV vectors for inner ear gene delivery to rescue the hearing in adult mice. To date, peptide library screening approach by inserting short randomized peptide exposed on the surface of viral particles, has been established as a AAV capsid engineering method for tissue-specific transduction. In this study, we generated a random peptide library using AAV2 and inoculated it into cochlear explant culture of neonatal mice. After several days, the supporting cells identified as Myo7a negative cells, were isolated from the explants and then AAV genomic DNA was extracted from these cells. AAV capsid gene was recovered through PCR amplification followed by re-cloning to create a next generation AAV library. Second and third round of directed evolution were performed using adult mice instead of neonatal explants. The next generation of the AAV random peptide library was injected into the cochlear perilymph of adult mice. After 4 weeks post-injection, CX26 positive cells were isolated from the cochlear tissue. Finally, several candidates were selected as gene transfer vectors into inner ear cells after the third round of directed evolution. To evaluate the transduction efficiency mediated the selected peptide insertions, we generated seven AAV2 mutant candidates harboring the AcGFP gene under the control of the CMV promoter and then inoculated these AAV vectors into neonatal mouse cochlear explants. As a result, two AAV2 candidates (AAV-TB4 and TB5) showed significantly high AcGFP expression in both hair cells (HCs) and supporting cells (SCs) of cochlear explants. The AcGFP expression of AAV-TB5 (designated SonuAAV™) was approximately 95-fold higher than that of AAV2 and nearly 80% of both HCs and SCs were transduced. We further examined whether SonuAAV expressing mouse CX26 could improve hearing in conditional CX26 knockout mice. The SonuAAV-CX26 vector was injected into the perilymph through the lateral semicircular canal of inner ear in 4-weeks-old deaf mice, and then the auditory function was monitored by auditory brainstem response (ABR) every two weeks. After 6 weeks, successful hearing improvement was observed in the SonuAAV-CX26 vector administrated mice. Further confirmation is still required for histological identification of Gjb2 protein expression and gap junction formation between the SCs by SonuAAV gene transfer in non-human primate models and human cells. However, our data demonstrates the significant potential of SonuAAV as an efficient gene delivery vector into inner ear cells and its effectiveness in improving hearing impairment.

493. Enhancing Gene Delivery in Gene Therapy: The Role of Adhesive Phenolic Molecules in AAV Assembly

Yu Ri Nam[1], Zheng Rong Lau[2], Jeong Pil Han[3], Su Cheong Yeom[3], Jae-Hyung Jang[2,4], Haeshin Lee[1,4]

[1]Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Korea, Republic of,[2]Yonsei University, Seoul, Korea, Republic of,[3]Seoul National University, Pyeong Chang-gun, Korea, Republic of,[4]GluGene Therapeutics Inc., Seoul, Korea, Republic of

Introduction The adeno-associated virus (AAV) has emerged as a remarkably effective tool in human gene therapy, owing to its notable safety record and non-replicative nature. This has resulted in the FDA and EMA approving a range of AAV-based gene therapies, highlighting the vast potential of gene therapy in developing novel treatments for genetic disorders. Despite its considerable promise, AAV's potential is tempered by its limited payload capacity, approximately 4.7 kb, making the delivery of larger genes for diseases such as Duchenne Muscular Dystrophy (DMD), Cystic Fibrosis, and Hemophilia A a significant challenge. Researchers have explored various solutions, including trans-splicing, overlapping, and hybrid dual AAV vectors, yet the simultaneous delivery of dual AAV vectors remains a challenge. To address this, in this study we propose a supramolecular AAV assembly using adhesive phenolic molecules. This innovative technique enables the assembly of viral capsid proteins for the targeted delivery of multiple genes to specific cells or tissues. **Methods** We prepared suprastructured AAV using adhesive phenolic molecules, mixing them with AAVs in volumetric ratios of either 1:1 or 1:9, based on the solubility of the molecules. To characterize these assembled particles, we utilized ultraviolet-visible (UV-Vis) spectroscopy, measuring at a wavelength of 600 nm (A600) to estimate aggregation. Additionally, the size and morphology of the particles were analyzed using atomic force microscopy (AFM) and transmission electron microscopy (TEM). To assess cellular uptake efficiency, human embryo kidney (HEK) 293T cells were employed; following a 48-hour transfection, the efficiency was quantified using fluorescence-activated cell sorting (FACS), and was visualized through fluorescence microscopy. Furthermore, for an in vivo gene delivery, intranasal injections of supra-structured AAVs carrying a cystic fibrosis gene into mice was administered. Post two weeks of injection, we performed ELISA analysis to evaluate the efficacy in gene delivery. **Results** In our experiments, the suprastructured AAVs showed a notable increase in turbidity at A600, correlating with the concentration of the phenolic molecule. Size analysis via AFM revealed a significant height increase in the suprastructured AAVs, ranging between 100 to 250 nm, compared to the approximate 22 nm height of single AAVs. TEM images further confirmed this aggregation, showcasing particles clustered by the adhesive molecules. In *in vitro* analyses, the suprastructured AAVs enhanced the co-transduction efficiency of dual AAV vectors, showing an improvement of 76-80% over treatments with non-assembled AAVs. This indicates a substantial increase in the effectiveness of gene delivery. Moreover, *in vivo* experiments yielded promising results, with a noticeable increase in the concentration of GFP in subjects treated with phenolic molecule-assembled AAVs compared to those treated with non-assembled vectors. **Conclusion** Our study showcases a breakthrough in gene therapy with the development of a supramolecular AAV assembly technique using adhesive phenolic molecules, effectively overcoming AAV's payload limitations and demonstrating enhanced gene delivery in both in vitro and in vivo models, thereby offering promising avenues for multiple therapeutic gene delivery.

494. Rationally Designed a Novel AAV Capsid for Intra-Articular Gene Delivery

Shuang Luo[1], Qing Xie[1,2], Qingwei Li[1], Qiang Zheng[1,2]
[1]Chengdu Origen Biotechnology Co., Ltd, Chengdu, China,[2]Sichuan Provincial Key Laboratory of Innovative Biomedicine, Chengdu, China

Arthritis is a musculoskeletal inflammation that affects various joints in the body. It is often accompanied by excruciating pain, impacting daily lives, and seriously affecting patients' physical and mental health. Current treatments include the use of nonsteroidal anti-inflammatory drugs. Systemic administration often leads to considerable side effects, while local administration requires patients to visit the hospital regularly for procedures, causing inconvenience. Gene therapy, which possesses a single administration with long-term effectiveness, has been explored to address the treatment of this disease. In the present study, an adeno-associated virus (AAV) mediated gene therapy was developed and evaluated in a collagen-induced arthritis (CIA) mouse and New Zealand rabbit model. Briefly, the AAV vector was intra-articular injected into the knee joint of the animals, and the transduction efficiency, types of transduced cells in the joint, off-target transduction in other tissues and duration of AAV expression in the joint were evaluated thereafter. Our vector consists of an engineered AAV capsid as a delivery vehicle and a coding sequence for anti-TNF (Enbrel) as the transgene. The results showed that the expression of the target protein in the joint of the New Zealand rabbit lasted for over 9 months after the injection with 1E11 vg AAVs for each knee. The tissue tropism of our engineered AAV was evaluated in CIA 57BL/6 mice's joints as well. In this experiment, 5E10 vg AAVs were administered to each knee of the mice. It showed our AAV vector mainly transduced A-type synoviocytes, DC cells and T cells, but not transduce B-type synoviocytes and chondrocytes after intra-articular injection of the mice. These results demonstrate that our vector has a high transduction efficiency in diverse joint cells and long-term expression after intra-articular administration.

495. Developing a Potent Gene Therapy Candidate for Facioscapulohumeral Muscular Dystrophy (FSHD) Through High Throughput AAV Capsid and Cargo Engineering

Saurav Seshadri, Kyle Brown, Shayan Tabebordbar, Edward Marsh, Jana Jenquin, Janelle Stricker, Brian Ferguson, Mark Fielden, Sharif Tabebordbar
Kate Therapeutics, San Diego, CA

Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal-dominant genetic disorder affecting an estimated 1 in 8,000 individuals. Patients with FSHD typically exhibit progressive weakness of muscles in the face, shoulders, upper arms, legs, and abdomen; approximately 20% of patients will eventually require the use of a wheelchair, and the majority experience pain and fatigue, often debilitating. De-repression of the transcription factor *DUX4* has been identified as the pathogenetic mechanism in FSHD. Insufficient epigenetic silencing of the *DUX4* gene in patient muscles results in aberrant expression of DUX4, which is toxic to mature myofibers. Therefore, knockdown of the *DUX4* transcript has been advanced as a therapeutic strategy for FSHD and has shown efficacy in preclinical models. Here, we demonstrate efficacy of a novel MyoAAV-mediated RNAi therapy

for FSHD both *in vitro* (in human patient-derived myotubes) and *in vivo* (in the ACTA1-MCM;FLExDUX4 mouse model, a bi-transgenic line with inducible expression of DUX4 in skeletal muscles, which reproduces disease-relevant biochemical, histological, and functional phenotypes of FSHD). First, we conducted a tiling screen to identify the most potent DUX4-targeting artificial miRNA sequences, using an engineered HEK293 cell line stably expressing a tagged mutant DUX4 transgene. Top hits from this screen were validated in FSHD patient-derived myotubes. These cells contain a disease-causing contraction in the D4Z4 region of chromosome 4q that is responsible for epigenetic silencing of *DUX4*, and upon differentiation, show expression of *DUX4* and its transcriptionally regulated target genes. Candidate miRNA sequences were ranked based on the magnitude of DUX4 and target gene knockdown achieved in these cells, and selected sequences were carried forward for additional characterization. We performed small RNAseq in human myotubes to assess processing efficiency of the miRNA-containing transcript. To ensure that our candidate miRNA sequences were specific for DUX4 and did not cause knockdown of unintended transcripts, we applied an unbiased, empirical approach using RNAseq in human primary myotubes. We selected our lead miRNA candidate based on optimal potency and processing, and minimal off-target effects. In separate experiments, we evolved liver de-targeted, muscle-tropic MyoAAV capsid variants in non-human primates. We packaged our lead miRNA sequence in our top liver de-targeted, muscle-tropic MyoAAV and tested the resulting candidate *in vitro* and *in vivo*. We confirmed potent knockdown of DUX4 and target genes, efficient processing, and minimal off-target effects at a relevant dose in human myotubes. To assess *in vivo* efficacy, we used ACTA1-MCM;FLExDUX4 mice. We dosed these mice with our candidate or vehicle, and induced DUX4 expression in all mice by injecting tamoxifen. Treatment with MyoAAV delivering DUX4 miRNA protected mice from severe impairment in treadmill time to exhaustion, prevented expression of markers of histopathology, and blocked elevations in DUX4 and target genes, all of which were observed in vehicle-treated mice. Taken together, these data support the further development and potential of our gene therapy candidate for the treatment of FSHD.

496. Rationally Engineered AAV Variants for Efficient Gene Delivery to Muscle

Philip C. Sin[1], Hanyang Hu[2], Zengmin Du[3], Dandan Li[2], Shihao Wu[3], Huaqing Xue[3], Wei Jiang[2], Xia Wu[2], Jane Zheng[3], Xiao Xiao[3]

[1]Belief BioMed Limited, Hong Kong, Hong Kong,[2]Research, Belief BioMed Limited, Shanghai, China,[3]Belief BioMed Limited, Shanghai, China

Background: Recombinant adeno-associated virus (rAAVs) vectors are among the most promising for *in vivo* gene therapy. AAV-mediated systemic gene delivery into muscle has been a major challenge for muscle disorders gene therapy, with capillary blood vessels posing the principle barrier and limiting vector dissemination. To achieve exceptional therapeutic efficacy, AAV-mediated muscular disease gene therapy often requires injection of a large dose of virus (>1E+14 vg/kg). Serious adverse events and toxicity have been observed in some high dose systemically delivered AAV gene therapy clinical trials, highlighting the need for more efficient AAV vectors to achieve efficacy at lower doses. **Method:** We utilize integrin overexpression cell and adenovirus helper to replicative screen the engineered AAVs with rationally designed short peptide insertion. The screening process was repeated a total of 5 times. In the very last round of selection, the engineered AAV capsid DNA were extracted and put through next generation sequencing. We identified several top clones as integrin targeted engineered AAV vector candidates. To evaluate rationally engineered AAV variants in muscles of rodents or non-human primate, we generated myotropic AAV candidates delivering reporter gene under the control of CB promoter and then injected these vectors intravenously. After 3 weeks, we analyzed reporter gene expression in whole-body, whole-tissue and sliced sample, and compared with AAV9 or myoAAV4. **Result:** Significant tdTomato expression mediated by three AAV9 mutations were detected in whole-body muscles and heart and the expression level and coverage were much higher than wild-type AAV9. Moreover, AAV9.P7, a non RGD motif peptide chimera, was efficient in myotropic transduction in common with myoAAV4A. We next mutated several sites of AAV9.P7, known to mediate receptor interactions and affect tropism, to reduce liver transduction. AAV9.P7.4, with a specific single site mutation, showed desired liver de-targeting and maintained efficient muscle transduction. In addition, we investigated whether we could transfer the peptide of AAV9.P7 to natural serotype, usually AAV5, due to its low seroprevalence. Fortunately, AAV5.P7, which carried the same inserted peptide of AAV9.P7, was the same in muscle infectivity as AAV9 but stronger than its parent AAV5. Interestingly, AAV5.P7 gained muscular tropism, and were no longer liver targeting, maybe due to peptide transplant destroyed sialic acid binding site. Novel capsids validated in rodents do not always translate to NHP. After validating the AAV9.P7 capsids in rodents, we therefore decided to assess its transduction potential in rhesus macaque, a common pre-clinical research model for AAV gene therapy. Compared with the parent AAV9, systemic delivery of AAV9.P7 packaged with CB-LacZ efficiently transduced cardiac and skeletal muscle in 2~3 years old rhesus macaque. **Discussion:** We demonstrate the rational design of AAV9 variants displaying integrin targeted peptides on the viral capsid and the identification of three myotropic AAV9 variants through cell based high-throughput method. Moreover, AAV9.P7, a non RGD motif peptide modified AAV9 variant, showed myotropic efficiency in systemic gene delivery in both rodents and NHP. We rationally designed AAV9.P7 and gained several mutations, including AAV9.P7.4, that showed high myotropic efficiency with liver de-targeted. The integrin targeting peptide rationally translated from AAV9.P7 to low seroprevalence serotype AAV5, enabled serotype switching to AAV5.P7 for broad application in clinic. Our results suggest that AAV9.P7, AAV9.P7.4 and AAV5.P7 are useful gene therapy delivery tool for muscular diseases.

497. Development of a Computational Pipeline to Improve Engineered Capsid Identification from Defined and Random AAV9 Peptide Insert Libraries

Rosemary L. Meggersee, Zhe Zhang, Daniel Lefever, Jenny A. Greig, James M. Wilson

Gene Therapy Program, University of Pennsylvania, Philadelphia, PA

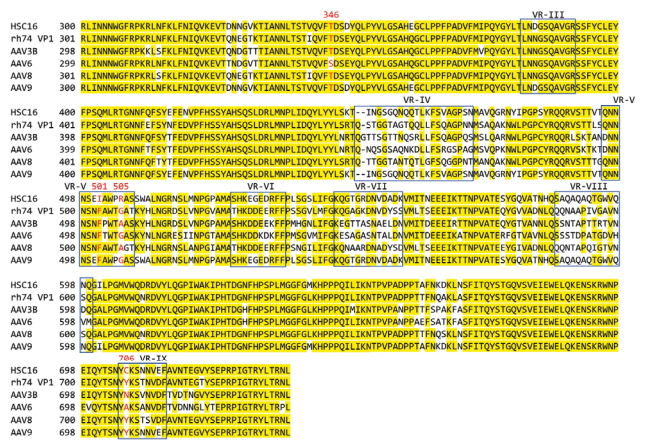
The large peptide insert libraries used to engineer AAV9 capsids for tissue transduction generate enormous amounts of data. Depending upon the target tissue, it is often difficult to identify candidates with

genuine transduction advantages. Bioinformatic analysis tools have helped to alleviate this issue, enabling the identification of several engineered capsids with greater tissue specificity. However, it has recently become apparent that these standard bioinformatic analysis methods have limitations. Multiple groups have found that their best capsid is not part of an obvious motif family and may not even be their top ranked capsid. To address this drawback, we have developed several analysis tools and "hit picking" methods for a defined library isolated from multiple nonhuman primate (NHP) tissues. The methods we employed included unsupervised principal component analysis to confirm that different tissues had distinctive profiles of peptide abundance. We applied k-means clustering to identify subgroups of peptides with identical patterns of relative abundance with respect to input vector across multiple tissues. We summarized the frequency of peptide positions by subgroups and compared peptides of the same subgroup with each other to evaluate their sequence similarity. This analysis pipeline enabled us to identify previously unseen and unappreciated patterns and associations that informed the selection of several candidates for follow-up studies. In vivo characterization of these identified capsids in mice and NHPs demonstrated that these capsids outperformed AAV9 in their respective tissue targets. In mice, we observed transduction activity of between 40 and 500 times that of AAV9 depending on the tissue type; increases of 10 to 20 times over AAV9 were observed in NHPs. We leveraged this knowledge to fine-tune our bioinformatics pipeline for a large, random insert library on tissues that are known to be difficult to transduce and to thus identify potential next-generation capsids.

498. Identifying Muscle Stem Cell Tropic AAV Variants through Directed Evolution

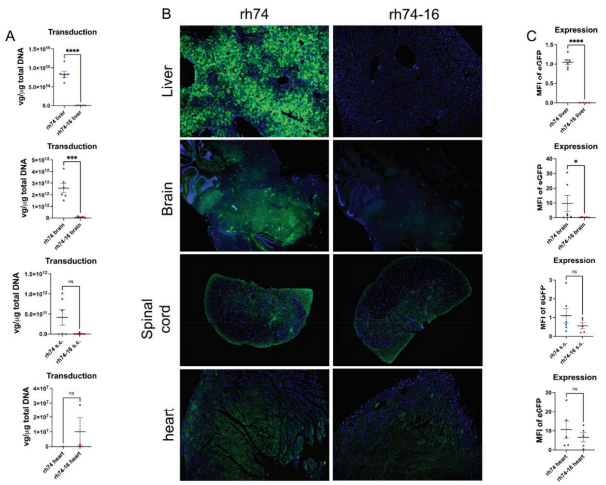
Harry M. Chen[1], Michael R. Emami[2], Courtney Young[2], Kevin Liu[1], Braeden Freitas[1], Emily Skuratovsky[1], Thomas A. Rando[3], Oluwatayo Ikotun[1], April D. Pyle[1], Melissa J. Spencer[1]

[1]UCLA, Los Angeles, CA,[2]MyoGene Bio, San Diego, CA,[3]Stanford, Palo Alto, CA



Duchenne Muscular Dystrophy (DMD) is a rare genetic disease caused by frameshifting mutations in DMD, resulting in a lack of dystrophin protein production. While AAV-microdystrophin gene replacement therapy was recently given accelerated FDA approval for DMD, the therapeutic efficacy appears to reduce with time, likely due to turnover of skeletal muscle and replacement by muscle stem cells. Redosing AAV is not an option; however, a strategy to retain durable dystrophin is to target Muscle Stem Cells (MuSCs) with CRISPR/Cas9 to correct genomic DNA in the proliferating cell population. We have previously identified 8 MuSC targeting and 10 Skeletal Muscle (SkMu) targeting AAVs through directed evolution of a 7 amino acid sequence, inserted between amino acids 589A and 590Q in the surface region VIII (VR-VIII) of AAV9. Individual validation of these variants through systemic administration in mice has revealed that they significantly outperform wtAAV9 in MuSC targeting while also retaining their SkMu tropism. In addition, in vitro studies in primary human myoblasts (HSMMs) have demonstrated a similar enhanced tropism compared to wtAAV9. These data have been confirmed through flow cytometry alongside qPCR of viral genomes. While further characterization must be done, these new variants provide a potential new platform for achieving long-term dystrophin restoration and durability when AAV is used to deliver CRISPR components in DMD and other myogenic diseases that involve muscle degeneration and regeneration.

499. Rational Design of AAV-rh74, AAV3B, and AAV8 with Limited Liver Targeting



Christopher Chan, Kathryn K. Harris, Sergei Zolotukhin, Geoffrey D. Keeler

Department of Pediatrics, University of Florida, Gainesville, FL

Introduction Recombinant adeno-associated viruses (rAAVs) are one of the most widely used vectors for gene therapy, with several adeno-associated virus vector-based gene therapies currently FDA-approved for the treatment of diseases such as Duchenne muscular dystrophy and hemophilia B. rAAVs are engineered to lack viral genes and are particularly suited for use in gene therapy because of their low immunogenicity, ability to transduce many different cell types, and persistent transgene expression after initial treatment administration. However, most AAV serotypes transduce the liver at a high rate when administered peripherally, thus increasing the necessary dose for the treatment of other tissues. High dosage of AAV has been associated with adverse side effects in recent clinical trials. To minimize this risk to patients, there is a need to produce rAAV vectors that effectively transduce target tissues at lower doses. De-targeting rAAV vectors from the liver would prevent rAAV from being removed from the bloodstream before reaching target tissues. One naturally occurring clade F AAV serotype, AAV hematopoietic stem cell 16 (AAVHSC16), has been found to show reduced liver transduction when administered peripherally compared to other closely related AAV serotypes. Three residues on the capsid surface of AAVHSC16 are associated with reduced galactose binding. We hypothesized that point mutagenesis of these surface residues in AAV serotypes from other clades would be associated with reduced transduction of liver tissue. **Methods** Four non-clade F, clinically relevant AAV serotypes were identified who differed from AAVHSC16 at the residues associated with reduced galactose binding: AAV3B, AAV6, AAV8, and AAVrh74. These serotypes were mutated at those three residues, and self-complementary rAAV-GFP vectors were produced for both the wild-type and mutant capsids. We assayed the wild-type and mutant vectors either *in vitro* in HuH7 cells or *in vivo* using a murine model to compare transduction and transgene expression.

Results While wildtype AAV3B transduced over 80% of HuH7 cells *in vitro* as assayed by FACS, the mutant capsid had effectively no transduction of HuH7 cells. AAVrh74 and AAV8 had significant reductions in transduction efficiency of the liver in their mutants, while AAV6 had overall low liver transduction in both the wildtype and the mutant. Our data indicates that mutagenesis results in decreased transduction and transgene expression in liver tissue.

Conclusion Mutagenesis at the residues associated with reduced galactose binding in AAVHSC16 resulted in decreased transduction and transgene expression in liver tissue by AAV serotypes from other clades. This method may be a means to de-target additional AAV vectors from the liver, which could result in the development of AAV therapies with more limited adverse side effects.

500. Structure Guided Design of the AAV9 Capsid Evading Antibodies Derived from Zolgensma Patients

Jon Zachary[1], Austin Nelson[1], Jane Hsi[1], Lindsay Potts[1], Paul Chipman[1], Mohammad Ghanem[2], Ian E. Alexander[3], Grant J. Logan[4], Juha Huiskonen[2], Robert McKenna[1], Mario Mietzsch[1]

[1]University of Florida, Gainesville, FL,[2]University of Helsinki, Helsinki, Finland,[3]Sydney Children's Hospitals Network, Westmead, Australia,[4]Children's Medical Research Institute, Westmead, Australia

A major challenge for wide-spread utilization of AAV vectors in gene therapy applications is the presence of pre-existing neutralizing antibodies (NAbs) in a large portion of the human population. These antibodies originate from prior exposure to naturally circulating AAVs and primarily target the capsid leading to vector inactivation and loss of treatment efficacy. As a result, patients having these antibodies or exceeding defined antibody titer thresholds are usually excluded from receiving these therapeutics. A strategy to circumvent NAbs is the design of novel AAV capsids capable of evading pre-existing antibodies. However, this capsid-engineering approach requires knowledge of the capsid-antibody interactions. Previously, we have mapped the overall binding sites of 21 monoclonal antibodies (mAbs) derived from three Zolgensma® patients to the AAV9 capsid by cryo-EM at a resolution range of 5-10 Å. For a detailed understanding of the interactions, high resolution cryo-EM data was collected for each of the capsid-antibody complexes. 3D-reconstruction of the data with imposed icosahedral symmetry resulted in cryo-EM maps for the different AAV9-Fab complexes at resolutions ranging from 1.88 to 3.27 Å. The capsids in all maps displayed high-resolution features, which allowed the building of reliable models. In contrast, the antibody portions of the complexes, with the exception of two, showed "blurred" densities preventing effective model building and characterization of the binding interface. These blurred antibodies were bound at or near an icosahedral symmetry axis. At these binding locations, the bound antibodies do not conform to icosahedral symmetry of the capsid and as a result appeared distorted in the cryo-EM maps. Localized reconstructions of these regions resolved the bound antibodies and allowed the unbiased modelling of the binding interface. Furthermore, these structures demonstrated induced structural changes of the capsid upon binding by the antibody. Subsequently, key amino acid residues were identified and new AAV9 variants produced via site-directed mutagenesis PCR. Ultimately, we produced a capsid variant with six amino acid substitutions relative to wtAAV9 that was capable of fully escaping 18 of the 21 mAbs at high antibody titers, while also displaying improved transduction efficiency and unchanged yields using standard AAV production methods. This study demonstrates that high resolution antibody binding mapping coupled with structure guided rational design is a powerful tool for the design of new AAV capsid variants that can expand the patient cohort treatable with AAV vectors to include patients that were previously excluded due to their pre-existing antibodies.

501. NAVIGATE: A Directed Evolution Platform for Engineering Novel Ocular and Muscle AAV Capsids in Non-Human Primates

Elad Firnberg[1], Sigmund K. S. Tejada[1], Samantha Yost[1], April R. Giles[1], Timur Gaynutdinov[1], Victor Chen[1], Steven Foltz[1], Kirk Elliot[1], Benjamin P. Heithoff[1], Jared B. [1]REGENXBIO Inc., Rockville, MD,[2]Institute for Quantitative Biomedicine, Rutgers, The State University of New Jersey, Piscataway, NJ

Most AAV vectors currently used in the clinic feature capsids from naturally occurring serotypes, but could be further optimized for specific indications and routes of administration. Directed evolution has proven itself as an effective method for engineering improved properties into proteins, included AAV capsids. In this work, we developed a new capsid discovery engine termed NAVIGATE (**N**ovel **A**AV **V**ector **I**ntelligent **G**uided **A**daption **T**hrough **E**volution), based on mRNA-expression selection in target tissues. We designed a library construct in which the AAV *cap* gene is expressed under a CMV promoter with an AAV *rep* intron to allow for library packaging and ubiquitous expression in all tissues of interest. Diversity was generated by insertion of 7-mer randomized peptides in the AAV VR-IV or VR-VIII surface-exposed loops. We optimized the plasmid library construction and plasmid transfection process to generate AAV libraries with a high diversity of up to 10^8 variants with minimal cross-packaging, mosaicism, and wildtype capsid sequence contamination. Library composition was evaluated on the AAV genome level by

next-generation sequencing (NGS) and on the protein level by LC-MS analysis of VP proteins. We constructed libraries for multiple AAV scaffolds including AAV3B, AAV5, AAV8, and AAV9. In addition, we incorporated a 496-NNN/AAA-498 mutation in AAV9 to impart a liver-detargeting phenotype. Libraries were administered to non-human primates (NHP) by two different routes of administration and tissues were collected after three weeks for mRNA extraction and NGS. Second round libraries were generated based on a subset of 2000-4000 peptides and selection repeated in NHPs. In the third round, top capsids were packaged individually with a barcoded CAG.TdTomato transgene and administered as a pool. Finally, top performing capsids were evaluated *in vivo* by single vector administration. Cryo-EM was used to elucidate the structure of evolved capsids and infer structure-function relationships. NAVIGATE campaigns were conducted for suprachoroidal space (SCS) delivery to ocular tissues and intravenous (IV) delivery to muscle. The SCS campaign identified cross-species compatible capsids with >200-fold improvement in mRNA expression in NHP RPE/choroid compared to AAV8 and >100-fold improvement in secreted transgene product level in mini-pig aqueous humor. The IV muscle campaign identified cross-species compatible capsids with 7-fold lower liver mRNA expression and 2-fold improved skeletal muscle and heart mRNA expression in NHP compared to AAV9. Liver-detargeting and muscle expression was reproducible in both C57Bl6/J and *mdx* mice with a CAG.TdTomato and Spc5-12.microdystrophin transgene, respectively. As such, the NAVIGATE platform is a powerful AAV capsid discovery engine that can evolve capsids with improved properties in primates for potential use in future gene therapies.

502. Engineered AAV Capsids for Efficient Muscle Transduction in NHP

Shuyuan Chen, Zhenhua Wu, Xiaodong Pang, Shaoyong Li, Zhongwan Li, Runyuan Zhang, Guanlin Li, Xing Lan, Yuling Jiang, Yanyan Zheng, Changpeng Wan, Guo-jie Ye

Exegenesis Bio Inc., Lower Gwynedd, PA

Systematic administration of muscle tropic Adeno-associated virus (AAV) vectors containing therapeutic payloads represents a promising treatment for muscular dystrophy. Currently, very high doses of AAV are generally administrated intravenously due to relative low transduction efficiency of AAV capsids in the muscles. The administration of high dose AAVs has been reported to elicit significant adverse effects, particularly hepatic impairment. We aimed to engineer AAV capsids with enhanced muscle transduction and liver de-targeting profile. By using our AAVarta® platform, an AI-aided AAV capsid evolution discovery technology, peptide insertion capsid libraries based on AAV9 were generated and screened in non-human primates (NHP). The screening process relies on functional mRNA recovery in the muscles by using an in-house developed potent synthetic muscle promoter. Three weeks after intravenous administration of AAV libraries in the NHP, the muscle tissues were harvested for total RNA isolation. The capsid-specific primers were used for reverse transcription and PCR. The purified PCR products were subjected to Next-generation sequencing (NGS). The top capsid candidates were selected by AAVarta® enrichment ranking analysis and individually produced as recombinant AAVs for validation. In mice, one variant AVT919 showed significant improvements in cardiac and skeletal muscles over MyoAAV2A, a benchmark myotropic AAV capsid. In Cynomolgus macaque, AVT919 delivered via intravenous injection also demonstrated significantly enhanced transgene expression over AAV9 in the cardiac and skeletal muscles, while the transduction in the liver is comparable to AAV9. To reduce the ability of AVT919 targeting the liver, two focused libraries containing point mutations in different loops were generated. After screening in NHPs, certain AVT919 variants showed complete liver de-targeting while maintaining efficient muscle transduction as indicated by NGS data. Top candidates were selected and packaged with reporter gene for multiplex validation studies. By analyzing transgene expression level and genome copies in the tissues, several variants demonstrated efficient muscle transduction and liver de-targeting in NHP. In summary, these engineered myotropic and liver de-targeted AAV capsids could provide efficient and safer delivery platforms for muscle-targeting gene therapies.

503. Generating Human-Evolved, Cell-Type-Specific AAV Capsids for Targeted Gene Delivery

Alba Guijarro Belmar, Panayiota Demosthenous, Riccardo Privolizzi, Marta Zinicola, Hanna Luniak, Brandon Roberts, Devan Parmar, Calvin Chad Smith, Miranda Mathews, Andrew Murray

Sania Therapeutics, London, United Kingdom

Targeted delivery of therapeutic genes remains a defining challenge in gene therapy. The ideal viral delivery system would target the cell or tissue type of interest with minimal tropism for other cell types or organ systems. Highly directed tropism would also allow the vector to be administered at a low dose and enable local delivery of the gene therapy, limiting toxicity and associated immune responses. Adeno-associated viral (AAV) vectors are safe and versatile and have recently emerged as the preeminent delivery vehicle for gene therapies. The main advantage of AAVs is that their tropism can be directed towards a particular cell type by recombinant engineering of the capsid through directed evolution. This process has resulted in numerous novel and effective gene therapy vectors. However, the major drawback of directed evolution is the highly species-specific properties of the new vector, where the tropism of a particular vector can vary from one animal species to the next. As directed evolution strategies typically occur in animal models, this severely hinders the translation of novel AAV vectors into human patients in the clinic. Sania's approach to AAV vector development aims to generate novel, targeted vectors that can be successfully and rapidly translated into the clinic. Our proprietary platform, R-Scan, utilises a combination of human induced pluripotent stem cell (IPSC) derived cell types and microfluidics to perform directed AAV capsid evolution in an in vitro human system. The first clinical application for R-Scan is in the neurological space, specifically in neuro-muscular disorders such as spasticity. Spasticity causes severe and painful muscle contractions in patients due to hyperexcitable spinal motor neurons and we have used R-Scan to evolve AAV vectors that can target motor neurons directly via intramuscular injection. We first recreated this spinal-motor neural circuit using a combination of IPSC-derived motor neurons and myocytes in our R-Scan platform. To ensure we capture the phenotypic diversity of the human population we use a pooled line of IPSCs from multiple donors. For capsid screening Sania has generated 16 different

proprietary capsid libraries based on six parental serotypes and three diversification strategies - 1) random mutagenesis across the full length of the genome or to the external loops of the capsid, 2) insertions of random peptide sequences in specific locations of the capsids and, 3) insertion of rationally designed motifs known to target our cell type of interest. So far, R-Scan has generated multiple AAV vectors that show superior transduction of both human motor neurons in vitro and human neuromuscular organoids. Capsids generated from the R-Scan platform also show efficient transduction of mouse motor neurons following intramuscular injection, demonstrating translatability from our in vitro system to whole animal. Biodistribution analysis shows that intramuscular injection of our motor neuron targeted AAVs prevents vector spread and transduction in off target tissues. Additionally, we have shown that our novel capsids can be manufactured to similar titers as wild type vectors. We are further developing R-Scan so we can generate human-evolved vectors for multiple neuronal circuits and cell types. Ultimately, our goal is to utilise R-Scan to deliver targeted, safe and enduring AAV gene therapies for disorders of high unmet need.

Wednesday Posters: AAV Vectors - Non-Human Primates and Large Animal Models

504. CAP-002: Systemic AAV Gene Therapy with Next Generation Capsids for Treatment of STXBP1 Encephalopathy

Allison Knoll[1], Alberto J. Lopez[1], Troy Sandberg[1], Brandon Wheeler[1], Kenna Whitley[1], Lubov S. Grigoryeva[1], Pedram Davoodian[1], Matthew Frias[1], Mark Chin[1], Celeste Stephany[1], David Goertsen[1], Evan Walsh[1], Pasha Tchourilov[1], Hari Acharya[1], Paul Denis[1], Wu Chen[2,3], Joo Hyun Kim[2,3], Alysee Michaels[2,3], Armando Rivera[2,3], Yusuf Sham[2,3], Catalina Elwonger[2,3], Jose Paulo Carneiro[2,3], Mingshan Xue[2,3,4], Swati Tole[1], Nick Goeden[1], Nicholas Flytzanis[1], Susan Catalano[1]

[1]Capsida Biotherapeutics, Inc., Thousand Oaks, CA,[2]Department of Neuroscience, Baylor College of Medicine, Houston, TX,[3]The Cain Foundation Laboratories, Jan and Dan Duncan Neurological Research Institute at Texas Children's Hospital, Houston, TX,[4]Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX

Syntaxin-binding protein 1 (STXBP1) encephalopathy is a rare, devastating neurodevelopment disorder and epilepsy affecting approximately 1:30,000 newborns and caused by *de novo* heterozygous mutations in the STXBP1 gene, which regulates neuronal communication through presynaptic vesicle and neurotransmitter and neuropeptide release. Genetic mutations that impair STXBP1 function alter neuronal excitability and cause a variety of clinical features with no approved therapies today: treatment-resistant epilepsy, severe intellectual disability, speech and language impairments, movement impairments, behavioral disruptions, and early mortality caused by sudden unexpected death in epilepsy. We performed dose-ranging pharmacology studies in a Stxbp1 haploinsufficiency mouse model that closely recapitulates the phenotypes of human disease. These studies allow for a detailed interrogation of phenotypic correction across the behavioral domains of epilepsy and cognitive and motor impairment. Using three different doses that achieve varying levels of STXBP1 supplementation throughout the brain, behavioral results support that dose-dependent reversal of disease phenotype can be achieved across all three domains, with long-lasting correction out to a year post-intervention. These results demonstrate that AAV gene therapy has the potential to be disease-modifying and provide a long-lasting solution for the treatment of STXBP1 encephalopathy but requires the biodistribution and supplementation of STXBP1 protein in neurons widely across the brain. Using our high-throughput, non-human primate (NHP)-based AAV engineering platform, novel AAVs have been engineered to cross the blood-brain barrier and efficiently deliver therapeutic cargo at breakthrough levels throughout the brain after intravenous delivery. The CAP-002 candidate consists of one such engineered capsid packaging the human STXBP1 gene, that can achieve brain-wide distribution in up to 70% of neurons in the NHP, depending on brain area, at low to moderate doses, and supplement STXBP1 protein at comparable levels that reversed disease phenotype in the mouse model. This breakthrough profile of brain transduction, coupled with significant de-targeting of the liver compared to AAV9, allows CAP-002 to be delivered at lower doses than historically used with systemically delivered gene therapies, providing a greater therapeutic window for mitigating potential toxicities and pathology associated with high-dose intervention. This well-tolerated efficacy profile is expected to provide a disease-modifying solution and achieve meaningful prospect of direct benefit for patients suffering from STXBP1 encephalopathy.

505. Assessment and Comparison of Safety of AAV9 Bicistronic HexA/HexB Vector Following Cerebrospinal Fluid Administration in Nonhuman Primate and Ovine Models

[1]UMass Chan Medical School, Worcester, MA,[2]Tufts Cummings Veterinary School, North Grafton, MA

GM2-gangliosidoses - Tay-Sachs disease (TSD) and Sandhoff disease (SD) are neurodegenerative disorders due to mutations in the genes that encode the α (*HEXA*) & β subunits (*HEXB*) of the enzyme Hexosaminidase A. TSD and SD disease are clinically similar and manifest in infantile, juvenile, and late-onset forms. While infantile and juvenile patients face early mortality, late-onset patients can have a normal lifespan but are wheelchair bound. An ongoing clinical trial for infantile TSD and SD utilizing two monocistronic AAVrh8 vectors encoding HEXA & HEXB has shown positive effects on disease progression and increases in CSF HEXA expression in TSD patients. However, to circumvent the need for two vectors and bi-thalamic injections, a bicistronic AAV9 vector encoding both HEXA & HEXB cDNA (AAV9Bicis_HexA/HexB) was developed. Here, we evaluated

the safety of the AAV9Bicis_HexA/HexB vector in wild-type nonhuman primates (NHPs) and sheep.NHPs and sheep were randomly assigned to an AAV9Bicis_HexA/HexB treated (NHP: n=2; sheep: n=2) or a PBS control cohort (NHP: n=1; Sheep: n=1). AAV or PBS was administered through combined bilateral intracerebroventricular injection, cisterna magna, and lumbar intrathecal injections, with treated animals receiving a total of 2.38E14 vg (2.9 x the proposed patient dose). NHPs were immunosuppressed (prednisolone 1mg/kg), for 1 month starting at the time of injection followed by a taper. Animals received a baseline evaluation and were then monitored for 90 or 180 days by physical & neurological examinations, MRI, sensory nerve conduction velocities (NCVs), urine, CSF, and blood analyses. At the endpoint, animals were terminated, and tissues were collected for analysis. Postoperatively, the PBS NHP developed seizures which responded to Levetiracetam. All subsequent NHPs received Levetiracetam without incident. No other neurological signs were noted in this study. NCVs showed no differences between time points. Weight changes, calculated as a percent change from baseline, showed an initial drop which was regained by day 180 in NHPs. All sheep demonstrated expected weight gain. Elevated LFTs were noted in all animals during the 1st week, returning to normal range thereafter. CBC, chemistry, and urinalysis were otherwise unremarkable. Analyses of CSF revealed no detectable protein in NHPs, with pending cytospin microscopic analysis. At 90 days histopathologic evaluation showed mild nerve fiber degeneration in the cervical and thoracic dorsal root ganglion consistent with AAV administration. Histopathology for the 180-day NHPs and sheep is pending. Neutralizing antibodies were detected in all NHPs and one of the AAV treated NHPs had a positive ELISPOT to AAV9 at day 30. No positive ELISPOTs to the transgene were noted. Sheep NAb and ELISPOTS are underway.These findings highlight the safety profile of the bicistronic AAV9 HexA/HexB vector for the treatment of GM2-gangliosidoses. We also demonstrate the potential for sheep as a surrogate to NHPs to highlight toxicities associated with CNS-directed AAV gene transfer. Forthcoming studies will include analysis of MRI data, HexA enzyme activity, and AAV vector biodistribution.

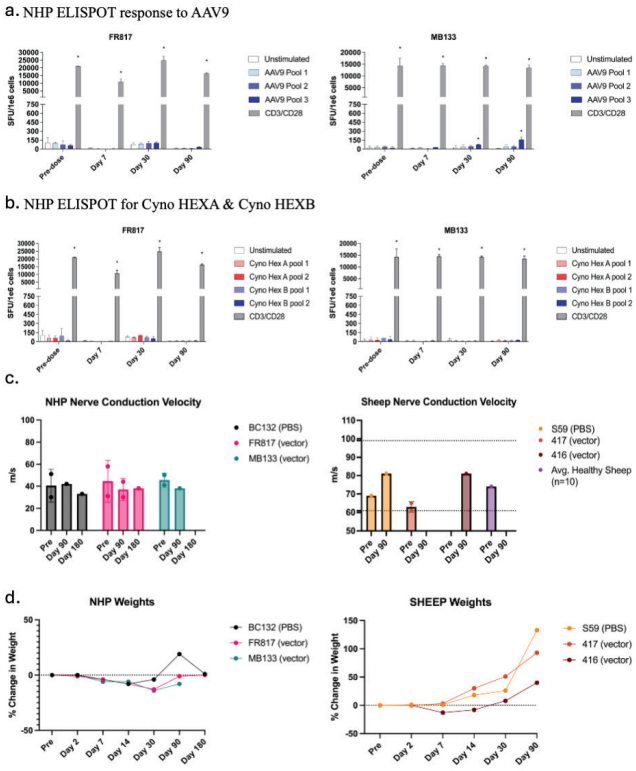

Figure 1. (a) ELISPOT response to AAV9 pools in treated NHPs (* indicates significant response). (b) ELISPOT response to Cyno HEXA & Cyno HEXB in treated NHPs. (c) NCV testing results comparison between models. (d) Fluctuations in weight as percent change from baseline, with a comparison between animal models.

506. Distinct Immune Signature of AAV9 Related Toxicity Following Intra-CSF Dosing of Cynomolgus Monkeys: Key Roles for IP-10, IP-9, MIG, IL-12 and IL-17

Ghiabe Henri Guibinga[1], Kelley Penraat[2], Xiaoguang Li[1], Justin Le[1], Jonathan Flynn[1], Sophie Lemire[3], Tony Del Rio[1], Keith Mansfield[2], Eric Johnson[2], Eloise Hudry[2], Emily Meseck[4], Fatih Ozsolak[1]

[1]Novartis, Biomedical Research, Biologics Research Center (BRC), San Diego, CA,[2]Novartis, Biomedical Research, Pre-clinical Safety (PCS), Cambridge, MA,[3]Novartis, Biomedical Research Disease of Aging and Regenerative Medicine, Data Science, Basel, Switzerland,[4]Novartis, East Hanover, NJ

Cells in the peripheral nervous system (PNS) and central nervous system (CNS) are the main intended targets of AAV9-mediated gene transfer, particularly when administered through intrathecal lumbar puncture (IT/LP). This method allows the AAV vector carrying the therapeutic gene to directly access the cerebrospinal fluid (CSF) cavity, potentially providing disease-modifying benefits for various neurological disorders. However, these benefits must be considered alongside the recognized toxicities associated with AAV9 IT delivery, such as immune cell infiltration and neuronal degeneration, which have been observed in non-human primates (NHP) in areas like the dorsal root ganglia, brain, and spinal cord. In our study, we utilized proteomic and multiplex-cytokine panels to analyze immune-related injury markers in CSF and serum samples from NHP following

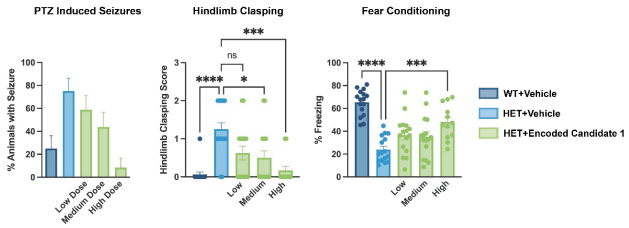
intrathecal delivery of AAV9. Our findings identify several cytokines and chemokines, including IL-12, interferon gamma induced protein 10 and 9 (IP-10 and IP-9) as well as monokine induced by gamma interferon (MIG), as potential key mediators of injury in the CNS and PNS after AAV9 intrathecal administration. The data demonstrate elevated levels of IP-10, IP-9, and MIG chemokines in the serum and CSF of NHP four weeks after AAV9-GFP intrathecal dosing. These changes in cytokines/chemokines may correspond to inflammatory and neurodegenerative events as evaluated through histopathology analyses. NHP treated with "empty" or transcriptionally inert AAV9-derived capsids did not show similar elevated levels of these pro-inflammatory chemokines, nor did they display apparent injury events in the CNS or PNS. Furthermore, the inclusion of miRNA-182 or/and miR-183 target sequences in AAV9-GFP encoding cargo to mitigate dorsal root ganglia (DRG) toxicity resulted in a reduction of GFP expression in cervical, thoracic, lumbar, and sacral DRG neurons. This reduction was accompanied by a lower incidence/severity of microscopic neuronal degeneration and immune cell infiltration. Specifically, animals treated with AAV9-GFP containing the double miR-182 and miR-183 elements exhibited the greatest reduction in GFP expression and the lowest incidence of DRG toxicity. However, in these animals, there was no simultaneous decrease in IL-12, IP-10, IP-9, and MIG levels in either the serum or CSF. Instead, a decrease in IL-17, a pro-inflammatory cytokine secreted by activated DRG satellite cells and known to be implicated in DRG-related neuropathic injury, was observed in the CSF and serum. Our data emphasize two distinct immune signatures following AAV9 intrathecal dosing in NHP: 1. The first immune signature is characterized by elevated levels of IL-12, IP-10, IP-9, and MIG, indicating broad immune-related events in the PNS and CNS that involves both innate and adaptive immunity and may extend beyond DRG toxicity. 2. The second immune signature is marked by changes in CSF and serum levels of the neuropathic-specific cytokine IL-17, which is present at the time of injury and may potentially be more closely associated with the incidence of DRG toxicity events. Therefore, if this is confirmed IL-17 could potentially serve as a more suitable marker for specifically tracking DRG toxicity in nonclinical studies.

507. Newly Identified Dorsal Root Ganglion-Enriched miRNAs Fail to Suppress AAV Transgene Expression *In Vivo*

Michael S. Fleming, Emily Crosier, Daniel M. Dubreuil, MiAngela Ramos, Shih-Ching Chou, Swathi Ayloo, Brenda Richards, Amy Richards, Shelley Nass, Bindu Nambiar, Denise Woodcock, Catherine O'Riordan, Martin Goulet, Christian Mueller, Shyam Ramachandran

Genomic Medicine Unit, Sanofi, Waltham, MA

Dorsal root ganglia (DRGs) sit at the interface of the central nervous system (CNS) and peripheral blood circulation. Due to their high vascularization by fenestrated capillaries and contact with subarachnoid cerebral spinal fluid (CSF), DRGs receive high exposure to AAV administered systemically or intra-CSF, often leading to significant transduction of DRG neurons. Recent reports have described subclinical histopathological findings in non-human primate (NHP), pig, dog, rat, and mouse DRGs following AAV administration. One mechanism hypothesized to underlie DRG toxicity is high levels of transgene expression in DRG neurons following AAV transduction. One approach to limit transgene expression in a tissue-selective pattern takes advantage of endogenous miRNA-mediated RNA knockdown and tissue-selective miRNA expression. Inclusion of miRNA target sequences in the UTR of an exogenous transgene can lead to the degradation of transgene transcript specifically in tissues endogenously expressing that miRNA. A recent study utilized DRG-enriched expression of miR183 to inhibit transgene expression in DRG neurons transduced by AAV, resulting in the prevention of histopathological findings in DRG. In this study, we aimed to replicate miR183-mediated detargeting of AAV expression while testing the DRG detargeting capacity of additional DRG-enriched miRNAs. We first identified DRG-enriched miRNAs from the literature and by small RNA sequencing of human and NHP DRGs, CNS tissues, and peripheral tissues. We identified seven miRNAs with enriched expression in human and/or NHP DRG relative to brain. We confirmed *in vitro* that the inclusion of the targets of these miRNAs, or miR183, in transgene UTR inhibited expression upon co-transfection with the matching miRNA mimic. We then administered AAV.GMU001 encoding a reporter gene and miRNA target sequences, either alone or in combination, to NHPs via an intra-CSF route of administration. We found no decrease in transgene expression in DRGs for transgenes containing targets of miR183 or the newly identified DRG-enriched miRNAs relative to an unmodified transgene. In a parallel study with a different reporter gene, we also found that inclusion of miR183 target sequences had no effect on transgene expression in NHP DRG. From these results, we conclude that miRNA-mediated detargeting of expression from primate DRGs may be context-specific and cannot be easily translated across different capsids, doses and/or transgenes.



508. Advancing Gene Therapy for STXBP1-Related Disorders Through Targeted Vector Engineering: Efficacy and Safety Results in Mice and Non-Human Primates

Rangoli Aeran, Annie Tanenhaus, Sheila Sears, Nathan Moerke, Adam Miller, Camille Artur, Yosr Bouhlal, Peter Bove, Alex Diaz de Arce, Saki Shimizu, Jason Le, Keith Place, Dixon Hoffelt, Jennifer Su, Ming Chen, Brooke Babineau, John McLaughlin, Myat Soe, Winnie Lin, Dhruv Bole, Kristen Valentine, Liz Hallam, Serena Liu, Puja Dhanota, Steven A. Tan, Ben Zhao, Raghu Hosur, Suresh Poda, Archana Belle, Stephanie Tagliatela

Encoded Therapeutics, South San Francisco, CA

Rationale and Methods: *De novo* heterozygous variants in the neuronal *STXBP1* gene cause severe, early-onset developmental and epileptic encephalopathy. Adeno-associated virus (AAV)-based gene replacement therapy offers the potential for a transformative, disease-modifying approach for *STXBP1*-related disorders. In proof-of-concept experiments, bilateral intracerebroventricular (ICV) injection of an AAV9-vectorized *STXBP1* transgene under the control of a ubiquitous (EF1a) promoter led to robust, dose-dependent transgene expression and rescue of key behavioral phenotypes in *STXBP1* haploinsufficient mice (*STXBP1*$^{+/-}$), supporting the viability of this approach. However, ubiquitous overexpression of the neuronal-selective *STXBP1* gene,

controlled by EF1a, led to off-target expression in non-neuronal tissues and DRG toxicity in non-human primates (NHPs). To address this limitation, we engineered potent, cell-selective promoters and DRG de-targeting elements to mitigate unintended effects. Through targeted vector engineering, we developed i. novel promoter cassettes to drive potent and selective *STXBP1* expression across excitatory and inhibitory neuronal cells, and ii. a novel 3'UTR regulatory element to de-target expression in the DRG. **Results:** In *STXBP1*$^{+/-}$ mice, optimized promoter candidates achieved robust neuronal expression and phenotypic rescue with minimal off-target expression. The addition of a DRG de-targeting regulatory element in the 3'UTR significantly reduced DRG transgene expression, while maintaining neuronal expression and behavioral rescue. In NHPs receiving a unilateral ICV injection, widespread vector biodistribution and consistent CNS transgene expression were observed. These vectors were well-tolerated for over 50 days with no adverse events post-administration. Furthermore, the 3'UTR DRG de-targeting element reduced DRG expression by 10-fold, rescuing DRG toxicity with no adverse histopathologic effects or nerve conduction alterations. **Conclusion:** Together, our preclinical studies demonstrate robust efficacy for these engineered gene replacement candidates in mice, with conserved expression and tolerability in NHPs. These data highlight the value of vector engineering and support continued development of a best-in-class gene therapy for *STXBP1*-related disorders. **Figure 1:** Dose-dependent rescue of tonic/clonic seizures, abnormal hindlimb clasping, and fear conditioning phenotypes in *STXBP1*$^{+/-}$ mice using a cell-selective promoter cassette to drive *STXBP1* expression.

509. Endoplasmic Reticulum Stress Induction at the Transcriptional Levels in the Liver of Non-Human Primates Dosed with Toxic Doses of AAV9PHP.B-CBh-SMN1

Pedram Moeini Gavgani[1], Elisabet Guruceaga Martinez[2], Thomas A. Lanz[3], Larry O. Whiteley[4], Gloria González-Aseguinolaza[1], Tomas Aragón[1], Carmen Unzu[1]

[1]DNA and RNA Medicine Division, CIMA, University of Navarra, Pamplona, Spain,[2]Bioinformatics Platform, CIMA, University of Navarra, Pamplona, Spain,[3]Pfizer Inc., Drug Safety Research & Development, Groton, CT,[4]Pfizer Inc., Drug Safety Research & Development, Cambridge, Cambridge, MA

Introduction: Adeno-associated viral vector (AAV)-mediated gene therapy has emerged as a leading *in vivo* gene delivery platform, particularly for treating rare diseases like spinal muscular atrophy (SMA). Despite its success, reports of serious adverse events and liver toxicity associated with the administration of high-doses of AAV (>1×10^{14} vg/kg) in both preclinical and clinical studies have raised concerns in the field. Liver toxicity manifests as elevated liver enzymes, liver failure and even death, and understanding the underlying mechanisms of hepatotoxicity has become crucial. Recently, recombinant AAVs have been shown to induce endoplasmic reticulum (ER) stress by overwhelming ER protein folding capacity and to promote the activation of the unfolded protein response (UPR). The UPR is a homeostatic mechanism that surveys the quality of protein folding within the ER to maintain normal proteostasis within the cell. However, in the event of unresolved stress the UPR can also promote apoptotic cell death. Since the UPR drives a well-established transcriptional response to cope with stress, the goal of this study is to analyze the transcriptomic signature of ER stress in RNA obtained from the liver of non-human primates (NHP) receiving increasing doses of AAV9PHP.B-CBh-SMN1, an investigational gene therapy for SMA, that caused severe hepatotoxicity. **Methods:** Principal component analysis (PCA), gene set enrichment analysis (GSEA) and the evaluation of the expression of UPR/ISR-specific genes were performed on RNA sequencing data from the livers of NHPs (males and females) and rats (males) receiving different doses of AAV9PHP.B-CBh-SMN1. 2×10^{13}, 5×10^{13} and 1×10^{14} vg/kg of AAV9PHP.B-CBh-SMN1 and sacrificed 4 days after dosing (Palazzi et al. 2021). **Results:** In NHPs, PCA analysis showed that RNAseq datasets clustering was driven by two principal parameters, dose and sex. In primate samples GSEA revealed the enrichment of genes related to cytotoxicity and genotoxicity as well as the loss of enrichment in genes related to liver function after high dose AAV administration. In contrast, in rats GSEA showed a clear enrichment of genes related to the IFN response and immune response, but not in toxicity-related genes, regardless of the AAV dose. Analysis of the expression of transcripts modulated by the integrated stress response (ISR) and either of the three independent UPR mechanisms revealed upregulation of the ISR related genes (PERK, GADD34, ATF4 and CHOP markers) and downregulation of BLOS1, CES1, CES2 and SCARA2 mRNA levels, indicating IRE1-dependent decay (RIDD) activation, in both male and female NHPs in a dose dependent manner. In contrast to NHPs, no activation of the ISR and IRE1 (RIDD) arms was observed in treated rats. **Conclusions:** Our gene expression analysis on liver samples of NHPs and rats revealed a dose-dependent activation of ISR/UPR in NHPs by rAAV9-PHP.B-CBh-SMN1 administration and suggests an important role for these cell intrinsic mechanisms in AAV-mediated hepatotoxicity in NHPs. We postulate that modulation of specific ISR/UPR mechanisms might provide an effective strategy to prevent hepatotoxicity resulting from high dose AAV therapies.

510. Expression and Distribution of AAV9 and a Novel AAV2 Variant Following Intrathecal and Subpial Administration in African Green Monkeys

Michael R. Weed[1], Addison Gralen[2], Ivette M. Sandoval[2], Kimicia Isaac[1], Ernell Nisbett[1], John Elsworth[1], Matthew S. Lawrence[3], Martin Marsala[4], Fredric P. Manfredsson[5]

[1]Virscio, Inc., New Haven, CT,[2]Barrow Neurological Institute, Phoenix, AZ,[3]Virscio Inc, New Haven, CT,[4]Department of Anesthesiology, University of California-San Diego, La Jolla, CA,[5]Barrow Neurologic Institute, Phoenix, AZ

Clinical efficacy of CNS-targeting AAV gene therapies has been limited by relatively narrow biodistribution and inefficient transduction of neurons after targeted CNS administration and intra-CSF AAV vector delivery. In the latter, transduction is often limited, with sporadic distribution of infected cells in various anatomical locations, but with a majority of transduction occurring in perivascular cells and in cells in close apposition to the choroid plexus. The current studies evaluated biodistribution and neuronal transduction of AAV9 and a novel AAV2 mutant, with modifications of the AAV2 capsid resulting in increased distribution and infectivity. AAV9 or AAV2 mutant vectors expressing green fluorescent protein (GFP) were administered to adult male (N=9) and female (N=9) animals into the lumbar intrathecal (L-IT), cisterna magna (CM) or C3-C4 subpial spaces (N=3 per vector/site). L-IT and CM administrations consisted of a dose of 5E12 vector genomes (vg) in 500 µL. Subpial administrations consisted of a dose of 1.5E11 vg in 300 µL. No adverse events were noted during the in-life portion of this study. Animals were euthanized 21 days post administration with the brains fixed intact for immunohistochemistry. Peripheral tissue samples were collected for vector biodistribution and transgene quantification. Postmortem evaluation of transduction shows that either capsid efficiently transduced brain parenchyma and cells in the spinal cord; however, efficacy was strongly dependent on delivery method, with IT and CM producing greater transduction of the parenchyma, and subpial delivery resulted in vastly improved transduction of the spinal cord.

511. High-Resolution Quantitative Analysis of Multiple AAV Capsids in Rodent and Primate Models Using Multiplexed Reporter Protein Tagging Platform

Matthew A. Child[1], Alexandra Tsolias[2], Charlotte Chung[1], Rupinderjit Kaur[1], Nilesh Pande[1], Amy Bruce[1], Chiso Egbuchulam[1], Jeff Thompson[1], Alexis Bloedel[1], Kyle Grant[1], Jeyashree Natasan[1], Ruohong Zhou[1], Dhiral Shah[1], Netsanet Gebremedhin[1], Mathieu E. Nonnenmacher[1]

[1]Voyager Therapeutics, Cambridge, MA,[2]Voyager Therapeutics, Inc., Lexington, MA

Technologies for directed evolution of Adeno-Associated Virus (AAV) capsid libraries have dramatically improved in the last decade, and the generalization of high-throughput functional *in vivo* screens (iTransduce, M-CREATE, TRACER™, TRADE, BRAVE, DELIVER, etc.) is generating vast number of capsids with promising characteristics. This abundance of capsid variants can generate a bottleneck at the characterization stage, especially in non-human primate models. For each capsid variant to move forward as a clinical candidate or an experimental tool, it is of paramount importance to acquire high-quality quantitative and qualitative data, such as viral genome quantification, transgene mRNA expression, percentage of transduced cells, cell type specificity and regional distribution. Existing platforms combining RNA barcoding and single cell RNA-seq have been validated with up to 30 capsid variants in a single animal, but they are limited by low spatial resolution and the lack of protein expression data. Here we designed a medium-throughput platform for simultaneous analysis of up to 10 capsid variants in a single animal while providing transgene DNA quantitation, transgene mRNA quantitation and transgene protein immunohistochemical detection. This was accomplished by 1) engineering a high-sensitivity reporter transgene scaffold to allow RNA and protein detection at low dose and 2) optimizing a series of C-terminally fused peptide tags that can be detected with distinct tag-specific antibodies. The Multi-Tag platform was first optimized in a mouse model using the neurotrophic 9P31 capsid and showed highly consistent detection in the brain at a well-tolerated dose. We then further demonstrated the validity of the platform in a 10-capsid pilot marmoset study and in cynomolgus macaque studies where we routinely tested 5 capsids per animal. Finally, we successfully demonstrated the compatibility of the multi-tag system with spatial transcriptomics in a mouse pilot experiment.

512. Efficient Intravenous Transduction of Schwann Cells in Neonatal Mouse

Yasemin Özgür Günes[1], Catherine Le Stunff[1], Andoni Echaniz-Laguna[2], Romina Aron-Badin[3], Pierre-François Bougnères[4]

[1]INSERM, Le Kremlin-Bicêtre, France,[2]Department of Neurology, APHP, Bicêtre Hospital, Le Kremlin-Bicêtre, France,[3]CEA, CNRS, Université Paris-Saclay, MIRCen, Laboratoire des Maladies Neurodégénératives, Fontenay aux Roses, France,[4]Therapy Design Consulting, Vincennes, France

We report a successful biodistribution study in peripheral nerves using intravenously administered rAAV9-MAG-GFP vector during the neonatal period (P10). Previous gene therapy attempts have used intra-thecal injections of AAV9 vectors *carrying Jet, Mpz, or CbH promoters* (Bailey 2018, Kagiava 2021, Bailey 2020 respectively). We confirmed the efficacy of this route of administration in 4 adult wild type mice and 1 adult *Macaca fascicularis* injected with rAAV9.MAG.eGFP (2E13 vg/kg) intrathecally. In this experiment, transgene expression was observed in >75% of Schwann cells in lumbar roots and in proximal regions of a peripheral nerve. Here, we generated a gene therapy mediated by a rAAV9 vector and the MAG promoter to deliver genes in mouse models of peripheral neuropathies. Four wild type mice were injected at the neonatal period at postnatal day 1 (P1) (n=2) and day 10 (P10) (n=2) with rAAV9.MAG.eGFP (5E13 vg/kg) through intravenous injections. We chose rodents of this age because the blood nerve barrier (BNB) is not functional before 13 days of life but that its function is established by 16 days. We observed transgene expression in >75% of Schwann cells in lumbar roots and in proximal parts of a peripheral nerve. This observation indicates that Schwann cells can be targeted via an intravenous route in the first few days of life.

513. Development and Preclinical Testing of an AAV-Based Gene Therapy Product for Parkinson's Disease

Teresa Torre-Muruzábal[1], Jose L. Lanciego[2], Anne Michel[3], Filip De Vin[1], Sofie De Munter[1], Tine Brouns[1], Duy Tien Ta[1], Caroline Eykens[3], Irina Thiry[1], Sofie Molenberghs[1], Kristel Vuerinckx[1], Kevin D'Ostilio[3], Maria del Carmen Romero Pita[3], Marcia Weber[3], Veronick Benoy[1], Michael Linden[3], Julie Tordo[3], Els Henckaerts[1]

[1]Trellis Research Group, KU Leuven, Leuven, Belgium,[2]Area de Neurociencias, Centro de Investigación Médica Aplicada (CIMA) and Centro de Investigación en Red de Enfermedades Neurodegenerativas (CIBERNED), Pamplona, Spain,[3]UCB Pharma S.A., Leuven, Belgium

Parkinson's Disease (PD) is a neurodegenerative disorder characterized by the progressive loss of dopaminergic neurons in the substantia nigra pars compacta (SNpc) and the appearance of intracellular α-synuclein inclusions. Besides motor symptoms, patients could also suffer from non-motor complications such as anxiety, depression and dementia and, currently available therapies are largely symptomatic. Aiming for a treatment that offers more than symptom control, we developed a gene therapy approach based on adeno-associated virus (AAV)-mediated overexpression of the lysosomal enzyme β-glucocerebrosidase (GCase). Mutations in *GBA1*, the gene which encodes GCase, are among the most common genetic risk factors for the development of PD. To select the most suitable construct, we created different ITR-containing transgene cassettes with promoters of variable strengths. After *in vitro* selection of the constructs, we produced AAV vectors and tested them *in vivo*. To achieve targeted delivery to the pathological brain areas, we used AAV-TT, a neurotropic capsid which has been shown to undergo efficacious retrograde transport in the brains of both small and large animal models. To deliver the therapeutic AAV, we performed intraparenchymal stereotactic injections in wild type rats as well as nonhuman primates (NHP). We assessed vector biodistribution and promoter strength in both models by analysing GCase expression and enzymatic activity in the target tissues. Leveraging the capability of retrograde transport of AAV-TT, administration of our selected construct in rat striatum induced an increase of GCase expression of 52% in the SN. Similarly, successful delivery to the SNpc in the NHP brain was achieved by administering bolus injections at 4 different sites in the caudate nucleus and putamen, which led to a significant increase of GCase activity in the SNpc compared to the contralateral hemisphere. Additionally, we tested the capability of our vector to travel retrogradely to the SNpc in NHP under conditions of MPTP-induced neurodegeneration, mimicking the level of neuronal damage present in patients at the time of treatment. Even with a severe dopaminergic lesion in the SNpc, expression of the GCase protein in the SNpc increased significantly after administration in the caudate nucleus and putamen. Finally, the AAV-based GBA1 therapeutic vector demonstrated potency and pharmacological efficacy in a rodent model of Gcase deficiency, and additionally led to neuroprotection and α-synuclein clearance in an NHP model of synucleopathy. In summary, these preclinical data demonstrate the early feasibility of an AAV-mediated GCase overexpression approach to treat PD.

514. Evaluation of a Novel AAV Capsid with Widespread CNS and Peripheral Biodistribution in Non-Human Primates

Jie Bu, Jessica Hogestyn, Swathi Ayloo, Jae Ryu, Ben Chou, Jeffery Ardinger, Miangela Ramos, Charles Miller, Lydia Blatnik, Yuxia Luo, Amy Richards, Catherine O'Riordan, Martin Goulet, Christian Mueller, Shyam Ramachandran

Genomic Medicine Unit, Sanofi, Waltham, MA

Lysosomal storage disorders (LSDs) are characterized by lysosomal dysfunction caused by the accumulation of toxic metabolites, leading to debilitating neurodegenerative symptoms. The current standard of care for many LSDs is enzyme replacement therapy (ERT), where recombinant enzyme is replaced via regular intravenous infusions. Gene therapy, the delivery of nucleic acids encoding a functional copy of the defective gene, is particularly suited for the treatment of LSDs, as they are typically well-characterized monogenic disorders. Furthermore, gene therapy has the benefit of being a one-time treatment, without the peak-to-trough fluctuations of ERT. Adeno-associated viruses (AAV) have emerged as the preferred delivery vector for neurological gene therapy due to their favorable safety profile and longevity of transgene expression in post-mitotic cells. However, clinical translation of AAV-based gene therapies has been limited due to the inability of naturally occurring AAVs to broadly transduce the human brain. We report here the development of a novel virus, AAV.GMU1, with improved transgene expression in non-human primate central nervous system (CNS) compared to the CNS-tropic AAVrh10. Importantly, AAV.GMU1 yields higher transgene expression compared to AAVrh10 at lower vector exposure in tissues, a finding with profound safety and dose-selection implications. Additionally, we evaluated AAV.GMU1 biodistribution by different administration routes relevant to the treatment of LSDs: intracerebroventricular (ICV), intra-cisterna magna (ICM) and intravenous. Both ICV and ICM infusions of AAV.GMU1 led to widespread transduction and robust transgene expression in the CNS, with ICV demonstrating enhanced exposure in subcortical brain regions. Safety findings were favorable for ICM, while bilateral ICV administration led to increased histopathological findings in the brain. Intravenous administration of AAV.GMU1 resulted in widespread systemic exposure and robust transgene expression in liver and different muscle groups. In summary, we present AAV.GMU1 for the treatment of LSDs requiring widespread therapeutic gene delivery throughout the CNS and peripheral organs.

515. Biodistribution Assessment across Eight Non-Human Primate Studies of AAV9 Uncovers Tissue Specific Variation in Virus Transcriptional Productivity

Muhammad Shahrukh, Tony Del Rio, Fatih Ozsolak

Novartis Pharma AG, San Diego, CA

Adeno-associated virus (AAV) based gene therapies have garnered significant attention and investment in recent years due to their commercial success in tackling retinal disease, spinal muscular atrophy, and hemophilia. These AAV vectors provide a means for effective delivery of therapeutic genetic material prompting disease

correction. When evaluating the safety and efficacy of recombinant AAV vectors, the biodistribution profile plays a critical role in novel therapy development. Herein, we performed a biodistribution metadata analysis of eight separate preclinical studies in which cynomolgus macaques (*Macaca fascicularis*) were dosed with versions of self-complementary or single-stranded AAV9 capsids equipped with chicken ß-actin or cytomegalovirus promoters expressing fluorescent reporter proteins. These studies cover a broad range of administration routes including intravenous (IV), intracisternal magna (ICM), and intrathecal lumbar puncture (IT) infusion. We provide unique insights into the biodistribution gradient that results from intrathecal infusion of self-complementary AAV9 in adult and juvenile cynomolgus macaques Through the metadata analysis of AAV9 biodistribution, distinct trends emerge that showcase variable transcriptional productivity of viral DNA, predominantly in the liver. To understand the observed difference in transcriptional productivity in liver tissues, we performed epigenetic profiling of tissue-localized viral DNA. These findings shed some light on plausible strategies to consider in preclinical development of AAV9 mediated gene therapies.

516. Non-Human Primate Evaluation of an Engineered AAV Capsid for Retinal Cell-Specific and Biofactory-Based Ocular Gene Therapies

Heikki Turunen, Amanda Miles, Barbara Diaz-Rohrer, Sarah Hilton, Sam Chen, Katie Maryak, Sam Sinai, Kathy S. Lin, Jamie Kwasnieski, Adrian Veres, Eric Kelsic

Dyno Therapeutics, Watertown, MA

Ocular diseases including glaucoma, wet age-related macular degeneration (AMD), geographic atrophy (GA) and inherited retinal diseases (IRDs) may be treated using new innovative gene delivery capsids that have safer profiles and are more effective at lower doses. To design novel AAVs with these properties, we iteratively train generative AI using in vivo data from cynomolgus monkey eyes injected with multiplexed AAV capsid libraries. Here we describe the characterization of a novel capsid discovered through this approach, which exhibits improved retinal cell transduction when compared to AAV2 and external engineered capsids, with favorable retinal cell-specificity and low ocular inflammation. To evaluate retinal transduction capability, cynomolgus monkey eyes were injected intravitreally (IVT) with a capsid library, or a single capsid. We measured transduction through bulk NGS, quantification of immunofluorescent histological images and expression of a secreted protein in ocular fluids from a biofactory approach. Bulk NGS measurements from variant-associated barcodes extracted from the retina indicate an 80x improvement over AAV2. Quantification of images indicate the novel capsid consistently outperformed a commonly referenced external engineered capsid, with a 2.6x increase in retinal transduction when co-injected into the same eye, each at ~1e11vg. Similarly a 2.5-3x increase in expression of the secreted protein in vitreous humor levels was seen when delivered by IVT injection compared to the external engineered capsid (~2-3e11vg). This improved biofactory-based expression directly demonstrates the novel capsid's high potential as a vector for delivering gene therapies to treat wet AMD, among other ocular therapies employing secreted payloads. Furthermore, no inflammation was observed when this capsid was delivered alone by IVT with a secreted protein reporter gene. Next, we evaluated the cell-specific transduction of the novel capsid by IVT delivery. We did this through single-nucleus RNA sequencing (snRNA-seq) and cell-specific immunostaining of histological sections. snRNAseq confirmed transduction of all major NHP retinal cell types, including ganglion cells, bipolar cells and rods. Cell-specific immunostaining also demonstrated ganglion cells were most highly transduced in the macula, whereas bipolar cells and rods were highly transduced in the peripheral and central retina. By snRNA-seq, this capsid showed 2-3x higher transduction across these cell types compared to the external engineered capsid, closely matching histology quantification results. These results demonstrate the potential of this novel capsid as a field-leading capsid for delivery of ocular gene therapies. Potential improvement in applications like biofactory-based gene therapy approaches for wet AMD or GA and higher cell specific targeting of cells including photoreceptors and bipolar cells for treatments of IRDs and optogenetic-based therapies are highlighted. With continued validation of capsids exhibiting high transduction or unique retinal cell specificity, we will continue to expand the applicability of AAV therapies to unique ocular disease profiles.

517. Swine Reporter Models for Somatic Cell Genome Editing

Jarryd M. Campbell[1], Rebecca Milliken[1], Sierra Long[1], Hinsoukpo Dagan[1], Dennis Webster[1], Derek Korpela[1], Daniel F. Carlson[2]

[1]Recombinetics, Inc., Eagan, MN,[2]Recombinetics, Eagan, MN

Delivery of gene editing reagents to the appropriate tissues and cells at an effective dose is a significant challenge for *in vivo* gene editing therapies. Rodent reporter models activated by recombinases or gene editing reagents have been indispensable for development of new delivery modalities. However, their small size and anatomy do not accurately mimic the effectiveness of delivery to large mammals. As part of the NIH Somatic Cell Genome Editing (SCGE) consortium, the Recombinetics Swine Reporter Models are swine models designed to track gene editing in any tissue or cell in the body. It does this by harboring a genetic reporter in every cell that can only be activated by gene editors like CRISPR or Base Editor or by Cre recombinase. Once activated, the reporter will permanently make fluorescent markers that can be used to track gene delivery in any tissue or cell in as soon as one week or in months to years even with non-viral vectors. The first Swine Reporter Model (SRM-1) harbors a genetic reporter that is based on the rodent Ai9 allele. The Ai9 allele has been modified to allow for activation by a SpCas9, SaCas9, AsCas12a, or Cre. The reporter is driven by a highly active and ubiquitous CAG promoter and was positioned at a safe harbor site by gene editing to avoid genotoxicity caused by the integration. After removal of a 3xStop cassette by CRISPR or Cre the cell will begin producing a fluorescent gene (tdTomato) and a sodium iodide symporter gene (NIS) that can be tracked by fluorescent activated cell sorting (FACS) or immunohistochemistry (IHC). The NIS gene also allows for non-invasive imaging of cell activation after injection with a radioactive iodide tracer using sensitive imagine modalities like single-proton emission computed tomography (SPECT) or positron emission tomography (PET). We intravenously

injected AAV9-Cre ($7.3x10^{12}$ GC/kg) into 3-week old SRM-1 piglet and collected 41 tissues after three weeks for analysis of AAV9 viral distribution and reporter activation measured by DNA recombination and tissue immunohistochemistry. AA9 injected in a male piglet was found to have widespread tropism with most accumulation in liver, muscle, adrenal glands, and testicular tissue. A subset of tissues was analyzed by immunohistochemistry, co-staining for tdTomato and NIS, to visualize the reporter activation. The resulting images showed clear and robust reporter activation can be visualized at the tissue and cellular level. The level of activation was highest in skeletal muscle, liver, and testicular tissue, followed by heart muscle, spleen, and no activation in the brain tissue. Overall, this experiment demonstrates the utility of the reporter for tissue- and cell-specific delivery of AAV. We next plan to deliver CRISPR editing tools by packaging mRNA with LNPs and delivering to the brain and liver to the reporter to further validate model utility. The second reporter animal, SRM-2, can be activated by adenine base editor and will also undergo *in vivo* validation studies. We anticipate these animal lines will be useful for both discovery studies of new delivery modalities and late-stage IND-enabling studies such as dose-escalation, pharmacokinetics, and pharmacodynamics analyses to streamline preclinical evaluation for gene editing-based therapies.

518. Determining the Maternal Safety of In-Utero AAV Gene Therapy (IUGT) Using a Sheep Model

Oluwaseun O. Babatunde[1], Martin Rodriguez[1], Sarah Wachtman[1], Jovanna Perez[1], Jennifer Wilson[1], Walaa Mohamed[1], William Vaughan[1], Anthony Atala[1], Christopher Doering[2], H. Trent Spencer[2], Christopher D. Porada[1], M Graça D. Almeida-Porada[1]

[1]Fetal Research and Therapy Program, Wake Forest Institute for Regenerative Medicine, Winston Salem, NC,[2]Aflac Cancer and Blood Disorders Center, Children's Healthcare of Atlanta and Dept. of Pediatrics, Emory University, Atlanta, GA

In utero gene therapy (IUGT) harbors the promise of curing a wide range of monogenic disorders and can preempt disease-induced organ damage that could occur during gestation, thus allowing for the birth of a healthy child. Still, ethical issues surrounding fetal therapies can never be overlooked, especially concerning the primary interests of the woman's well-being. Here, using sheep as a model, we investigated whether the pregnant ewes were affected by IUGT using AAV5-PGK-eGFP (n=4), AAV6-PGK-eGFP (n=3), and excipient alone (n=2). Here, using sheep as a model, we investigated whether the pregnant ewes were affected by IUGT when sheep fetuses at 60-65gd received PGK-eGFP-AAV5 or PGK-eGFP-AAV6 at a dose of $3x10^{13}$ vg/kg, or excipient as a control. All the injected fetuses were confirmed to be transduced by the respective vectors. Blood samples were collected from the pregnant ewes, prior to, immediately after, four days, and fourteen days post-AAV IUGT. Blood samples were analyzed by digital PCR (dPCR) for the AAV-eGFP transgene and the AAV-ITRs to determine whether circulating AAV DNA was present in the maternal plasma, and to assess whether circulating maternal blood cells had been transduced (eGFP and ITRs copies/cell).dPCR performed on plasma and hepatic tissue-derived DNA demonstrated AAV5- or AAV6-derived ITRs or eGFP were never present, at any time point, in the circulation or in the hepatic parenchyma of any of the ewes. In addition, ELISAs to detect anti-AAV5 IgG and anti-AAV6 IgG were performed on maternal plasma to determine if an immune response had developed against the AAV vectors. No anti-AAV5 or anti-AAV6 antibodies were detected in plasma samples collected from any of the ewes, either prior to IUGT or fourteen days post-fetal injection of AAV5-PGK-eGFP and AAV6-PGK-eGFP, confirming that after IUGT, AAV5 and AAV6 vectors are confined to the fetal environment and are absent in maternal circulation/tissues. In addition, we investigated whether delivery of AAV vectors to the fetus resulted in placental or cord tissue transduction by performing dPCR for the eGFP transgene and immunohistochemistry (IHC) for the eGFP protein. The copies/cell of AAV5-eGFP transgene in the placenta(s) and umbilical cord(s) were 0.5±0.3 and 0.5±0.4, respectively; and AAV6-eGFP transgene copies/cell in the same tissues were 0.00005±0.0007 and 0.06±0.04, respectively. However, despite the presence of copies/cell in placenta(s) and cord tissue(s), IHC revealed the absence of eGFP protein expression in all tissue(s) analyzed. Therefore, in the sheep model, IUGT using AAV5 or AAV6 vectors does not pose a risk for the pregnant ewes, and the placenta might serve as a selective barrier, preventing the passage of AAV vectors injected in the fetus to the ewe's circulation/tissues.

519. Defining *In Vivo* Biodistribution and Transduction Efficiency of AAV5 and AAV6 Vectors for *In Utero* Gene Therapy Using a Fetal Sheep Model

Oluwaseun O. Babatunde[1], Martin Rodriguez[1], Sarah Wachtman[1], Jovanna Perez[1], Jennifer Wilson[1], Walaa Mohamed[1], William Vaughan[1], Anthony Atala[1], Christopher Doering[2], H. Trent Spencer[2], Christopher D. Porada[1], M Graça D. Almeida-Porada[1]

[1]Fetal Research and Therapy Program, Wake Forest Institute for Regenerative Medicine, Winston Salem, NC,[2]Aflac Cancer and Blood Disorders Center, Children's Healthcare of Atlanta and Dept. of Pediatrics, Emory University, Atlanta, GA

AAV gene therapy (GT) for hemophilia A (HA) was poised to fulfill the promise of a safe, affordable, correction after a single treatment. Yet, clinical trials (CT) have underscored the risk of hepatoxicity and genotoxicity in adult HA patients receiving GT. Also, pre-existing AAV immunity prevents CT eligibility, and it is unknown whether GT will avoid induction of FVIII inhibitors. We hypothesize that performing in utero AAV-based GT (IUGT) will enable correction prior to birth circumventing both AAV- and FVIII-related immune hurdles. Here we used fetal sheep to define in-vivo biodistribution and transduction efficiency of AAV5 and AAV6 vectors encoding eGFP, under the control of the constitutively active PGK promoter, after IUGT. Sheep fetuses at 60-65gd (equivalent of 16-18gw in humans) received PGK-eGFP-AAV5 (n=6), PGK eGFP-AAV6 (n=8) at a dose of $3x10^{13}$ vg/kg or excipient (n=4). Fetal tissues were analyzed at 14 days post IUGT by digital PCR (dPCR) to determine eGFP and ITRs copies/cell. PGK-AAV5-eGFP transgene copies/cell in the brain, lung, duodenum, spleen, thymus, reproductive organs, kidney, heart, liver and bone marrow were 0.7±0.4; 1.7±0.7; 9.9± 3.0; 18.2±7.9; 3.7±2.4; 10.4±5.9; 3.5±1.3; 3.5±1.5; 2.4±0.6 and 0.13±0.006 respectively, and PGK-AAV6-eGFP transgene copies/cell in the same organs were 0±0.00; 0.013± 0.01; 0.05±0.02; 0.014±0.007; 0.1±0.06; 0.06±0.032;

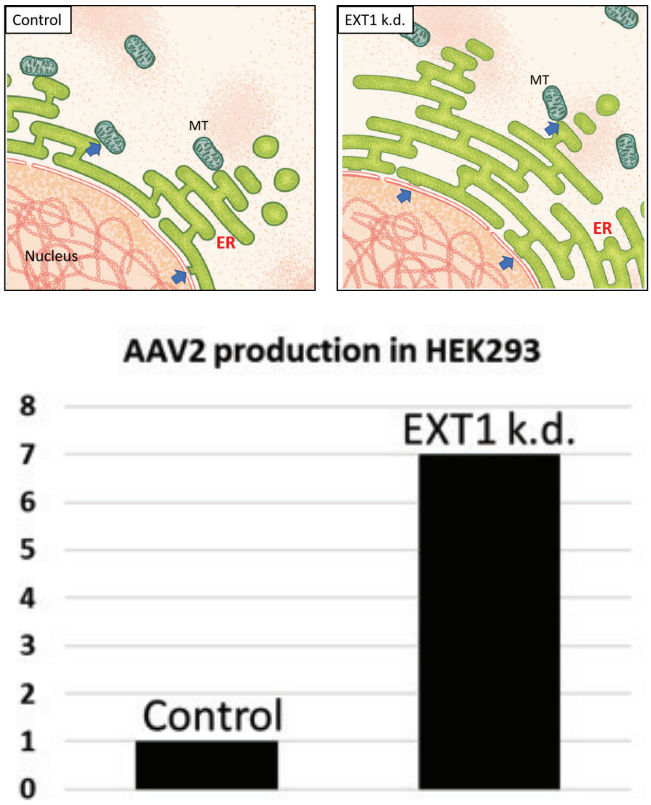
0.03±0.02; 0.03±0.005; 0.07±0.02 and 0.08±0.04 respectively. RT-dPCR for eGFP mRNA on liver, lung, and spleen of AAV5 animals were 40.4±27.9; 30.5±12.9; 64±27.8 per 10,000 copies of RPL13A and AAV6 44± 23.6; 2.8±2.4; 6±3.5 all per 10,000 copies of the housekeeping gene RPL13A. Immunohistochemistry (IHC) was performed for the detection of the eGFP protein and ELISA to quantify the of amount eGFP expressed in the liver and lungs of the different animals. Animals that received AAV5 and AAV6 had 96.5±45.9 and 20.5±14.4 pg/ml of eGFP protein in the lungs and 121±45.6 and 338±131.8 pg/ml in the liver respectively. In summary, both AAV5 than AAV6 transduce the majority of the organs during the prenatal period with AAV5 exhibiting higher transduction efficiency than AAV6 except for the bone marrow. Nevertheless, despite higher copies/cell of AAV5 in the liver than AAV6, the two AAV serotypes exhibited similar copies of eGFP mRNA transcripts with AAV6 translating into more GFP protein than AAV5. However, the eGFP transcripts were translated into more protein in the livers transduced with AAV6 than AAV5, underscoring the need for further studies to investigate the mechanism(s) by which the AAV capsid can influence transgene expression independent of vector copy number in the target cell.

Wednesday Posters: AAV Vectors - Product Development Manufacturing and Approval Considerations

520. Breaking Boundaries in AAV Production: Exploiting High Salt Concentrations for Enhanced Process Efficiency

Dmitry Zabezhinsky

Merck Life Science KGaA, Darmstadt, Germany



Enhancing adeno-associated virus (AAV) production is of utmost importance in the field of gene therapy. In this study, we have confirmed previous approaches to boost AAV production utilizing higher salt concentrations during the lysis process. Our research yielded impressive results, demonstrating that elevated salt levels, such as 500mM, effectively enhance AAV process intensification by eliminating adhesive DNA from the AAV capsids and reducing aggregation. However, it is worth noting that high salt concentrations exceeding 200mM hamper the activity of standard endonucleases, which are virtually inactive at high salt environment. To overcome this challenge, we have engineered a cutting-edge enzyme called the Benzonase® Salt Tolerant Endonuclease, specifically designed to function optimally in high salt conditions ranging from 500-1000mM. This remarkable enzyme efficiently digests DNA fragments shorter than 10 base pairs and remains fully compatible with commonly used detergents. By incorporating 500mM salt in the lysis buffer, we have achieved remarkable outcomes. Our experimental results indicate a substantial improvement in AAV titers by 20-30% (evaluated using ELISA) and a remarkable 10-fold enhancement in viral transduction capability. These findings provide valuable insights to intensify AAV production, solving one of the key bottlenecks of the gene therapy industry: AAV production yield. The design of this new Salt Tolerant IPEC GMP endonuclease also contributes to meet the highest patient safety standards.

521. Enhancing Viral Vector Production Through Genetic Engineering of Host Cells

Maximilien Lopes, Jean-Claude Twizere

Viral Interactomes Networks, University of Liege, Liege, Belgium

Our engineered Extra-HEK293-AAV cell line boosts viral vectors production by two to sevenfold. Viral vectors stand out as widely used and effective delivery agents of gene therapies. However, one of the main challenges confronting their manufacturing lies in the scaling up of production and addressing the relatively low productivity of host cells, leading to high production costs. In practice, large dosages are required for patient treatment and these viral vectors are packaged in mammalian cells such as human embryonic kidney (HEK293). In the pursuit of enhancing the quantity and quality of gene therapy products, ongoing efforts focus on refining upstream and downstream processes, including culture medium composition, transfection agents, and purification techniques. As a complementary strategy, our focus is directed to the optimization of host cells intracellular machinery required for viral vector production. Specifically, our approach involves genetic engineering of HEK293 cells, designed to yield higher quantities of viral vectors at an industrial scale. We previously demonstrated the regulatory role of the Exostosin 1 (EXT1) glycosyltransferase enzyme in shaping the morphology and dynamics of the Endoplasmic Reticulum (ER). Through the targeted reduction of EXT1 gene expression using shRNAs, multiple pathways are impacted, influencing ER network and associated cellular processes. These observations led us to consider potential applications of depletion of EXT1 in enhancing the efficiency of biomanufacturing. The subsequent work resulted in an improved capacity of the cells to generate recombinant viral vectors, with a production multiplied by a factor of 2 to 7. Following our findings, validation studies were conducted comparing the production capabilities of wild-type cells against the modified cells at the laboratory scale. Subsequently, we adapted our solution from adhesion culture to suspension culture, using serum-free media, a critical step for widespread industrial adoption. This transition was succeeded by a scaling-up phase, incorporating the use of fixed bed bioreactors for adhesion culture and stirred tanks for suspension culture. Recognizing the significance of accurate cell characterization in the pharmaceutical industry and considering the abundance of HEK293 derivatives cells, we took a proactive approach by creating a comprehensive identity card for our cells. This was achieved through a multi-omics study, encompassing the whole genome sequence using NGS PacBio HIFI, transcriptomes analysis using Illumina, and targeted metabolomics. The whole genome sequence facilitates the precise identification of this cell line, when used in highly controlled clinical settings. The transcriptomics and metabolomics data will contribute to the study of the impacted pathways following the EXT1 knockdown, revealing the regulatory mechanisms that underscore the enhanced productivity. Future studies aim to investigate complementary gene interplays and refine the optimization of this HEK293 cell line to produce recombinant biomolecules.

522. Fit from Development to Manufacturing - A Successful rAAV9 Scalability Study in a Suspension Process Using HEK293

Matthias Boscher, Johanna Wagner, Sinisa Petrik, Jared Babic, Beatriz Larena Carnio, Dila Bitnel, Sirri Ndonwi, Regina Staffler, Johanna Weizenegger, Eleni Tsiaousi, Christos Mantzoros, Tobias Kloetzler, Marina Magerl, Gora Matthias, Anita Heinlein, Henze Sandra, Christine Zach, Sebastian Ritter, Andreas Schulze, Alexandra Schobert, Melanie Langhauser, Karl Heller, Markus Hoerer, Ahmed Youssef

Ascend Gene and Cell Therapies GmbH, Planegg, Germany

Design of experiment (DoE) approaches performed in robust scale-down devices such as small-scale bioreactors for upstream process development allow product specific optimization of modular platform processes at speed and with reasonable development costs. However, scaling up the process to larger bioreactors can be challenging. To stay in a single provider's system for all scales can be a good starting point, as most of them already deliver a homologue vessel height to diameter ratio as well as respective impeller, baffles, and sparger designs. But as often in sensitive biological systems, this is not enough. Several process specific and defining conditions like mixing time, power input, impeller tip speed or oxygen transfer rate (OTR) cannot be kept constant together throughout all scales. Also, factors independent of the bioreactor but dependent on scale, such as process parameters and volumes of the cell seed train, must be considered, as they can impact the cell's performance. The aim of this study is to demonstrate scalability of AAV productivity and consistency of product quality across all different bioreactor scales of Ascend's AAV manufacturing platform offering. Many critical quality attributes related to product impurities including full/empty ratio, residual plasmid and host cell DNA (HCD) packaging are strongly determined by the design and choice of the biological starting materials and the upstream process. Therefore, we consider it essential to scale-up processes with the target of consistent quality and productivity across all scales to be able to support our clients across a product's life cycle. This in turn necessitates robust, fit for purpose analytics allowing in-depth product characterization. Here we present AAV batch data from 250 mL to 200 L bioreactor size using several proprietary analytical methods to assess both quantity and quality of the material generated. In summary, we demonstrate a successful scale-up of the upstream process of our modular AAV manufacturing platform using our split two plasmid platform, from bench-scale to 200 L production scale meeting our stringent development target of consistent quality at expected volumetric yield increase. Our commitment to our clients is to support development of their products through all stages, from early preclinical and tox studies to Phase 3 and commercial manufacturing with a de-risked CMC regulatory pathway.

523. Enhanced Transfection Complex Performance for AAV Production

James J. Ludtke[1], Nicolas Rossi[1], Yuyuan Wang[1], Oksana Hart[1], Neha Andhole[1], Austin Stork[1], Jennifer Swanson[1], Becky Reese[1], Laura Juckem[2]

[1]Mirus Bio LLC, Madison, WI,[2]Mirus Bio, Madison, WI

Adeno-associated virus (AAV) has emerged as a leading platform for gene delivery for the treatment of a variety of human diseases. AAV manufacturing is an expensive and relatively complicated multi-step process, which often includes transient transfection, harvest, downstream processing, quantitation and quality assessment. The transient transfection step of AAV manufacturing is arguably the most critical step for efficient AAV production, and is dependent on a robust and reliable transient transfection protocol. Transitioning to large-scale bioreactors is required to meet the increasing demand for AAV gene therapies. The scale-up process of generating transfection complexes presents several technical challenges involving the combining and mixing of large volumes of liquids, a complex formation incubation period, followed by transfer to the bioreactor. Transfection complexes can have a relatively short time window for optimal transfection efficiency, compromising flexibility and convenience within the upstream workflow. Optimal transfection complex formation times (TCFTs) vary from as short as 10 minutes to up to 60 minutes, depending on the transfection reagent and transfection complex specifics (complex formation buffer, DNA concentration, reagent-to-DNA ratio, etc). Mirus Bio has developed tools that can extend the optimal TCFT. Transfection complexes formed with the modified formulation and/or workflow have optimal TCFTs from between 30 minutes to greater than 2 hours. This increased window allows manufacturers to more consistently achieve the optimal time for transfection complex formation reducing the risk of compromised performance and/or failed runs. Data will be presented showing the particle size of the transfection complex via dynamic light scattering and AAV genome and capsid titers. Stabilization will be assessed with

varying transfection formulations, ranging from multi-component lipid and polymer formulations to single component polymeric compounds. The effects of AAV serotype and gene of interest will also be evaluated. The data presented in this poster illustrates extended TCFTs while at the same time generating maximum AAV titer and percent full capsids. This will shift the paradigm for reproducible and large-scale production of AAV by transient transfection.

524. Comparability Study Between Ion-Exchange Monolith and Affinity Resin for Purification of AAV8

Janja Merkelj Koren, Rok Žigon, Andrej Mihevc, Marko Šnajder, Maja Leskovec, Aleš Štrancar

Sartorius BIA Separations, Ajdovščina, Slovenia

The main objective of every downstream process of Adeno-associated virus (AAV) is to achieve high recovery while delivering the purest, most potent product possible. In manufacturing setting capture step is either affinity or cation exchange chromatography, which both concentrate the product and remove impurities. Following capture, the eluate is generally further processed on anion exchange monolith to enrich full capsids and further reduce impurities. In this poster, a side-by-side comparison of capture step on CIMmultus SO3 column and commercially available affinity resin, followed by polishing on CIMmultus QA will be presented. Results will show process and step recoveries, measured by two orthogonal analytical methods -dPCR and PATfix. Comparison will include impurity reduction, with final full AAV purity by PATfix and mass photometry, residual hcDNA, pDNA, host cell protein and endotoxin data. Product column capacity will be presented for both process strategies. Finally, processing time will be calculated and discussed.

525. Unveiling L4-22K and -33K as Novel Adenovirus Helpers for Improved AAV Manufacturing

Michael Gapinske[1], Eduardo Aguilar[1], Brandon S. Razooky[1], Andy Tran[1], Kailey Myers[1], Kenny Shimada[1], Christos Galanis[1], Alexandra Cole[1], Min Zong[1], Raquel Vega[1], Gilad Doron[2], Bryan St. Germain[2], Jason Carte[1], John F. Kerwin[2]

[1]Resilience, San Diego, CA,[2]Resilience, Waltham, MA

Adeno-associated virus (AAV) gene therapy has emerged as a promising therapeutic avenue for a myriad of genetic disorders, leveraging the inherent ability of AAV vectors to deliver and express therapeutic genes in target cells. Producing AAV requires the expression of a multitude of proteins and RNAs, categorized into 4 classes; Capsid (Cap), Replicase (Rep), the transgene of interest (GOI), and Helper. For the last 25 years, the established dogma has maintained that the minimally sufficient system for maximal AAV productivity using Adenovirus Helpers only requires the proteins E2A DBP, E4orf6, E1A, and E1B-55K as well as the viral-associated RNA (VARNA). Here, we present an additional Adenovirus gene, L4-22K/33K, as a necessary component for maximal AAV productivity. We utilized a comprehensive screening approach, dissecting a canonical Adenoviral helper plasmid to determine the L4-22K and -33K protein products are required for high-titer AAV production. These findings facilitated the development of a novel Tetracycline-inducible Helper system with a 100-fold improvement in AAV production over a system lacking the L4 gene, improving our ability to generate a stable cell line for the production of AAV.

526. The Potential of Global Regulatory Harmonization in Gene and Cell Therapy

Claire Marasco, Ashley Marie Shay, Christopher J. Shilling

Regulatory Affairs, Forge Biologics, Inc., Grove City, OH

Global regulatory convergence has the potential to enable faster and more widespread patient access to gene therapy products, especially for rare disease indications. Even so, with 10 in vivo gene therapy approvals in at least 11 global regions over 7 years, the progress toward convergence is unclear. Success in this area has been demonstrated by Project Orbis. Project Orbis, conducted through FDA's Oncology Center of Excellence, has facilitated the parallel review and 205 total approvals of 75 unique oncological drugs in the US, Australia, Canada, UK, Singapore, Israel, Brazil, and Switzerland. With these successes in mind, Project Orbis has been discussed at major industry conferences as a potential model for a gene therapy global regulatory framework. Regulatory frameworks that may be leveraged exist today, including parallel scientific advice, equivalent designation pathways and conditional marketing authorizations. These frameworks will be discussed in this presentation. Though commercial in vivo gene therapy has arrived in at least 11 regions, these approvals are concentrated in the US, EU, and UK. That said, the global industry continues to make important steps toward convergence in the gene therapy regulatory environment. This presentation will share the case studies of industry groups creating "playbook" approaches to gene therapy development that have the potential to expand to a global scope. Further, the presentation will discuss the actions that regulators and standards-coordinating bodies are taking to promote convergence, like ATMP cluster teleconferences, the IPRP, APEC, and the WHO gene therapy regulatory framework. Recently, Dr. Peter Marks from US FDA announced the CoGenT Pilot to promote global collaboration in the regulation of gene therapy products. This is an exciting basis on which harmonization could flourish in this industry, especially as it draws many parallels to Project Orbis, which will be discussed in this presentation. With robust discourse and careful alignment on expectations and priorities in the evaluation of gene therapy products, there is an opportunity to create the scale of success seen with Project Orbis for gene therapies, enabling access to life-changing medicines for patients across the globe.

527. From Benchtop to Cleanroom; Designing an Optimized Platform Purification Process for rAAV Production to Meet the Growing Demand

Blake Gursky, Corben Davis, Smita Menon, Keerthana Subramanian, Ganesh Krishnamoorthy, Frank Agbogbo, David Dismuke

Forge Biologics, Grove City, OH

Recombinant adeno-associated virus (rAAV) vectors have garnered significant attention from the gene therapy community, with their proven clinical success in addressing debilitating chronic diseases

and conditions. However, a major challenge lies in developing an optimized, cost-efficient, and scalable purification process for all rAAV serotypes, including novel capsid designs, to meet the growing global demand for these therapies. Capital investment, time to perform development, high vector requirements, and manufacturing expertise all pose potential obstacles for gene therapy developers. At Forge Biologics, we introduce a tailored downstream platform process designed to support expedited therapeutic rAAV pipeline programs, delivering high yield and high product quality. In our platform process, crude lysate from the optimized upstream process is clarified using systematically tested depth filters. Following clarification, the rAAV vector is captured using a predetermined resin-buffer combination, based upon our experience with multiple serotypes. Depending on the outcomes, a more customized affinity resin process with specific buffer conditions is incorporated into the process for high recovery and product quality. Subsequent enrichment of the vector material involves separating full capsids from empty capsids through either cesium chloride ultracentrifugation or anion exchange chromatography. The method of enrichment is determined by program needs and timeline. The final step involves taking the full rAAV capsids through the final formulation process and filling the drug product utilizing state of the art fill/finish processes. This process yields a highly pure rAAV suitable for early preclinical applications, toxicological studies, or clinical use. At the start of a typical project, process parameters are determined at a 1L scale and then scaled up to larger batch sizes, reaching up to 1000L, depending on the specific client's needs. The success of each purification step is verified through stage-appropriate analytical testing, including GOI titer by ddPCR, residual plasmid DNA by ddPCR, product purity by SDS-PAGE or capillary electrophoresis, genome integrity through next-generation sequencing, empty:full particle ratio by analytical ultracentrifugation, potency through qualified cell-based assays, residual host cell DNA, residual host cell protein, endotoxin, and other relevant tests. This presentation will cover key experimental highlights in the development of Forge's platform purification process.

528. Development of a Scalable Upstream Process for Suspension HEK 293 rAAV Production in Single-Use Bioreactors for Efficient Manufacturing of Gene Therapy Products

Danielle Sexton[1], Jessie Chua[2], Steven Wesel[1], Frank Agbogbo[3], David J. Dismuke[4]

[1]ForgeBiologics, Grove City, OH,[2]Process Development, ForgeBiologics, Grove City, OH,[3]Forge Biologics, Grove City, OH,[4]Forge Biologics, Columbus, OH

The need to supply large patient populations with gene therapy medicines produced using recombinant adeno-associated virus (rAAV) vectors continues to increase with scientific advancement, positive clinical data, and commercial approvals. A pivotal challenge has involved the bottleneck associated with vector yield from suspension bioreactors and establishing a scalable production process. Forge Biologics has developed a platform process based on the transient transfection of Ignition™ HEK293 cells in single-use bioreactors, which has allowed us to help our clients navigate from benchtop to clinic more quickly than traditional development pathways. Our targeted process development approach leverages the benefits of a platform while also allowing clients the ability to optimize critical parameters to ensure overall process robustness. To further enhance yields and productivity, especially for lower-producing serotypes and problematic gene of interest (GOI) vectors, additional examination of growth and purification processes can often lead to substantial improvements in vector yield. This presentation will provide examples of process optimization studies at the plasmid design, transfection, and harvest steps. Product-specific enhancements can include transfection DoE studies, capsid design and screening, and lysis and harvest optimization. The transfection process can often be enhanced by evaluating plasmid DNA (pDNA)/reagent complexes for entry into cells or by changing the ratios of three plasmids traditionally used in rAAV productions. The data presented explores the optimization of transfection parameters, including plasmid ratios, DNA/cell, PEI/DNA ratios, transfection reagent, and feeds. Capsid design and screening can establish effective rAAV rep/cap plasmids, which are critical for yield and quality in rAAV production. Data will be presented on how the manufacturability of rAAV can be improved through optimization of the rep/cap design. Some rAAV capsids, such as rAAV2 and rAAV6, bind to the cell mass, which should be considered for lysis, harvest, and clarification optimization. The data presented demonstrates that harvest timing and lysis conditions can improve the release of the rAAV from the cell debris for improved vector recovery. Beyond these product-specific enhancements, Forge Biologics systematically characterizes the platform across multiple scales. This comprehensive approach enables efficient progression through process development and facilitates the adjustment of manufacturing processes to achieve optimal yield and reduced variability. Data including cell growth and productivity impacts of process improvements will be shared.

529. Characterization of Engineered AAV Capsids from Different HEK293 Cell Culture Fractions, Crude Lysate versus Cell Pellet Material

Heidy Morales, Hari Acharya

Capsida Biotherapeutics, Inc., Newbury Park, CA

Recombinant adeno-associated virus (rAAV) has emerged as a promising delivery vehicle for gene therapies. Building on the capabilities of wildtype AAV serotypes, engineered capsids with improved tissue tropism and reduced toxicity are being developed. Engineered capsids create opportunities to address unmet medical needs for both rare and common diseases across all ages. As the therapeutic space expands, so does the need for higher yielding production processes with consistent product profiles. The main production platform for rAAV uses triple transient transfection of HEK293 cells. Typically, cells are expanded to a target density, transfected with plasmids, incubated, and lysed to harvest the product. Crude lysate includes product from both the supernatant and cell pellet fractions. How does the distribution of product and attribute profile compare between these fractions? Here, we characterize the material from the different cell culture fractions (crude lysate (CL), cell pellet lysate (CPL), supernatant (SN)) and assess product distribution. We also compare material taken through an affinity chromatography capture step or an iodixanol ultracentrifugation step to understand the impact on attribute profiles. The respective downstream trains

offer different benefits for high-throughput screening work. We find the product is not evenly distributed between the fractions and the attribute profile varies (e.g, residual DNA, host cell protein, %fulls). Information generated from characterizing the different fractions can be used to adjust incubation durations, harvest approaches, and downstream processing.

530. Alternative Plasmid Designs Including Two Plasmid Transfection Systems for Improved Production and Packaging of Engineered AAV Capsids

Lysa-Anne Volpe, Jenna Rodden, Heidy Morales, Garrett Garrido, Hari Acharya

Capsida Biotherapeutics Inc., Thousand Oaks, CA

Recombinant adeno-associated virus (rAAV) vectors are one of the most promising delivery systems for gene therapy. Building on the success of wild-type AAV serotypes, engineered AAV capsids for in vivo gene delivery are being developed to improve target tissue tropism, increase transduction efficiency, and reduce toxicity. These novel capsids create opportunities to address unmet medical needs for both rare and common diseases across all ages. The increasing use of engineered capsids in clinical trials has highlighted the need for scalable, higher-producing, cost-effective processes to meet the material and quality demands for commercial manufacturing. To date, triple transient transfection with plasmids is the most common and widely used platform for rAAV generation due to its ease, flexibility, and speed for sequence modification. Although effective, the three-plasmid manufacturing system is complex to optimize, requires higher costs of critical raw materials, and can lead to lot-to-lot variability. Here, we report the development of a two-plasmid transfection system and compare production and packaging performance to our triple transient transfection process. Various plasmid configurations were explored to identify design benefits and functional components to group together. To assess plasmid design impacts, various process conditions were evaluated, including performance in HEK293 cell lines, plasmid backbone selection markers, plasmid molar ratio, DNA input, and transfection reagent optimization. Evaluation of the transfection systems were performed using a HEK293 suspension production process at small scale and purified rAAV particles were measured for encapsidated residual plasmid and host cell DNA levels. Preliminary results from these studies display improved viral production, higher percentage of full particles and decrease in packaged residual DNA impurities.

531. Membrane Chromatography for Preparation of AAV at the Manufacturing Scale

Julio Miguel Huato, Aydin Kavara, Mark Schofield, Kurt Boenning

Cytiva, Westborough, MA

The recent FDA approval of several adeno-associated virus (AAV)-based gene therapies is driving demand for AAV production. One of the biggest manufacturing challenges is removing "empty" capsids, which do not contain the gene of interest. Anion exchange chromatography has emerged as a solution for scalable empty and full capsid separation. Here we develop a process for baseline separation of empty and full AAV capsids using Mustang Q anion exchange membrane chromatography. This process development approach utilizes AAV serotypes 5, 8, and 9 and traverses initial screening using Mustang Q XT 0.86 Acrodisc unit up to manufacturing-scale processes with Mustang Q XT 140. Process development of a two-step elution was performed via response surface DoE, exploring conductivity and the length of the first elution step. Empty and full capsid percentages were quantitated with ELISA and ddPCR assays as well as mass photometry. The results from response surfaces were used to construct statistical models of the process operating space. These models provide optimal conditions for recovery and purity, both of which can exceed 80%. Model predictions were then validated at small scale prior to scale-up. We present the results from our scale-up purification and show that purity and yield are consistent with the results obtained from the response surface model. To demonstrate that Mustang Q membrane chromatography can be a robust manufacturing technique, we tested three different feedstreams of AAV5 on three unique lots of Mustang Q. The feedstreams varied by cell line (HEK and SF9) and cell culture technique (adherent and suspension). Drastic differences in the separation conditions and operating space were identified. Here we show that despite the differences in feedstreams, reproducibility and robustness are high across membrane lots. We demonstrate the ability to cycle Mustang Q membrane nine times to achieve reproducible, back-to-back separations.

532. IsoTag™ AAV as a Versatile, Scalable Method for Screening and Producing AAV at Multiple Scales and Volumes

Kimberly Anderson, Jennifer Haley, Jarrett Dobbins, Chris Ocker, Sophia Petraki, Michael Dzuricky, Kelli Luginbuhl

Isolere Bio, Durham, NC

Adeno-associated virus (AAV) is a prevalent vector used within the gene therapy space due to its safety profiles and tissue tropism. With the popularity of this vector, there is a need for efficient purification of potential AAV candidates at every scale, from small-scale laboratory screening to larger scale manufacturing. IsoTag™ AAV is an affinity-based purification reagent that utilizes liquid-liquid phase separation and can be used at all scales of the development process through manufacturing. IsoTag™ AAV reagent binds and sequesters AAV capsids into droplets, which can be washed to remove contaminants, and subsequently eluted from the droplets for collection of the purified product. The IsoTag-AAV reagent can be utilized for separation at a small scale using low speed centrifugation or utilized at a larger scale in a tangential-flow filtration (TFF) format. Using low speed centrifugation, volumes of 0.1mL to 1L can be processed in 2 hours, independent of starting titers, with >90% capture and up to 80% recovery. The low-speed centrifugation method can serve as a rapid high-throughput method, showing compatibility for multiple serotypes, including serotypes 2, 6, 8, 9, and engineered capsids, and it provides a streamlined purification process for more efficient screening. For volumes starting at 0.5L and above, TFF can be used with commercially available 0.22 to 0.65 micron pore filters. Using TFF, AAV9 was purified using TFF, demonstrating a capture efficacy of >90% and an overall recovery of 70-80% using a neutral pH elution

buffer. Volumes of up to 8L have been successfully purified in under 4 hours. Overall, IsoTag™ AAV provides a versatile solution that can be used to streamline screening of multiple AAV candidates, as well as providing a platform for accelerated process development and scaling of AAV purification for manufacturing.

533. Adeno-Associated Virus (AAV) Production: A Collaborative Approach to Accelerate Process Optimisation

Paul Young, Gareth Berry, Spyros Gerontas, Taelor Patterson

Process Science, Pharmaron Gene Therapy, Liverpool, United Kingdom

Pharmaron believes that forming effective partnerships are critical to advance the chemistry, manufacturing and controls (CMC) development of viral vectors to bring these life changing medicines to patients. By combining expertise and knowledge with collaborative working with industrial and academic partners, Pharmaron has developed a scalable and robust multi-serotype AAV manufacturing platform. Effective partnering with upstream experts has enhanced their transfection system for large scale manufacture of AAV viral vectors in suspension cell culture and driven a significant increase in viral titre and infectious particles. Further, through collaborations on purification science, Pharmaron has developed a toolbox approach to purify different AAV serotypes and products. Through this development they have carefully balanced the purity of AAV vectors, the separation of genome containing (full) from genome-free (empty) AAV capsids and improved process recovery using Pharmaron's state-of-the-art AAV platform analytics. In this presentation they will show how working collaboratively with strategic industrial partners is key to continuously improving Pharmaron's processes and advancing gene therapy innovation into commercial solutions.

534. An Alternate Approach to AAV Purification

Paul Young, Taelor Patterson, Gareth Berry, Spyros Gerontas

Process Science, Pharmaron Gene Therapy, Liverpool, United Kingdom

Pharmaron Biologics, as a leading cell and gene therapy CDMO, have successfully collaborated with BIA Separations (now part of Sartorius) to develop and establish a platform purification process to efficiently, effectively and reproducibly purify AAV gene therapies across multiple products and serotypes which overcomes the challenges of traditional methods of AAV purification. This CIMmultus monolith-based platform can effectively clear impurities and allow for empty: full separation of AAV capsids to produce highly pure, monomeric virus containing the therapeutic gene of interest. This approach, in combination with out multi-serotype upstream production platform, allows Pharmaron to efficiently scale up to a 500L bioreactor in their cGMP manufacturing facility, with the ability to reproducibly generate upwards of 90% genome containing capsids and a reduction in downstream processing time of over 60% in a fully scalable manner from bench to large scale production, benefiting both our customers and their patients through the manufacture of effective gene therapies.

535. Implementing Virus Filtration to Ensure Pathogen Safety of Cell and Gene Therapy Products

Daniel Strauss

Asahi Kasei Bioprocess America, Glenview, IL

Ensuring pathogen safety is critical in the manufacture of biological products to reliably provide safe medicines to patients. Production of cell and gene therapy (CGT) products provides new challenges for the assurance of pathogen safety compared to traditional recombinant products due to raw materials which can pose higher risk of virus contamination and downstream purification steps which provide limited capability to remove or inactivate potential virus contaminants. One of the most effective and robust unit operations for removal of viral contaminants is virus filtration. Unfortunately, the very size-based mechanism which leads to its high degree of virus removal also makes virus filtration difficult to implement for many CGT manufacturing processes. Here, we performed virus spiking studies to evaluate removal of a model virus contaminant from a parvovirus-containing feed utilizing a 35nm pore size filter. The data show robust virus removal and excellent product yields even when challenged with various filtration fluxes and with interruptions in the process. Additionally, case studies will be shown demonstrating the applicability of virus filtration in AAV manufacturing process. Finally, we will discuss strategies and feasibility for the incorporation of filtration as an upstream barrier for protection of other gene therapy and cell therapy products as well. Overall, the increased risks associated with new therapeutic modalities call for implementation of the robust protection capability that only virus filtration can provide.

536. Impact Assessment of ITR Instability Observed in AAV Plasmids on Vector Productivity and Potency

Xingcheng Chen[1], Rashi Batra[1], Lukas Morgan[1], Wen Jin[2], Catherine Moroski-Erkul[3], Vignesh Chinnasamy[4], Siyang Xia[5], Tal Kramer[2], Chia Chu[1], Francesca Vitelli[1]

[1]Viral Vector Process Development, Intellia Therapeutics, Cambridge, MA,[2]Gene Editing Platform, Intellia Therapeutics, Cambridge, MA,[3]Exploratory Pharmacology & Toxicology, Intellia Therapeutics, Cambridge, MA,[4]Analytical Development, Intellia Therapeutics, Cambridge, MA,[5]Computational Sciences, Intellia Therapeutics, Cambridge, MA

Recombinant adeno-associated virus (rAAV) vectors have emerged as effective *in vivo* gene delivery vehicles to treat monogenic diseases. Manufacture of rAAV is more complex than traditional biologics given the limited process understanding and corresponding impact on vector potency. Triple plasmid transient transfection in HEK293 cells is a proven method with approved products on the market. AAV Inverted Terminal Repeats (ITRs), a cis-acting element on the plasmid with multiple essential viral functions, are prone to base pair deletions due to high GC content and strong secondary structures. Recombination and deletion of ITRs in AAV vectors may affect vector function given its known interaction with viral replication proteins and its role as origin of replication. Though we have been successful in minimizing ITR instability events through screening of E. coli strains, short base pair deletions in plasmids can still occur at various levels. Using PacBio sequencing here, we present a case study in which low levels of ITR

instability events in plasmid did not propagate into the genome of purified AAV and high viral titers were still achieved. Furthermore, functional assessment of the produced vector using an *in vivo* model confirmed no impact on vector potency.

537. Design of Experiments (DoE) to Optimize Capture and Recovery of rAAV from Clarified Cell Culture Using Aqueous Two-Phase Extraction

Daniel Crosby, Vijesh Kumar, Ohnmar Khanal
Spark Therapeutics, Philadelphia, PA

The current method for large-scale downstream capture of recombinant adeno-associated viral vectors (rAAVs) using affinity chromatography incurs a high cost and potential alteration of the capsid following a low pH elution, which can impact capsid efficacy. In this work, we used aqueous two-phase extraction (ATPE) to capture rAAVs from clarified cell culture harvest selectively. ATPE utilizes a polymer, typically polyethylene glycol (PEG), and a salt at a high concentration to drive liquid-liquid phase separation. ATPE can recover viral capsids from cell lysate in the interfacial region of the two-phase system, allowing for purification and concentration of the capsids. Particularly for the rAAVs that do not show sufficient affinity to the few commercial capture resins, ATPE is a promising alternative capture step. Compared to the steep cost of AAV capture resins, ATPE uses inexpensive components. However, optimizing ATPE is tedious because several parameters need to be optimized simultaneously. To overcome this challenge, we used a DoE approach to screen multiple conditions to select the optimal rAAV recovery. Using a full factorial DoE, various concentrations of salt and PEG were directly mixed with cell lysate containing rAAVs. Once the two phases were formed, the AAV-rich interface was extracted, and its rAAV concentration was determined using analytical affinity chromatography. The regression model built with the DoE data allowed us to select the PEG and salt concentrations for optimal recovery and purity. The model provided the entire design space for AVV recovery in various conditions. and predicted that lower molecular weight PEG gives higher recovery, which is consistent with the previous studies[1]. The optimal conditions were validated, and ATPE proved a potential alternative to costly affinity resins in capturing AVV from cell culture harvest. 1. Fu XQ, Leong HY, Wang GA, et al. Enrichment and separation of recombinant adeno-associated virus particles by aqueous two-phase extraction. *Biochem Eng J*. 2023;200. doi:10.1016/j.bej.2023.109115

538. Advancing Safety in Bioprocess Purification with Saltonase

Joanna Niska-Blakie[1], Felix Küttner[2], Hanna Kubiak[1], Katarzyna Anczykowska[1], Domenica Martorana[2], Peter Porschewski[2]
[1]QIAGEN, Gdansk, Poland,[2]QIAGEN GmbH, Hilden, Germany

In the dynamic landscape of biologics development, stringent requirements for final product purity, manufacturing consistency, and overall safety demand a thorough removal of plasmid DNA and host cell nucleic acid impurities. The regulatory standards established by the US FDA and other global regulatory agencies emphasize the importance of the purification step, recommending quantifiable limits for host cell DNA at 10 ng/dose, with DNA fragments smaller than 200 bp. This underscores the primary challenge in achieving efficient host nucleic acid removal, which pertains to the robust structure of chromatin, intricately composed of negatively charged DNA and positively charged histone proteins. The disruption of this compact structure is crucial for eliminating impurities. In response to this challenge, our efforts have been directed towards the development of a novel salt-active endonuclease, Saltonase. Engineered to elevate safety standards in bioprocess purification, Saltonase's distinctive strength lies in its ability to sustain activity in both high and physiological salt concentrations among a broad spectrum of pH. Additionally, it exhibits high thermal stability and digestion robustness. These remarkable traits not only facilitate the destabilization of chromatin for enhanced endonuclease access but also ensure the enzyme's efficacy and robustness across diverse workflows. By leveraging these safety advantages, bioprocesses gain an augmented capability to meet regulatory standards, ensuring the utmost safety in the production of viral vectors, exosomes, and other biologics pivotal in gene therapies and targeted nucleic acid delivery. This establishes Saltonase a steadfast and secure choice for bioprocess purification.

539. Towards an AAV Platform Production Media and Process for the Gene and Cell Therapy Community

Nelson Ndahiro[1], Justin Sargunas[1], Junneng Wen[1], Michael Betenbaugh[1], David McNally[2], William Brakewood[1]
[1]Johns Hopkins University, Baltimore, MD,[2]MassBiologics, Fall River, MA

Introduction: This study aims to illuminate the HEK-mediated adeno-associated virus (AAV) production process by developing an open-sourced production platform incorporating a defined serum-free medium, transfection process, and AAV content analytics. Initial attempts using an open-source CHO-medium resulted in cell aggregation, slow growth, and an inability to transfect and produce AAV. Therefore, we endeavored to create an HEK-friendly medium and process conducive to healthy cell growth, transfection, and vector production. Nutrient consumption rates were also studied to elucidate metabolic activity associated with AAV production. **Methods:** To optimize the AAV production process, medium design experiments including medium knockouts and spiking studies were conducted, focusing on identifying inhibitors of cell growth and transfection. Then, metabolic consumption rates were studied to discern differences between AAV-producing cells, non-producing PEI-transfected cells, and un-transfected cells. Additionally, AAV production characteristics for different serotypes were examined. **Results:** The study identified distinct nutrient consumption rates between un-transfected cells, AAV-producing cells, and non-producing PEI-transfected cells. Through medium design experiments, transfection and AAV production was realized in the open-source medium. Nutrient consumption in AAV producers were also examined for different serotypes. **Conclusion:** By developing an HEK-friendly medium where all nutrients are known, and refining the AAV production process, this study will serve to develop a valuable resource for advancing the production of adeno-associated viruses in the field of biomanufacturing. Indeed, this study

will contribute to the establishment of an AAV production platform for the scientific community, offering insights into the optimization of the complex bioproduction process for this crucial class of medicines.

540. Robust Adeno-Associated Virus Aggregate Analysis with Reduced Sample Consumption on Biozen™ dSEC-7 Size Exclusion Column

Tran Pham
Phenomenex, Torrance, CA

Size Exclusion Chromatography (SEC) is widely accepted to separate adeno-associated virus (AAV) monomer from its aggregates but analysis with current SEC columns require high volume sample consumption and lack robustness. Herein, Biozen™ dSEC-7, a chromatographic (SEC) column, is described and tested for various AAV serotype aggregates. Its 700 Å pore size, inert particle chemistry, and applicable particle size(s) are found to enable highly reproducible baseline separation and recoveries of the AAV monomer and its aggregates, even amongst batches of columns, within 10 minutes. The percentage relative standard deviations of the peak area, retention time, and % monomer were all < 1 % with as little as 0.5 µL of sample. This performance enables faster and more accurate determination of AAV aggregates, a critical quality attribute (CQA) in drug substances and drug products, without compromising data quality.

541. The Evolution of AAV Production: Scaling Through Nature Instead of Brute-Force

Lucia Fernandez, Dan Brownell, Matt Ercolino, Jade Bose, Jonathan Morgan, James Huynh, Shangzhen Zhou
VintaBio, Philadelphia, PA

The Cell and Gene Therapy industry witnessed its re-birth and rapid growth in just over one decade. This rapid expansion posed a conundrum to manufacturing engineers: how to scale vector production. While the initial wave of success was largely achieved with vectors generated in adherent production systems, the natural state of the widely used HEK293 cells, the field witnessed a broader shift to suspension-based process. This shift was prompted by the lack of readily available and reliable bioreactors for adherent cells. Despite the great success of suspension-based processes in biological manufacturing, the transition to suspension-based process for viral vector faces many challenges. A number of experiments indicate reduced production efficiency in suspension systems leading to increased production lot size. Furthermore, it was reported that suspension processes generate increased impurities in the crude harvest than their adherent counterparts. The increased production size and impurity burden created significant stress to the downstream purification process. Given the recent advancements in adherent bioreactor technology, particularly the development of fixed-bed bioreactors, the scalability concerns of adherent systems have been greatly diminished. There is potential for production engineers to re-examine the initial production success achieved through simple, cost-effective adherent-based processes, and scale this success to large commercial production to solve some of the industry's biggest bottlenecks. Our goal in this study is to comprehensively examine the scalability and in-process characteristics of our adherent process through the following aims: 1) Evaluate the scalability, repeatability, and process robustness of adherent vs. suspension processes. 2) Investigate material consumption, including plasmids and transfection reagents on viral production in both adherent and suspension processes. 3) Assess the impact of adherent vs. suspension on process characteristics including impurity profiles and specific virus production per cell. Our results indicate adherent processing offers advantages in terms of productivity, process control, downstream processing, and potential improvements in vector quality. As technology has advanced, the scalability challenges traditionally associated with adherent cultures are becoming a thing of the past. We show scalability from roller bottle to large scale fixed-bed bioreactor with excellent repeatability in our adherent system.

542. Comprehensive AAV Characterisation Using Orthogonal Methodologies for Empty/Full Capsid Analysis and Genome Integrity

Colin Guy[1], Hazel Staton[1], Rose Andryszewska[1], Martin Squires[1], Annahita Sherkat[1], Jennifer Courtney[2], Calvin VonOpstall[2]
[1]BioPharmaceutical CMC Solutions, Labcorp Drug Development, Harrogate, United Kingdom,[2]Genomics, Labcorp Drug Development, Indianapolis, IN

Adeno-Associated Virus (AAV) remains the viral vector of choice for *in vivo* gene therapy. However, there continues to be safety concerns regarding AAV therapeutics. The empty:full ratio of AAV vectors has been highlighted as an important critical quality attribute (CQA), with high proportions of empty capsids resulting in reduced genome titre, increased total protein load and potential toxicity. It is also important to characterise the integrity and purity of the viral genome, to ensure the safety and efficacy of the product. Despite advancements within the field, there remain challenges for the CMC analytical characterisation of AAVs. There are a variety of analytical methods employed for product characterisation and to monitor AAV CQAs. However, these methods are unable to provide a complete picture of the quality of the product, with each method having limitations that need to be fully understood so the data is interpreted appropriately. Therefore, it is important to implement a panel of orthogonal methods to enable comprehensive analysis of the AAV and ensure product safety and efficacy. We have assessed a portfolio of analytical methodologies and technologies to assess the viral genome payload, the viral vector proteins and the empty:full capsid ratio. We acquired commercial research grade AAV2-eGFP samples; two lots of 'full' capsids and 1 lot of 'empty' capsids. Samples were analysed using CryoEM, which is considered one of the gold standard techniques, to determine the empty:full ratio. The data confirmed that one lot of AAV contained a high full capsid content (>90% full), while the second lot contained more empty capsids (74% full). This data was then used to evaluate other methodologies including transmission electron microscopy (TEM), analytical ultracentrifugation (AUC), capillary isoelectric focusing (cIEF), mass photometry and UV-Vis/DLS. While these methods provided valuable data, each method presented challenges, including limitations on sample throughput, concentration and composition, implementation of the methodology and interpretation of the data. While these methodologies are important tools for AAV characterisation, they are unable to determine the quality of the viral genome. Therefore, these methods need to be used in conjunction with a suite of analytical methods including q/ddPCR, capillary electrophoresis, and next

generation sequencing (NGS). This combined analytical package enables a comprehensive dataset which can demonstrate the consistent manufacture of AAV therapeutics and, in conjunction with pre-clinical and clinical data, ensure the product safety and efficacy.

543. Quantitative Analysis of Capsid Loading in Gene Therapies with High-Precision Tunable Laser Spectroscopy

Bryan Hassell

Nirrin Technologies, Billerica, MA

In the rapidly evolving field of gene therapy, the successful delivery of genetic material via capsids is paramount. A critical quality attribute in the development and manufacturing of these therapies is the accurate determination of the ratio of empty to full capsids, a metric that directly impacts their efficacy and safety profiles. Traditional methods for quantifying these ratios often fall short, being laborious, time-intensive, and lacking in precision, particularly when handling crude samples. Our novel technology harnesses the power of tunable laser spectroscopy, providing an unparalleled blend of accuracy and robustness, specifically designed to tackle the challenges of capsid loading analysis. Our advanced methodology utilizes a unique tunable laser system, capable of dissecting the spectral signatures of capsids with remarkable resolution. Leveraging sophisticated signal processing algorithms, we can distinguish between empty and full capsids with extraordinary precision, in real-time. The robustness of our platform ensures consistent performance, even when processing heterogeneous, crude samples, thereby simplifying the workflow from sample preparation to final quantification. Our technology not only streamlines the analytical process but also boosts the speed and reliability of measurements. By delivering a rapid and accurate evaluation of capsid loading, we enable researchers and manufacturers to make timely, informed decisions, thereby enhancing process development and formulation optimization in gene therapy. The presentation will provide a detailed overview of our technology, demonstrate its application in measuring the ratio of empty to full capsids from crude samples, and explore its significant implications for the gene therapy sector. We will also present comparative data underscoring the superiority of our approach over traditional techniques, emphasizing our technology's potential to redefine the standard in capsid analysis.

544. Replacing Vector Genome Titer Readouts with NanoDrop UV-Based Concentration Metrics for Short Turnaround Time (STAT) Testing

Darren W. Begley[1], Libby McClelland[1], Dave Foster[1], Ginny Knight[1], Nelson Reticence[1], Allison Fleck[1], Patrick Starremans[2]

[1]Analytical Development - Gene Therapy Franchise, Resilience, Inc - Gene Therapy Franchise, Waltham, MA,[2]Resilience, Inc., Waltham, MA

Fast or short turnaround time (STAT) testing is a critical support parameter for biologic drug manufacturing unit operations. The concentration of genome-containing capsids have a direct impact on preparations for specific unit operations in adeno-associated virus (AAV) manufacturing, including buffer exchange by tangential flow filtration (TFF) and capsid enrichment by column chromatography. STAT titers are often deployed using quantitative or droplet digital PCR methods to assess AAV concentration in preparation for these unit operations, challenging methods to run under the time constraints required for manufacturing. As important as PCR-based methods are for final drug substance/drug product quantitation, it is questionable if such methods are absolutely required to get ready for TFF buffer exchange or column packing. In this study, we look at PCR and UV absorption data acquired by NanoDrop for several serotypes of AAV, to see if a suitable correlation could be used to permit the use of the latter for STAT concentration metrics. Predictive models utilizing a machine-learning algorithm shows that for certain sample types, a quick NanoDrop can provide sufficient information to permit unit operations to proceed, at a fraction of the time, cost and effort used for genome titer methods.

545. Introduction to Genevoyager's One-Bac 4.0 System: Addressing the Bottlenecks and Challenges of Adeno-Associated Virus (AAV) Manufacturing

Hui Wang

Genevoyager, Philadelphia, PA

Viral vectors play a crucial role in gene therapy, with Adeno-Associated Virus (AAV) emerging as the preferred vector for *in vivo* gene therapy due to its safety profile and the ability to sustain prolonged gene expressions. AAV offers advantages such as low immunogenicity, broad tropism, and a variety of serotypesGenevoyager's proprietary One-Bac 4.0 system marks a novel development in large-scale AAV production platforms, addressing the bottlenecks associated with commercial development of gene therapy products.Key Features of the One-Bac 4.0 system:1) Optimizing the Cap and Rep expression cassettes to increase the AAV full capsid ratio and enhance infectious activity;2) Achieving stability and yields ranging from 1E+15 to 5E+15 vg/L during scale-up manufacturing (500L-2,000L);3) Ensuring a safety profile with minimal impurities, and the absence of replication competent AAV (rcAAV);4) Delivering high potency through increased infectivity and high full capsid ratios (>70% in crude harvest), enhancing the therapeutic efficacy;5) Providing high accessibility with reduced manufacturing costs, enabling an affordable pricing model that addresses the medical needs of a broad patient population.The innovative One-Bac 4.0 system effectively tackles the challenges in AAV manufacturing by offering high yields, sustained stability, elevated full-capsid ratios, enhanced infectious activity, reduced cost, and accelerated production timelines. This system introduces new approach for scalable and efficient production of AAV vectors.

546. A Comparison Between CDMS and Q-Exactive UHMR for the Determination of AAV Empty/Full Ratios

Daniel Haq

National Resilience, Waltham, MA

During the production of AAV considerable amounts of capsids with no genome, often referred to as empty capsids, are produced. Due to potential immunogenic effects, empty capsids are considered

undesirable and need to be quantified. Most of these empty capsids are purified out, but a percentage of final product still contains residual levels. Determination of levels of empty and full capsids is required for release of material. Capsids are very large, rendering many commonly used analytical techniques not suitable. Currently the preferred method for the determination of empty and full levels is analytical ultracentrifugation (AUC). While AUC is reliable and accurate, it is not without drawbacks. AUC requires significant amounts of product and suffers from non-compliant software for the analysis. Charge detection mass spectrometry (CDMS) is another method that produces very reliable results that are consistent with AUC but currently is not commercially available. Here we investigate the feasibility of using the Thermo Q-Exactive Ultra High Mass Range (UHMR) mass spectrometer with Direct Mass Technology as an alternative to CDMS, while using levels determined by AUC as the benchmark. With a mass range up to 80,000 m/z, the Q-Exactive UHMR proved to be a suitable alternative to the commonly preferred methods for determination of capsid empty/full ratios without.

547. Optimal Drug Product Presentation and Container Closure Selection for AAV-Based Genomic Medicines

Madhura Som, Varna Kanapuram, Diego Vargas, Katelyn Esposto, Benson Gikanga, Sandeep Yadav
Formulation & Fill/Finish, Sangamo Therapeutics, Brisbane, CA

The majority of current AAV-based commercial drug products and clinical drug candidates are stored at frozen conditions due to the potential impact on stability associated with long term 2-8°C storage. While conventional container closure systems such as glass vials offer unique benefits like low product adsorption and impermeability to moisture and gas exchange, the risk of glass breakage with frozen AAV storage necessitates the assessment and implementation of alternative container systems. Polymeric vials are a great option to address these challenges, however, they may not provide chemical durability needed to ensure the drug product remains stable and efficacious throughout the drug product life cycle. In addition, the physical durability of the inner surface of the vials is crucial and needs to be assessed for any corrosion or delamination. This study evaluates the compatibility of AAV-based products and related manufacturing stresses in commercially available polymeric vials. The drug products were subjected to thermal and freeze/thaw stability stress. The samples were assessed for changes in critical quality attributes (CQAs) such as pH, osmolality, appearance, aggregation, free DNA, vector genome, and capsid titer. The physical durability of the inner surface of the vials was assessed using light microscopy and Scanning Electron Microscope/Energy Dispersive Spectroscopy. A side-by-side comparison of CQAs impacted as a function of stress and container type is presented to enable a rational selection of container closure system for AAV based products with long term frozen storage.

548. Improving Transient AAV Manufacturability through Model Driven Process Development

Anna Prendeville, Jeff B. McMahan, Kate Dray, Omar El-Ghouch, Kevin D. Smith
Asimov, Boston, MA

Triple transfection of AAV plasmids into HEK293 cells is one of the most widely used production methods for AAV vector generation. However, this approach is met with long development timelines that typically require plasmid ratio optimization, upstream process optimization, and scalability testing. The process parameters are often evaluated one at a time as the transfection process is scaled up from a shake flask to large-scale bioreactors. One option for faster process optimization is the use of a high-throughput bioreactor system. While this high throughput system can be beneficial, it can be difficult to manually parse the results to evaluate the impact of each independent variable (for example, agitation speed, dissolved oxygen percentage) on each dependent variable (titer and percent full) and to determine subsequent experiments to run. To overcome the experimental complexity, we have developed a data-driven approach for experimental design by using Partial Least Squares (PLS) regression to analyze the results of each experiment and choose conditions for the next iteration. This approach has enabled prioritization of experimental exploration in the highest-performing regions of the process design space, leading to rapid optimization of the process in a small number of experiments. We have combined this model-guided experimental design approach with a superior performance clonal HEK293 host cell line, sequence-optimized plasmids, and a high-throughput bioreactor method with integrated metabolite analysis to significantly accelerate the HEK293 AAV triple transfection process development timeline. Cell line aggregation has been addressed through the generation of a clonal, serum-free, suspension HEK293 cell line. This cell line grows with an average of 23 hour doubling time, minimal nutrient consumption, minimal clumping, and is shown to produce a high percentage of fully packaged capsids in a transient system. Using our model-guided approach, optimized growth conditions for the improved host were established at the ambr250 and the 2L scale. This was followed by transfection and process optimization at the ambr250 scale and shown to apply across 5 different serotypes and 3 genes of interest (GOIs), including eGFP and two approved AAV gene therapy GOIs. The harvested clarified lysate across all GOIs and serotypes showed titers of ≥1e11 or higher (measured via primer/probe specific ddPCR) and percent fully packaged of ≥20% (measured using Capsid ELISA and confirmed using analytical ultracentrifugation). Lastly, we demonstrated that optimization of the GOI coding sequence increases the expression of the genetic payload in transduced cells. Overall, by integrating a robust host cell line, sequence optimization tools, and an improved triple transfection process, we showcase an effective system for producing clinical material for new AAV based gene therapies.

549. Enhancing AAV Productivity through Plasmid Design and Plasmid Ratio Optimization

Laure Robert[1], Eric Mauro[2], Jonathan Havard[3], Solène Jachez[1], Mathieu Porte[4], Sylvain Julien[1], Patrick Erbacher[4]

[1]Polyplus, Illkirch-Graffenstaden, France,[2]Polyplus, Illkirch, France,[3]Polyplus-Transfection, Illkirch-Graffenstaden, France,[4]Polyplus-Transfection, Illkirch Graffenstaden, France

Harnessing rAAVs as viral vectors for therapeutic transgene delivery still requires improvements in yields and specificity to lower vector doses, and therefore manufacturing cost, as well as to improve patient safety. To this end, our research is focused on developing novel technologies to ensure manufacturing of high yielding rAAV particles using transient transfection, as well as enhancing viral particles quality and specificity. Here we present our state-of-the art approach to design new helper plasmids (pHelpers) with the aim of improving both the genomic titers and the infectivity (TU/mL) of the viral particle obtained from suspension cultures. We took the opportunity to exploit our proprietary DNA assembly method technology to explore the synergies of multiple genetic features modularly assembled in synthetic plasmids. We then explored how plasmid ratio optimization could further enhance AAV productivity through a Design of Experiment with a mixture design approach. This work led us to identifying plasmid ratios improving both VG titers and Empty to Full ratios.

550. Optimizing Triple Transfection Production of AAV in Upstream Manufacturing Using Design of Experiment

Rebecca Reese, Jennifer Swanson, Austin Storck, Laura Juckem

Mirus Bio LLC, Madison, WI

Recently there has been a surge in the number of registered clinical trials examining the use of recombinant adeno-associated virus (AAV) in gene therapy. There are five AAV gene therapies approved by the FDA to date, three of which were approved in the past two years alone. As AAV therapies move to broader patient populations and systemic indications, the need for highly efficient production processes greatly increases. The upstream production of these therapies is largely driven by transient transfection of suspension HEK293 cells with multiple plasmid DNA constructs encoding essential virus proteins. There are a multitude of factors that can be considered when optimizing upstream manufacturing processes for AAV production including, but not limited to, cell density, plasmid ratios, DNA dosage, transfection reagent-to-DNA ratio, complex formation time, and more. Optimizing these factors individually is time-consuming and costly; instead, Design of Experiments (DOE) provides method of quickly examining the relationship between multiple variables simultaneously. DOE is a branch of applied statistics which allows for the study of multi-variable interactions while reducing the necessary number of runs or experiments. Here we describe efficient experimental designs which take advantage of DOE to model and predict the conditions that will yield the highest AAV titers when using the *Trans*IT-VirusGEN® Transfection Reagent. To streamline the DOE process, we utilized a scale-down system with non-treated 6-well plates containing 2 mL of culture, thereby reducing the necessary reagents and overall cost per condition tested. Using multiple genes of interest (GOIs), we first show that a DOE mixture design is effective in determining the optimal Transfer:RepCap:Helper plasmid DNA ratios under recommended starting transfection conditions. Using these improved plasmid ratios, we then compare two types of response surface methodologies (RSM), a 3-factor central composite design (CCD) and a Box-Behnken design, to determine the DNA dosage, the *Trans*IT-VirusGEN:DNA ratio, and cell density that will yield the highest AAV titers. These conditions were then tested in combination with a range of the *Rev*IT™ AAV Enhancer to further increase genome titers by >2-fold. Taking advantage of DOE allows for rapid and cost-effective optimization of transfection conditions to maximize titers and generate more patient doses per manufacturing run.

551. Standardization and Reproducibility in Gene Therapy Analytics Using Digital PCR-Based Determination of AAV Reference Standard Genome Titers

Jonathan Thorn[1], Anida Mesihovic[2], Dana Holzinger[3], Katharina Hammer[3], Andreas Hecker[2], Domenica Martorana[1], Francesca Di Pasquale[1]

[1]R&D, QIAGEN GmbH, Hilden, Germany,[2]Product Management, QIAGEN GmbH, Hilden, Germany,[3]PROGEN, Heidelberg, Germany

Recombinant adeno-associated virus (rAAV) vectors are widely used as vehicles for gene therapy in both clinical and research applications. To help ensure product safety, reference standard materials (RSMs) are key. The use of viral vector RSMs is particularly important to normalize laboratory internal controls, for the calibration of medical products and procedures and as best practices for manufacturing and testing of ATMPs. Additionally, AAV RSMs are often used for assay validation and optimization. All in all, the use of well-characterized AAV RSMs and orthogonal methods is indispensable to meet current authority guidelines. Since the production of such is not achievable for a large number of companies, it is important to resort to commercially available AAV RSMs for the most commonly used AAV serotypes. These standards underlie a comprehensive characterization process including determination of vector genome and capsid titer, filling grade, purity and aggregation. One of the critical quality attributes needed for AAV reference materials is the viral vector genome titer which is usually determined using qPCR. Here we demonstrate a digital PCR-based streamlined workflow for quantification of genome titers of commercially available, high-quality rAAV reference standards that allows to complete the characterization with increased precision, accuracy and robustness. Additionally, the integrity of the viral vector genome can be assessed ensuring quality and safety of the final product.

552. Simple and Rapid Adeno-Associated Virus Genome Titration with CRISPR-Cas12a Diagnostics

Zach Hetzler[1], Stella Marinakos[2], Noah Lott[3], Noor Mohammad[1], Agnieszka Lass-Napiorkowska[4], Jenna Kolbe[1], Lauren Turrentine[1], Delaney Fields[1], Laurie Overton[3], Helena Marie[5], Angus Hucknall[2], Oliver Rammo[5], Henry George[4], Qingshan Wei[1]

[1]Chemical and Biomolecular Engineering, North Carolina State University, Raleigh, NC,[2]Biostealth, Durham, NC,[3]Biomanufacturing, Training, and Education Center (BTEC), North Carolina State University, Raleigh, NC,[4]Millipore-Sigma, St. Louis, MO,[5]Merck KGaA, Darmstadt, Germany

The field of gene therapy has seen significant growth in clinical applications, with adeno-associated virus (AAV) achieving much clinical and research interest due to its widespread use as a vector. AAV manufacturing faces several challenges to meet clinical demand, one of which is a lack of robust process analytical technology (PAT) for AAV product quality monitoring. To address this need, we developed a CRISPR-Cas12a assay for quick and simple and accurate at-line determination of the AAV genome titer within 30 minutes. The **CR**ISPR **AAV** **E**valuation (CRAAVE) assay was developed to function universally across genetic constructs by targeting the inverted terminal repeats (ITRs) of the AAV genome. The CRAAVE assay was demonstrated on constructs from AAV samples from three different serotypes as well as accurately titrating samples. The CRAAVE assay was developed for maximum sensitivity with limits of detection below 5e8 vg/mL for all serotypes in 30 minutes. The CRAAVE assay was also translated to a diagnostic chip format with pre-deposited lyophilized reagents with similar analytical metrics and analytical power as the traditional microplate assay format. We believe this new analytical technology with a flexible format and readout will minimize sample-to-result time, particularly for high throughput analysis in process development.

553. Advancing Plasmid Impurity Analysis through Comprehensive, Fragment and Full-Length Kanamycin (*nptII*) Gene Quantification in Gene Therapy Products by Multiplex Digital PCR

David Dobnik[1], Nejc Košir[2], Nejc Jakoš[3], Rebecca Vollmeier Kovačić[2]

[1]National Institute of Biology, Ljubljana, Slovenia,[2]Niba Labs, Ljubljana, Slovenia,[3]Niba Labs Ltd., Ljubljana, Slovenia

Recombinant adeno-associated virus (rAAV)-encapsidated plasmid impurities pose challenges in vector manufacturing, comprising heterogeneous DNA fragments from production plasmids. Regulatory agencies necessitate precise quantification of DNA impurities. However, currently used PCR-based methods used for detection focus on quantifying small fragments, offering limited insights into the actual length of encapsidated plasmid DNA fragments. The potential risk of horizontal gene transfer of resistance genes is not yet completely understood, as current analytical methods were not able to quantify the number of full-length genes packed in rAAV capsids. This is also the area of current scrutiny of regulatory agencies. In response, we present an innovative approach to assess the fragment populations of plasmid-derived antibiotic resistance gene (*nptII*) impurities in rAAV products. This method expands the scope of impurity analysis by providing quantitative information on four different kanamycin fragments, including the full-length gene. We've developed a triplex digital PCR assay and evaluated the performance of the assay against a standard set of criteria (e.g. repeatability, precision, accuracy, range, LOD, LOQ). We've addressed the current limitations in existing techniques and provided a method that offers a valuable enhancement to quality control measures in vector manufacturing, ensuring a more thorough evaluation of plasmid impurities and, consequently, advancing the safety and regulatory compliance of gene therapy products.

555. Potency Method Development Roadmap for AAV Gene Therapy

Kimberley Beattie, Michael MacArthur, Martha Nattyaba, Eugenia Fandunyan, Kalyani Natu

Analytical Development, Bioassays, Oxford Biomedica (US) LLC, Bedford, MA

Potency method development for AAV gene therapy products is complex due to product-specific mechanisms of action. Assessment of biological activity often requires multiple assays. Here we describe a platform approach to potency method development for AAV gene therapy. Product lifecycle-specific implementation of assays and examples of common challenges are discussed.

556. Single-Use Process with In-Line Cell Lysis in Plasmid DNA Purification Using a Single Chromatographic Step for Cell and Gene Therapy

Vicky Argyropoulou[1], Matthias Craig[1], Wu Huacheng[2], Bhargavi Kondragunta[2], Julien Glibert[1], Sebastien Gillet[1], Kistler Christopher[2], Victor Vinci[3], Nuria Gomez Santos[1]

[1]Catalent Pharma Solutions, Gosselies, Belgium,[2]Catalent Pharma Solutions, Baltimore, MD,[3]Catalent Pharma Solutions, Bloomington, IN

Plasmid DNA (pDNA) serves as a critical starting material for the production of advanced therapy medicinal products (ATMPs) in the field of cell and gene therapy. The growing demand for pDNA requires the development of manufacturing processes that can meet aggressive timelines while maintaining cost-effectiveness. Here we present a robust single-use process that enables seamless scale-up from research and development (R&D) to good manufacturing practice (GMP) grade. This process involves bacterial cell growth in fermenters, alkaline cell lysis, and a streamlined chromatographic step. A key aspect of this approach is the implementation of a controlled cell lysis step, ensuring the production of high-quality pDNA that complies with regulatory agency standards. Notably, this process achieves efficient purification and polishing with just a single chromatographic step, simplifying the manufacturing process as well as reducing costs. We will provide an overview of the platform process and share results on the quality attributes obtained through its implementation. Our findings demonstrate the effectiveness of this approach in generating pDNA that meets quality requirements set by regulatory agencies.

557. Quality Control for Adeno-Associated Virus Genome Preparations Using Nanopore Sequencing

Hayley Greenfield, Heather Jeffery, Phill James
Applications, Oxford Nanopore, Littlemore, United Kingdom

The adeno-associated virus (AAV) is a small replication deficient virus that is currently a favourable gene therapy vector. As it stands, five AAV based gene therapies are already approved by the FDA and in 2022, 134 AAV based clinical trials were being undertaken for the treatment of 55 differing diseases. However, to ensure efficacy in downstream clinical applications it is crucial to gain an accurate view of the composition of AAV preparations as part of the quality control (QC) of these vectors. Plasmids containing the transgene of interest, flanked between inverted terminal repeats (ITR) signifying the ends of the AAV genome, are co-transfected into packaging cells with *rep/cap* and helper plasmids allowing for virus and AAV vector propagation. However, truncated AAV genomes, host DNA and both *rep*/*cap* and helper plasmid DNA can result naturally in the process of rAAV manufacturing but can contaminate final rAAV preparations. These contaminations can affect the efficacy of the AAV-based therapy and also cause downstream adverse effects including hepatotoxicities and neuropathological issues, displaying why the QC of rAAV is crucial to contribute to Good Manufacturing Processes (GMP) before use in downstream treatments. At present, there is no standardized QC method, with PCR-based assays, that are unable to identify truncations and contamination, being the most utilized methods. Long read sequencing has been identified as an exciting opportunity for the improvement of GMP in the QC of rAAV preparations. Here, we demonstrate the ability to sequence full length (ITR-ITR) native rAAV vectors and detect both contamination and truncated AAV genomes using a released end-to-end protocol from Oxford Nanopore. A quick library preparation turnaround time of less than five hours allows six AAV samples to be multiplexed on our MinION™ and GridION™ devices. Optimisations of protocol steps including viral extraction and annealing methods were carried out to facilitate the accurate characterisation of rAAV preparations. Additional to the released protocol, a workflow from EPI2ME™ labs, wf-aav-qc, facilitates fast and concise analysis for the easy assessment of contamination and truncation events, as well as the number of full length AAV genomes and proportions of self-complementary AAV (scAAV) and single stranded AAV (ssAAV). We have also successfully sequenced plasmids used for transfections, contributing an additional level of quality control prior to the creation of rAAV. In summary, we demonstrate rapid comprehensive sequencing of native rAAV vectors, identifying contamination, truncated genomes, and optimizing protocols for accurate characterisation.

558. Adventitious Viral Agents Control Through Robust rAAV Production Platform

Ashish Sharma, Thomas Thiers, Luke Mustich, Richard Gilmore
Oxford Biomedica (US) LLC, Bedford, MA

The ICH released its latest revision of ICH Q5A [R2] guideline on viral safety evaluation of biotechnology products derived from cell lines of human or animal origin in 2023. The revised guideline calls for a risk-based approach to ensuring viral safety of biological products such as adeno-associated virus (AAV). This presentation will first introduce a full spectrum control strategy highlighting how Oxford Biomedica's transient transfection platform, implemented across multiple AAV serotypes, de-risks endogenous and adventitious virus contamination through raw material control, single-use closed aseptic processing throughout the platform, dedicated viral intermediate testing, and the final drug product characterization. We will then share a rAAV9 viral clearance case study demonstrating robust upstream inactivation kinetics and downstream viral removal performance to deliver significant log reduction value (LRV) clearance throughout the process (Detergent Inactivation->4.67 LRV, Affinity-4.69 LRV, AEX-4.38 LRV), utilizing orthogonal chromatographic modes of separation, namely affinity capture and AEX polishing. We utilized the small-scale model of manufacturing process at current operating parameters, for spiking studies using enveloped Xenotropic murine leukemia virus [XMuLV] and non-enveloped Minute Virus of Mice [MVM] as representative AAV model viruses. We selected MVM due to similar morphology and physicochemical properties as AAV, which may pose competing challenge to be virally cleared from the process. We will showcase that negligible viral particle were detected in the intermediate product pools and no discernible difference in load and elution chromatographic profile was observed, compared to chromatographic profile with no model virus spike [only AAV9]. We will also showcase how this intensified platform is not affected by process feed stream conditions within normal operating range and the data is robust in nature to potentially offer similar LRVs across multiple serotypes, without the need for retentive viral filters (viral filters need process feed adjustments post polishing and pre UFDF steps, impacting product yield). To our knowledge this could be the first showcased dedicated study from a drug developer utilizing both upstream enveloped viral inactivation and downstream non enveloped viral clearance for a "process evaluation" Phase I/II stage of a rAAV platform. Finally, we will outline the value proposition offered by Oxford Biomedica's rAAV platform for drug developers in four distinct ways: robust controls put in place provide barriers to entry and carryover of adventitious agents in the final product, robust viral clearance from orthogonal chromatography unit operations without the need for retentive viral filters, a robust regulatory IND/BLA package which adheres to the newly released guidance, and the advantage to treat patient populations in a safe and economical manner, with negligible immunotoxin profile.

559. ELEVECTA™ Transient Cell Line: Enabling rAAV Production with Low-Level hcDNA Encapsidation

Ben Hudjetz[1], Sabine Schmidt-Hertel[1], Tamara Grabeck[1], Keerthana Srinivasan[1], Michael Mühle[1], Christian Niehus[1], Michelle Hussong[1], Kelly Cybulski[2], Tala Calvi[2], Anne MacIntyre[2], Akshay Gutha Ravichandran[2], Adam Hejmowski[2], Michelle Olson Peabody[2], Nikola Strempel[1], Markus Krieger[1]
[1]Cytiva, Cologne, Germany,[2]Cytiva, Westborough, MA

The landscape of recombinant adeno-associated virus (rAAV) manufacturing is witnessing a transformative shift, with stable producer cell lines emerging as the cell factories of the future. However, the move towards producer cell lines is a nuanced journey, requiring the use of

transient transfection cell lines in the research and development phases. This dual approach acknowledges the key role of transient transfection in the early stages of candidate AAV development. To address this need, we developed a novel HEK293 cell line, ELEVECTA™ transient cell line. Parental suspension HEK293 cells were genetically modified to decrease hcDNA encapsidation during rAAV production. Then, single-cell cloning resulted in a clonal cell line, which was adapted to a new animal-component-free, chemically defined, and transfection-ready culture medium. The resulting ELEVECTA transient cell line grows in single-cell suspension mode to high density and supports high-titer rAAV production for multiple serotypes with significantly reduced levels of encapsidated hcDNA compared with common HEK293 cell lines used for this purpose. In tandem with ELEVECTA producer cell line, ELEVECTA transient cell line effectively addresses the market demands for high-titer manufacturing of excellent-quality rAAV products from R&D through commercial manufacturing. With their distinctive attributes, these cell lines are poised to contribute significantly to advancing the field of gene therapy and meeting the ever-growing expectations for efficacy and quality.

560. A Modular Approach of AAV Process and Analytical Development Expediated FIH CMC Timeline by 30%

Xiaotong Fu[1], Oliver Meade[1], Colin Haws[1], Darren W. Begley[2], Mukesh Mayani[3], John Kerwin[1]

[1]Resilience, Waltham, MA,[2]Resilience, Inc., Waltham, MA,[3]National Resilience, Inc., Chelmsford, MA

The lengthy timeline from molecule development to phase I trials remains a notable bottleneck in the gene therapy field. The prolonged duration and substantial resources required for clinical material manufacture not only impede patients' timely access to innovative therapies but also expose gene therapy innovators to financial risks as more investors withdraw funds from the biotech sector. Consequently, to expedite the path to clinical with cost-efficiency, we propose to redefine the AAV manufacturing "platform". Here we introduce a modular approach that departs from a singular platform solution, allowing for development at the unit operation level. Each module undergoes an assessment of critical process input against corresponding output, presenting potential tools to address platform permutations arising from different serotypes or consumable availability. This approach allows maximum platform flexibility while constructing an accelerated timeline heading into IND filing. In this work, we want to highlight several modular tools we developed at the unit operation level that helped to reduce development timeline and resource requirements by 30%: **1.** Identification of critical transfection elements led to productivity and packaging efficiency improvement by 2-4 folds. We also established a high-throughput purification workflow that enables at-line product quality monitoring during cell culture development. **2.** Discovery of various levers to improve AAV empty and full separation with different polishing resins. Successfully raised the %full from 15% to 70% for several AAV serotypes, even surpassing 90%. **3.** Establishment of an analytical toolkit for AAV empty and full characterization, incorporating AUC, CDMS, Mass photometer, and SEC-MALS. With a comprehensive understanding of each tool's capabilities and confirmed comparability, the AAV platform can selectively implement the right tool at different phases, ensuring development speed and process robustness. **4.** Identification of key scale independent parameters allows good process robustness during scaling up, leading to consistent batch yield from PD to manufacturing.

561. Manufacturing of a Broad Range of AAV Capsids Using a Suspension Platform Process

Rupert Derler, Martina Ohme, Sandra Henze, Elisabeth Schweigert, Florian Dunker, Markus Hoerer, Andreas Schulze, Florian Sonntag

Ascend, Planegg, Germany

A broad range of naturally occurring and synthetically engineered adeno-associated virus (AAV) capsid sequences have been reported until today and are applied in AAV gene therapy programs to target specific tissues and organs with high efficiency. There is an increasing demand to manufacture high quality AAV vectors based on various AAV capsids in large quantities for pre-clinical and clinical trials as well as approved therapies. Yield and quality parameters can differ from one AAV capsid to another, impacting the manufacturing processes and requiring modularity of a manufacturing platform to be able to address product dependencies. Based on our proprietary HEK293 cell line and split two plasmid system, we have developed a robust suspension platform process, that is optimized towards yield at best possible quality with full scalability. We present here the comparison of a range of AAV capsids (amongst others AAV1, AAV2, AAV3B, AAV8 and AAV9) produced using our suspension platform process. We analyzed yield and quality parameters that are known to be strongly impacted by the design and choice of the biological starting materials and the upstream process. A panel of analytical methods was applied to enable a comprehensive and detailed comparison of many different attributes. Manufacturability of the AAV capsids was demonstrated in the Ambr® 15 platform which has been shown to be predictive for the larger production scales of our manufacturing offering (currently up to 200 L). Overall, very similar vector genome yields within a 3-fold range were observed for the majority of AAV capsids. Serotype-dependent release of AAV particles from cells into cell culture media during production as described in literature was seen. Therefore, our manufacturing platform is designed to recover both, cell-attached vectors and those released into the cultivation medium. A high-throughput one-step affinity purification protocol was developed to allow screening in small-scale format. Despite the same vector genome cassette used for all productions, differences in the levels of plasmid- and host cell DNA-derived mispackaging were determined in a serotype-dependent manner. These data are highly valuable as they inform on specific development needs and underpin the need of a modular platform. Our results demonstrate the applicability of our suspension platform rAAV production process for a broad range of AAV capsids. We continuously invest in further CMC innovation to optimize yield and quality for all capsids.

562. Engineered Cell Lines Can Improve Crude Lysate Titer and Non-Empty Capsid Percentage of AAV Vectors

June Deng, Nannan Jia, Shiliang Hu, Yinxing Chen, Noel Walsh, William Lee, Kayla Iozza, Lauren Drouin, Matthias Hebben, Mariana Nacht, Jing Liao

Alexion Genomic Medicine, AstraZeneca Rare Disease, Lexington, MA

Manufacturing cost of goods is a significant challenge in the gene therapy field. At Alexion, we utilize transient transfection of suspension HEK293 to produce our AAV products. This approach provides scalability and flexibility for swapping therapeutic genes. To optimize the upstream process, we employ optimal transfection conditions determined by the design of experiment (DOE) to achieve high vector yields. Additionally, the generation of a super producer cell line through cell line engineering could potentially reduce manufacturing costs. To achieve this goal, we initially subcloned the polyclonal HEK293F cell line through a series of dilutions in semi-solid media. We selected the top-performing cell line, #159, from 300 cell lines. Subclonal cell line #159 exhibited a 2 to 4-fold enhancement in crude lysate titer over the parental cell line when producing different AAV serotypes (LK03, sL65, DJ, AAV2, and AAV9) using the transfection reagent PEI in the conventional 3-plasmid system. We further enhanced cell line #159 by overexpressing or knocking down target genes using lentivirus. Our previously reported novel 2-plasmid design, mAAVRx, demonstrated high-yield, high-quality, and potent AAV vectors in scalable suspension HEK293 cells. Therefore, we compared different plasmid systems, mAAVRx and the conventional 3-plasmid system, in our engineered cell line with different serotypes. Using mAAVRx, the engineered cell line with target gene knockdown improved the crude harvest titer for different serotypes by approximately 1.5-fold while maintaining the non-empty capsid percentage. Notably, the enhancement of crude harvest titer was found to be transgene, capsid, and plasmid system dependent. For instance, the super producer cell lines for different transgene cassettes were different, even with the same capsid. In summary, we have successfully combined subcloning and cell line engineering to generate a high producer cell line for AAV manufacturing. Our new cell lines can be applied to different plasmid transfection systems and capsids from multiple serotypes. The AAV vector titer of most capsids can be improved. Consequently, the increased vector titers and improved vector purity may reduce the cost of goods per patient and enhance product safety, respectively.

563. AAV Capsid Titer Determination of AAV Standard Material by Orthogonal Methods

Lisa Mutz[1], Robert Mildner[2], David Golonka[2], Francisco Ramirez[3], Chris Heger[3], Katharina Hammer[1], Caroline Odenwald[1], Dana Holzinger[1]

[1]PROGEN, Heidelberg, Germany,[2]Waters | Wyatt Technology, Dernbach, Germany,[3]Bio-Techne, San Jose, CA

Today, AAV-based gene therapy is one of the most promising and fastest growing branches of modern medicine. Moving forward to a more clinical focus in this field, the use of reliable AAV standards and orthogonal methods is indispensable to meet current regulatory guidelines. Since the production of comprehensively characterized, internal standard material is not feasible for many companies and a lack of commercially available reference material, we now offer AAV standard material for the most used AAV serotypes. We have established a comprehensive characterization process for these commercially available standards. Besides testing several characterization parameters (e.g., vg and capsid titer, filling grade, purity, and aggregation), this process also contains the analysis with a set of suitable orthogonal methods ensuring the utmost level of accuracy and reliability of the data. In terms of capsid titer determination, our ELISA still represents one of the most frequently used industry standards due to its robustness and accuracy of measurement. However, the evolution of new biophysical methods such as Size Exclusion Chromatography Multi-angle Light Scattering (SEC-MALS) and Dynamic Light Scattering (DLS), or alternative immunoassays, e.g. Biolayer-Interferometry (BLI), and Capillary Electrophoresis (CE) enables the obligatory, orthogonal measurement of AAV capsid titers. Here we present data of blind measurements of our eGFP-filled AAV standards with the methods mentioned above for comparison of independently determined total capsid titers and to underline the reliability of our established characterization process. The capsid ELISA, SEC-MALS, and BLI showed low assay variation resulting in CVs of around 5%, while CE and DLS showed higher CVs of 6-14% and 10-35%, respectively. Compared to the capsid titer determined by ELISA, each method showed a serotype-dependent average deviation. In summary the average deviation across serotypes compared to ELISA was 13% for SEC-MALS, 46% for DLS, 16% for BLI, and 19% for CE. The use of reliable standards within diverse orthogonal methods ensures not only the most accurate result but also the safety of the final product in compliance with current regulatory requirements. Therefore, we present the reliability of our characterization process for AAV standards, thus demonstrating their reliability and suitability for biophysical and immunological applications, respectively.

564. Next Gen rAAV Production: A Scalable Platform to Revolutionize Gene Therapy Manufacturing

Chris Brown[1], Cameron Fulco[1], Rick Niu[2], Ann-Sophie Reinshagen[3], Anne Wolters[3], Jing Zhu[2], Xiaojun Liu[1]

[1]Process Sciences, ReciBioPharm, Boxborough, MA,[2]Process Sciences, ReciBioPharm, Watertown, MA,[3]ReciBioPharm, Cuxhaven, Germany

Recombinant adeno-associated virus (rAAV) vectors have been proven to be effective tools in delivering therapeutic payloads designed to address various debilitating genetic disorders. Nonetheless, the manufacturing process for these vectors can pose significant challenges, resulting in elevated costs and hindering commercialization. There is a critical need to expedite the development and optimization of rAAV manufacturing processes to meet the growing demand for gene therapies. Here, we demonstrate the development of a robust and scalable rAAV production platform, yielding rAAV8 at a concentration >2.0E15 GC/L and achieving greater than 50% full capsids at harvest, some of the highest reported yields so far using transient transfection. Our introduction of a novel transfection enhancer and optimization of various upstream process parameters has allowed us to increase rAAV yield and % Full capsids by greater than 20-fold and 3-fold, respectively, over a traditional transient transfection process using PEI. The design of experiments (DOE) methodology was employed to identify optimized transfection conditions including cell density, enhancer concentration,

DNA amount, and DNA to transfection reagent ratio, resulting in additional enhancement of rAAV yield and quality. The broad applicability of this optimized platform has been further validated via testing across various wild-type and engineered rAAV serotypes and across various transgenes representative of therapeutic programs seen in the market today. In addition, we have demonstrated our capability to successfully scale-up using Sartorius single-use bioreactor systems, demonstrating the scalability of this platform when used with various serotypes, transfection reagents, and transgenes. The broad applicability of this platform will allow us to reduce process development time and expeditiously ramp up the manufacturing of new products. In summary, this work demonstrates our ability to efficiently increase rAAV yield and quality via optimization of upstream process parameters, an approach which is easily transferrable across rAAV serotype and gene-of-interest. The development of this robust and scalable platform offers a promising and innovative approach to enhance rAAV manufacturability, offering increased yield, reduced cost, and an acceleration of the drug development timeline.

565. Optimizing Transfections for Increased AAV Titers and Effective Media Evaluations

Jessica J. Haywood[1], Kim Schrag[2], Kate Hellman[1], Nathan Stegemann[1], Katelyn McLaughlin[1], Charlotte Javalet[3]

[1]Upstream R&D, MilliporeSigma, Lenexa, KS,[2]MilliporeSigma, Lenexa, KS,[3]MilliporeSigma, Meylan, France

Adeno-associated virus (AAV) has become a prominent vector for gene delivery to treat life-threatening genetic diseases. One of the major limitations for product development and treatment availability is the need for high levels of infectious AAV particles, therefore, media and process optimization is vital to achieving high AAV titers. To maximize AAV titers across multiple HEK293 cell lines, media development for AAV production was performed with three HEK293 cell lines with different growth rates. Following media development, transfections for AAV production were optimized with Design of Experiment (DoE) studies in small scale and confirmed with bioreactor runs. In addition, optimized transfection parameters and smaller DoE designed transfection parameters were applied to cell cultures grown and transfected in media from other vendors. Each media formulation required different transfection parameters to achieve optimized AAV titers.

566. Development and Characterization of a Rhabdovirus-Free Clonal Sf9 Cell Line for Enhanced Safety and Enhanced AAV Production in the Baculovirus Expression Vector System

Gina Zhang[1], Michelle Martin[1], Brendan Leung[1], Chinmay Patkar[1], Christopher Casey[2], Jeffrey Kan[2], Ting Yang[2], Robert Lu[3], Yiling Fang[1]

[1]Analytical Development, Frontera Therapeutics, Bedford, MA,[2]Process Development, Frontera Therapeutics, Bedford, MA,[3]Technical Operation, Frontera Therapeutics, Bedford, MA

The widespread use of *Spodoptera frugiperda 9* (Sf9) cell lines in biological product manufacturing has revealed the presence of a novel rhabdovirus identified in 2014. While downstream purification successfully eliminated rhabdovirus, the desire for a virus-free cell line prompted the development of an in-house rhabdovirus-free clonal Sf9 cell line. The rigorous characterization employing a comprehensive panel of safety assays, established in house, confirmed the absence of rhabdovirus. Evaluation of the cell line's performance in baculovirus generation and Adeno-Associated Virus (AAV) production demonstrated superior yields and product quality compared to the conventional Sf9 cells, spanning multiple AAV serotypes (AAV2, AAV5, AAV8, and AAV9). The successful development of this rhabdovirus-free cell line marks a significant advancement, ensuring heightened safety and efficiency in future process development and Good Manufacturing Practice (GMP) productions.

567. Correlation Analyses of the Quality Attributes of Adeno-Associated Virus Vectors Revealed the Positive Impact of the Viral Protein 2 Ratio on Transduction Efficiency

Takahiro Maruno[1,2], Mitsuko Fukuhara[1,2], Yasuo Tsunaka[2], Aoba Matsushita[2], Kiichi Hirohata[2], Karin Bandoh[2], Megumi Onaka[1], Risa Shibuya[2], Yuki Yamaguchi[2], Yoshiki Nagashima[3], Daisuke Higo[3], Toshie Kuwahara[2], Tomoko Ueno[2], Masaharu Maeda[4], Guirong Kanai-Bai[2], Noriko Yamano-Adachi[2], Tetsuo Torisu[2], Takeshi Omasa[2], Susumu Uchiyama[2]

[1]U-Medico Inc., Suita, Japan,[2]Graduate School of Engineering, Osaka University, Suita, Japan,[3]Thermo Fisher Scientific, Yokohama, Japan,[4]Osaka Consolidated Laboratory, Manufacturing Technology Association of Biologics, Suita, Japan

Adeno-associated virus (AAV) vector capsids, composed of viral proteins (VPs), not only protect the therapeutic nucleic acids but also play an important role in gene delivery and transduction. Among the three types of VPs (VP1, VP2, and VP3), the amino acid sequence of VP3 is identical to that of the VP3 region in VP1 and VP2. VP2 and VP1 have an extended region at the N terminus of VP3 and VP2, respectively. VP1 and VP2 are considered to play important roles in the gene transduction, whereas the VP3 and VP3 regions in VP1 and VP2 are essential for capsid formation. The typical stoichiometry of VP1:VP2:VP3 is roughly estimated to be 5:5:50. The VP ratio is considered to be one of the quality attributes (QAs) that require evaluation. In fact, a higher ratio of VP1 and VP2 leads to higher gene transduction. However, there is limited information on how the QAs affect the transduction efficiency of AAV vectors manufactured using the HEK293 suspension cell line system. In this study, we performed an investigation into how the QAs affect the transduction efficiency of the AAV vectors manufactured using the HEK293 suspension cell line system. To evaluate various QAs of AAV vectors with the same serotype and the same GOI manufactured under different conditions, we manufactured 10 lots of AAV vectors (AAV8-CMV-EGFP) with different conditions modulated within an empirical range in the upstream process and with unified conditions in the downstream process. We monitored the in-process results regarding the cell viability in the upstream process, affinity chromatography (AC) peak area,

A260/A280 after AC, density gradient ultracentrifugation (DG-UC) peak area, A260/A280 after DG-UC, yield, and A260/A280 of the product in the downstream process. Next, we evaluated various QAs including the particle size, particle distribution, full-empty ratio, VP purity, VP stoichiometry, deamidation ratio of VPs, host cell protein, host cell DNA, and transduction efficiency of manufactured AAV vector samples. Remarkable variations in VP stoichiometry were observed; wide variation was observed in VP2 and VP3, whereas little variation was observed in VP1. By performing correlation analyses among the QAs, we identified several attributes that could affect the transduction efficiency. To give one example, the significant positive correlation between the number of VP2 molecules and the transduction efficiency. We plan to discuss correlation between upstream and downstream in-process results and QAs of the products in our presentation.

568. Continuously Improving Quality and Efficiency in AAV Manufacturing

Mathias Kahl

IDT Biologika GmbH, Dessau, Germany

This work explores continuous improvements of quality and efficiency in AAV manufacturing processes. Operating within non-GMP and research-focused environments, the study places a significant emphasis on consistently optimizing both the quality and efficiency of AAV processes, which can be transferred easily into a GMP setting. Utilizing IDT Biologikas' proprietary HEK293 cell line, which we benchmarked against commercially available AAV manufacturing solutions, we are investigating how our platform approach is responding to ongoing advancements in AAV manufacturing. While implementing a generic manufacturing platform for AAV´s we evaluate a broad set of upcoming technologies and trends that might potentially redefine quality attributes, safety profiles and contribute to reducing serious adverse effect. In this Talk we will report about IDT´s journey in implementing a generic concept for AAV manufacturing and about the current standards in production processes, giving a future perspective on the upcoming activities, while evaluating new available technologies from a GMP manufacturer point of view. The exploration of new technologies in AAV manufacturing strives to set new benchmarks. A ready-to-use platform, along with cutting-edge techniques and a proprietary cell line, become instrumental in achieving sustained quality and efficiency. In particular we will allude on further optimization in AAV manufacturing by integrating the use of small molecules and plasmids technologies and the implementation of post-translational modifications characterization by use of analytical solutions beyond the current regulatory requirements. Thus potentially supporting the definition of standards for quality and efficiency for gene therapeutic products.

569. High-Throughput Chromatography Studies to Improve Process Understanding and Reduce Risks in Gene Therapy Clinical Manufacturing

Jeff Plegaria, Matthew Petroff, Qi Lin, Jonathan Palmer, Mi Jin

Spark Therapeutics - Philadelphia, PA, Philadelphia, PA

AAV downstream processes face significant challenges due to high levels of product variants and complex characterization of these impurities. These challenges are further compounded by timeline pressures to generate clinical lots and limited historical information in AAV manufacturing. To address these issues, we present high-throughput case studies for early assessment of platform fit. Using Design-of-Experiments and miniaturized chromatography, we optimized downstream performance while simultaneously identifying key process parameters for control, to ensure manufacturing success. These studies contribute to early process understandings, risk assessment, and control strategy, thereby reducing the risks associated with process changes during early-phase clinical manufacturing.

570. Design of Experiments Approach to Increase rAAV Yield through Optimization of Transfection Conditions

Igor Alves Mancilla[1], Maria Nicla Loviglio[2], Megane Denu[2], Paul Giroud[2], Jean-Thomas Issenhuith[2], Irene Ferreira[3], Carl J. Christel[3], Kimchi Audrey Strasser[1]

[1]Process Development, Revvity Gene Delivery (SIRION Biotech Legacy), Graefelfing, Germany,[2]Polyplus-Transfection, Illkirch, France,[3]Cell & Gene Therapy Platform Innovation & Management, Revvity Gene Delivery (SIRION Biotech Legacy), Graefelfing, Germany

A widely employed method for large-scale production of rAAV vectors involves co-transfecting HEK293-derived producer cell lines with three plasmids. The producer cell line and production plasmids are manufacturing starting materials, which not only influence rAAV Critical Quality Attributes (CQAs) for purity and potency, but also positively affect manufacturability parameters like productivity. Increasing process productivity is an effective strategy to reduce the cost of goods in preclinical and clinical development, as well as in the commercialization phase of a gene therapy product. Concurrently, another avenue to explore involves selecting starting materials that offer optimal cost-effectiveness. Here, we report the application of a design of experiments (DoE) approach to simultaneously increase productivity and investigate a more cost-effective transfection reagent, FectoVIR®-AAV (Polyplus®). An initial DoE was designed by Polyplus® using the MODDE® software, where the factors tested were: amount of plasmid DNA, ratio of DNA to the transfection reagent, complexation time, and day of cell seeding. We produced pAAV-Rep2Cap8 in 26 independent 3-plasmid transient transfections in the Viral Production Cell 2.0 (Gibco™), a HEK293F-derived subclone, with Viral Production Medium (Gibco™), in 30 mL cultures in shaker flasks. We harvested 3 days later and clarified by alluvial filtration. The clarified lysate was measured by ITR-qPCR, where the result was expressed in VG/mL of cell culture. Titers varied from 5.3E11 to 2.6E9 VG/mL. By fitting the results to a response surface model and performing a ridge analysis, we

could determine that higher concentration of DNA and lower ratio of DNA to FectoVIR®-AAV are key factors. However, complexation time and day of cell seeding were not significant factors for this model. To validate these results and to precisely determine the optimal values of plasmid DNA and ratio of DNA to FectoVIR®-AAV, we conceived a follow-up experiment which included 3 different cell concentrations and 4 different complexation buffers. This design was developed through an R-based DoE pipeline using optimal design of experiments. We produced the same vector as previously in 32 independent 3-plasmid transient transfections. The method of production was similar to the one previously described, but with 10 mL cultures in 50 mL mini-bioreactors. We found that the narrower range of DNA amount and ratio of DNA to FectoVIR®-AAV did not excessively impact productivity, showing the robustness in the range tested. Taken together, these results demonstrate the possibilities of utilizing a DoE approach for process development before proceeding with non-GMP productions for preclinical studies. Thus, a DoE approach should not only be considered for developing a cost-effective GMP manufacturing process, but also as a cost-effective non-GPM manufacturing process for preclinical batches.

571. Tackling AAV Manufacturing Process Industrialization Challenges Using a Standard Platform Approach

Emilie Gateau, Andy Reniers, Camille Lemaigre, Solène Arnoult, Claire Favre-Felix, Tiago Albano, Julien Caballero-Montes, Antonio Salgado-Somoza, Kassandra Watillon, Sylvain Fauquenoy, Vasily Medvedev, Hanna P. Lesch

Exothera, Jumet, Belgium

AAV is considered as one of the most versatile tools for gene therapy applications, with its target tissue specificity and its non-replicating property benefits. Therefore, a growing number of AAV clinical trials are initiated each year and increasing safety concerns come with the need to strengthen our understanding of the manufacturing process and its impact on the final product quality. For this purpose, we developed a standardized manufacturing process following QbD principles ensuring sustainable yields for commercial stages and compliance with CMC requirements. Supportive analytical tools are instrumental in the delivery of a high-quality product and a key component of our proprietary platform. With our CMC roadmap, we defined upfront a set of advanced analytical methods to characterize AAV products. We have developed an integrated methodology to evaluate total residual DNA and encapsidated residual DNA on multiple serotypes using ddPCR, targeting host cell DNA and residual plasmid sequences. For infectious particle titration, we also rely on an alternative method to the recognized TCID50. To optimize the comparability with TCID50, general aspects of the cell culture approach have been retained. Our strategy is based on the titration of internalized genomes 24 hours after infection, by ddPCR, using a system of helper virus-free and HeLa cells. We focused our upstream development on key current AAV bottlenecks, *i.e.* delivering high yields and scalable manufacturing processes. Working toward starting material selection and supplementation strategies, we managed to increase our titers by a 4.5-fold factor going from 1E11 VG/mL to 5E11 VG/mL at AAV2 harvest. We have determined how a cell line could also impact quality attributes such as the percentage of full and empty capsids, or the host cell impurity level having drastic consequences on downstream operations. We worked on a methodology to ensure right-first-time process scale up to 1000L bioreactor scale with consistent titers. We then improved our downstream toolbox to deliver optimal product purity. To target the removal of impurities acceptable for highly concentrated AAV product, we used design of experiment methodology to optimize our endonuclease treatment, chromatography and filtration steps leading to a reduction of up to 2 logs of host cell DNA, 5.5 logs of host cell proteins and 2.7 logs of endonuclease. Thanks to this development, our platform reaches overall recoveries of 30-40% after polishing and enrichment up to 90% of full particles determined by AEX-HPLC, directly aligned with latest CMC needs. In conclusion, we demonstrated that a systematic approach can address CMC needs to achieve product quality objective. Through the development of this process, we have successfully engineered a standardized platform that consistently delivers according to industry expectations.

572. Demonstration in Scalability of a Flexible, High-Producing Triple-Transfection rAAV Platform

Cameron Fulco[1], Chris Brown[1], Yeonji Kim[1], Rick Niu[2], Ann-Sophie Reinshagen[3], Anne Wolters[3], Jing Zhu[2], Xiaojun Liu[1]

[1]Process Sciences, ReciBioPharm, Boxboough, MA,[2]Process Sciences, ReciBioPharm, Watertown, MA,[3]ReciBioPharm, Cuxhaven, Germany

The use of recombinant adeno-associated virus (rAAV) is still a key method for DNA delivery to target cells in patients with over 100 companies working on rAAV in some capacity. Depending on numerous factors such as the target disease and route of administration, typical doses can range from 5e8 GC/eye to 1e14 GC/kg. The higher dosing strategies can prove challenging for some companies or institutions to be able to target specific diseases or maintain a broad portfolio of targets. While triple-transfection methods are among the more expensive production processes, their flexibility in product generation and streamlined development timelines can allow for a truly established platform capable of delivering multiple products. Development of a scalable, high-producing upstream platform for AAV generation is paramount for treating more patients with fewer batches. Having fewer batches in turn reduces the manufacturing costs therefore greatly offsetting the costly transfection plasmids and transfection reagent in addition to a reduction in GMP suite time and manufacturing timelines from the larger vessel size. We demonstrate here our capability to scale-up a variety of difference upstream conditions including different capsid serotypes, transfection reagents, and transgene lengths with comparable harvest yields and quality. In addition, through cell health metrics along with harvest yield, we demonstrated the scalability of this HEK293-based Upstream process from shake-flask to 50L scale, while generating harvest yields >1.0E15 GC/L with >40% full capsids.

573. Enhancing AAV Purification: Strategies for Improved Recovery and Quality for Downstream

Yeonji Kim[1], Chris Brown[1], Cameron Fulco[1], Rick Niu[2], Ann-Sophie Reinshagen[3], Anne Wolters[3], Jing Zhu[2], Xiaojun Liu[1]

[1]Process Sciences, ReciBioPharm, Boxboough, MA,[2]Process Sciences, ReciBioPharm, Watertown, MA,[3]ReciBioPharm, Cuxhaven, Germany

In gene therapy manufacturing, proper extraction of adeno-associated virus (AAV) material from transfected cell cultures during the upstream process is pivotal for downstream success. However, challenges in AAV manufacturing include limited titer production and difficulties in high recovery in the extraction of full capsids. This study aims to optimize the initial stages of the downstream process using high-titer AAV material with diverse analytical methods. An exceptionally high titer of >1E12 vg/mL, surpassing the normative threshold post-lysis, as the starting post-lysis material is noteworthy. High-quality AAV purification is crucial to establish a preliminary downstream purification standard before chromatography. Filtration steps eliminate residual host cell proteins and DNA while preserving viral particles. A comparative analysis of three vendors was conducted with each vendor providing the top three of their best performing depth filters. Following filtration, various Tangential Flow Filtration (TFF) methods were assessed to pinpoint the optimal approach for maximizing recovery and purification. During these tests, multiple analytical methods quantified viral particle counts of AAV. Among the methods is ddPCR, a robust method to quantify DNA and viral particles. The comparison involved evaluating each filtrate against pre-filtered materials, examining turbidity reduction, reduction in host cell protein and DNA levels, viral particle recovery, aggregation, and considering factors like time and throughput. The selected methodology concluded from the filtration and TFF study, supported by advanced analytics, demonstrated >95% recovery, even with lysate titer of 1E12 vg/mL, generating pure AAV materials ready for chromatography. The total throughput calculated was ~180 L/m2. Data from viral titer recovery using ddPCR and assays gauging residual host cell proteins and DNA provide valuable insights for optimizing AAV purification processes. This research enhances efficiency and quality in AAV production, advancing gene therapy applications.

574. Knowledge Management Tool for Fast Tech Transfer from Client to IND

Yvette Valenzuela, Catherine Siglin

Resilience, Waltham, MA

Rapid progress is paramount in the development of a promising drug candidate, particularly when navigating the stages of GMP manufacture and IND approval. The challenges are amplified by the inherent uncertainties that accompany early-stage drug development, where process developers operate with limited insights into a scale-appropriate and representative process, compared to what was initially developed in the laboratory. The success of a program hinges on avoiding misinterpretations of critical parameters, order of operations, or materials, as any mistranslation can lead to significant setbacks. Within the Gene Therapy Franchise at Resilience, we've implemented a streamlined tech transfer workflow process to efficiently transfer knowledge from clients to the process development team and seamlessly integrate it into clinical manufacturing. Our innovative approach involves merging the process definition and facility fit exercises, resulting in an impressive 50% reduction in cycle time. This accelerated timeline allows us to assess gaps, identify and track mitigation actions, and facilitate necessary revisions to the process description. The self-service tool we've implemented serves as a versatile platform for knowledge transfer, extending its benefits to supporting functions such as Manufacturing, Supply Chain, Engineering, QC, and Regulatory functions. The result has been the successful maintenance of program timelines, ensuring the timely execution of manufacturing batches and meeting stringent regulatory filing requirements. In essence, our strategic and integrated approach expedites the development process and enhances the precision and reliability of each stage, contributing to the program's overall success.

575. AAV Harvest Lysate After Varying Upstream In-Process Steps Show Comparable Yield and Product Quality

Kenneth J. Cunningham, Hsuan-Ni Lin, William Kaiser, Shohanuzzaman Shohan, Vini Sheth, Sadie Alperson, Elliot Jersild, Clarissa Tjoanda, Sarah Kudman, Adnan Arnaout, Stanley Ng, Jessica Cheng, Mary Ng, John Chan

Prevail Therapeutics (A Wholly Owned Subsidiary of Eli Lilly and Company), New York, NY

During adeno-associated virus (AAV) production, several methods are available for preparation of column load prior to chromatography purification, including clarification, concentration (UF), or diafiltration (DF) of crude cell lysate. The method used can depend on several factors, such as process differences between manufacturing platforms or differences in developmental stage. At the small-scale screening and development stage, the cell lysate volume is not typically large enough to go through the full UF/DF processing, while during large-scale manufacturing it is preferable to concentrate cell lysate volumes to reduce downstream column loading time. However, it is not well understood how differences in upstream processing after cell lysis and the subsequently different column load matrices will impact AAV yield and quality. This study aims to evaluate the impact of using column load sourced from different upstream in-process steps which can support process flexibility and characterization.AAV cell lysate produced for this study was divided into five groups with equal viral genomes (vg) per study condition. These five groups aim to evaluate the impact on the affinity capture step after loading bulk cell lysate prepared by centrifugation, depth filtration, concentration (UF-1), concentration and diafiltration (UF-1/DF), or additional concentration and diafiltration (UF-2/DF). To ensure process intermediate stabilities were comparable, After the five column loads were purified, eluates were split into two groups and either frozen immediately or frozen after a 7-day hold at 2-8C. Affinity chromatograms of the five different column loads were compared and analytics were performed to measure yield, product quality, and residuals. Step yields across each upstream arm and downstream purification were determined by ddPCR. Product quality was evaluated by measuring expression potency. Dynamic light scattering (DLS) was used to measure the AAV size distribution and aggregation. ELISA was used to measure host cell protein (HCP)

levels and clearance across each study condition. This study concludes that there is no significant difference from using varying column loads from different upstream in-process steps post-cell lysate clarification on purification performance. This study further characterizes upstream in-process steps and provides additional downstream hold time stability data. Taken together, these findings support additional process flexibility, allowing AAV from platforms with different matrices to be compared equivalently.

576. Adapting a Hybrid Analysis for AAV Characterization by Combining Long and Short Read Sequencing Techniques

Brianna C. McManus, Rebecca A. Bova, Christina Kalinyak, Maggie Luce, Servane Orozco, Bradley Hasson

BioReliance Corporation (MilliporeSigma/Merk KGaA), Rockville, MD

Adeno-associated viruses (AAV) are one of the most widely used viral vector-based gene therapy delivery systems in the industry. The manufacturing of such products commonly uses a series of 3-4 plasmids that are transfected into a producer cell line in order to assemble the viral particles. Each plasmid contains a critical element for viral production, whose product is an AAV particle containing the gene of interest flanked by two inverted terminal repeat (ITR) regions. NGS has become a widely used tool for biosafety testing for a variety of viral and gene therapy products. Short-read techniques such as Illumina, while effective, can be improved upon. PCR based library preparation methods can introduce levels of biases, and the highly repetitive ITR regions are difficult to sequence due to their repetitive nature, sequencing read length is limited by the number of cycles per sequencing kit. While long-read sequencing technology is a relatively new platform, it aims to mitigate these risks, however, in comparison, it can have reduced quality scores. To analyze these types of samples more effectively, a hybrid-analysis approach can be employed. By combining short and long read methods a genome assembly can be created with deeper coverage, longer reads, and retaining both quality and accuracy. Long-read sequencing with Oxford Nanopore technologies gives direct sequencing data without PCR, genome fragmentation, or limitations on read lengths. There are a wide variety of kits available with ranges of sample inputs. Testing has been performed to optimize the process of extraction through sequencing for these challenging primarily single-stranded molecules. We have tested various serotypes of AAVs through both long and short read NGS methods that were developed. The samples are first treated with Benzonase® endonuclease to remove any non-encapsidated sequences. This allows for the sequencing and analysis of the contents of the capsid DNA. The samples are extracted, amplified, then libraries are prepared using the Ligation Sequencing Kit V14 for sequencing on the GridION instrument. These generated sequences can be analyzed using currently used bioinformatic approaches and combined with short-read data for increased depth of coverage, characterization approaches, and can aid in genome assembly. The reads generated by both methods are directed into an analysis pipeline to assess known residual sequences. Through the analysis, reads can be mapped to multiple sequences that are used in the manufacturing process including plasmids and cell line genomes. It has been observed that by combining the two sequencing methods this would allow for deeper coverage of difficult to sequence regions such as ITRs than short read methods alone. Utilizing NGS to assess these known residuals that may be contained with the capsid allows for an overall understanding of what is seen within various capsid profiles. These methods mentioned above can be used to characterize the contents of capsid whether the capsid is expected to be full, empty or even partially full. By knowing what is in each payload this can help ensure a safer product.

577. A Rapid and Robust Construct Manufacturability Screen Enhances Therapeutic Candidate Selection

Tim Brantley, Samantha Gall, Leah Machlin, Samantha Lasater, Nick Wessler, Charles Pugh

Kriya Therapeutics, Durham, NC

Recombinant AAV vectors are defined by quality attributes that should remain consistent throughout the product development lifecycle, irrespective of process scale. A screening model to assess manufacturability of preclinical candidate constructs can eliminate product candidates with quality attribute challenges early in the development process and avoid the high costs associated with failure at scale. This work demonstrates the comparability of a staged construct screening and selection approach utilizing deep well plates, shake flasks and 1L bench scale bioreactors. A 24-well deep well plate upstream transfection process was developed to rapidly screen transgene constructs for their productivity and ability to package complete transgenes as measured by vector genome integrity capillary electrophoresis. At the cell culture harvest stage, packaged genome and capsid titer were within 21% and 18%, respectively, when comparing plates, shake flasks, and 1L BioBlu bioreactors across 3 transgene constructs. To measure vector genome integrity, a 24-well filter plate affinity chromatography system was developed to purify the culture harvest sufficiently for measurement of vector genome integrity. The 24-well filter plate affinity system was compared to column chromatography on an Akta chromatography system and step yields were between 75-80% for both systems. Once the number of therapeutic constructs has been narrowed down, we compared the final 2 transgene constructs in AAV1 across multiple batches using a scaled-down process designed to mimic our large-scale production processes. This process begins with inoculating and transfecting 1L BioBlu single-use bioreactors, cell lysis and filtration, followed by a two-column purification process. The two transgene constructs were evaluated for their upstream productivity, %full ratio of affinity eluate, AEX column step yield, % full ratio, and vector genome integrity in the final drug substance. The results demonstrated comparability of a staged construct screening and selection approach utilizing deep well plates, through shake flasks to1L bench scale bioreactors. This inclusion of rigorous analytical testing, uncommon at early stage of rAAV product development, ensures that the selected clinical candidates meet critical quality attributes and manufacturability needed to support successful product development.

578. Building a Chromatography Platform for Purification and Full Capsid Enrichment on AAV8

Rick Niu[1], Ann-Sophie Reinshagen[2], Yeonji Kim[3], Anne Wolters[2], Cameron Fulco[4], Chris Brown[3], Jing Zhu[1], Xiaojun Liu[3]

[1]Process Sciences, ReciBioPharm, Watertown, MA,[2]ReciBioPharm, Cuxhaven, Germany,[3]Process Sciences, ReciBioPharm, Boxboough, MA,[4]ReciBioPharm, Boxboough, MA

In the creation of AAV as a gene therapy drug product, empty capsids are formed. These are capsids that do not contain the gene of interest yet can increase the chance of immune responses in patients[1]. Therefore, different methods have been used to remove empty capsid and increase full capsid percentage. The most widely used are cesium chloride ultracentrifugation, iodixanol gradient ultracentrifugation, and anion exchange chromatography (AEX). Given the numerous benefits of chromatography over ultracentrifugation in terms of scalability, this mechanism was chosen to be further developed. The material utilized in this development was made in-house. AAV8 was grown on suspension HEK293 cells with GFP as the gene of interest. Following lysis, it was clarified via depth and sterile filters, then concentrated and diafiltered through tangential flow filtration (TFF). Purification on the TFF retentate was performed by affinity chromatography. To optimize this process, different resins, loading conditions, buffers, and run parameters were compared. Success criteria were evaluated by comparing recovery percents determined by digital droplets polymerase chain reaction (ddPCR). Following the optimized affinity chromatography, the elution was utilized as the starting point for AEX development. Four different columns were screened with varying buffers, load conditions, and modalities. Full capsid enrichment was primarily analyzed with DLS via Stunner by Unchained Labs and cross referenced with SV-AUC and TEM. Promising conditions were then analyzed by ddPCR to determine recovery percentage. Several approaches produced very high full capsid enrichment (95%) while also recovering the majority of product.

579. Evaluating AAV Production Platforms Using Commercially Available Host Cells and Plasmid Systems

Pratima Cherukuri, Lily Ong

Genezen Laboratories, Indianapolis, IN

Adeno-associated viruses (AAVs) are an effective gene delivery platform for gene replacement, regulatory and gene editing applications. However, the challenge of efficient vector manufacturing persists, exacerbated by numerous serotype options and capsid variants. Additionally, a robust and scalable manufacturing process often requires a significant amount of time and investment. Rather than customize the process for each transgene and serotype, a platform process would be most impactful especially for rare and ultrarare indications. To tackle this complexity, we applied a design-of-experiment (DOE) methodology to systematically optimize a production process that is capable of producing high quality, full capsid enriched harvest with downstream purification process agnostic to capsid/serotype variations. Our approach involved evaluating multiple production parameters, including two different suspension-based host cell lines and three commercially available helper plasmid systems with variations in the plasmid DNA-to-cells ratio. By simultaneously adjusting transgene, packaging, and helper plasmid ratios, total DNA concentration, and cell density, we systematically examined their combined effects to enhance titers and achieve superior empty-to-full ratios. Additionally, we evaluated the integrity of the genomes using single genome analysis to ensure the highest quality and potency. The data from the initial DOE studies were used to assess the scalability of the platform at the 50L scale.With an attempt to stay agnostic to capsid and serotype variations, we introduced ultracentrifugation to agnostically improve empty versus full ratios, along with Anion Exchange Chromatography (AEX) in downstream processing. Mass photometry served as a rapid and efficient analytical tool for aggregate and empty-to-full AAV capsid ratio analysis. The results of this approach will be discussed in this presentation. This integration of commercial upstream materials and a serotype-agnostic downstream processing (DSP) process will be used to establish a universal high-quality manufacturing process for AAV viral vectors.

Wednesday Posters: Metabolic Diseases

580. Defining Clinical and Laboratory Biomarkers in Propionic Acidemia to Guide AAV Gene Therapy Clinical Trial Endpoints

Carolina I. Galarreta Aima, Oleg Shchelochkov, Jennifer L. Sloan, Camryn Hall, Abigael Gebremariam, Susan C. Ferry, Carol A. Van Ryzin, Irini Manoli, Charles P. Venditti

Organic Acid Research Section, National Human Genome Research Institute, Bethesda, MD

***Background*:** Patients with propionic acidemia (PA), caused by a deficiency of propionyl-CoA carboxylase alpha (PCCA) or beta (PCCB) subunits, display diverse clinical symptoms and laboratory abnormalities. Currently, clinical management is limited to carnitine supplementation, restricted dietary protein intake, and, for severe patients, elective liver transplantation to restore propionyl-CoA carboxylase activity. Systemic AAV9 gene therapy is being developed as an alternative to organ transplantation for both *PCCA* and *PCCB* PA by the NCATS Platform Vector Gene Therapy (PaVe-GT) and the Bespoke Gene Therapy Consortium (BGTC). Similar to other rare metabolic disorders, the evaluation of outcome measures and surrogate biomarkers important for protocol development and regulatory approval remains challenging. ***Methods*:** To help define clinical parameters and laboratory biomarkers associated with disease severity and response to treatment, we have conducted a prospective study at the NIH Clinical Center (**ClinicalTrials.gov Identifier: NCT02890342**). Protocol visits included a battery of subspecialty evaluations, nutritional assessments, imaging studies, laboratory and molecular genetic testing, including trio exome analysis, the collection of biospecimens, and the generation of EBV and/or fibroblast cell lines from all participants. Cardiac, renal, hematological, hepatic, ophthalmic, neurological and metabolic parameters were systematically examined. Patients underwent a 1-^{13}C-propionate oxidation breath test (POBT), a non-invasive whole-body measurement largely reflective of

residual propionyl-CoA carboxylase activity in the liver, expressed as cumulative percent isotope dose metabolized in 60min. ***Results:*** 42 PA patients, including 23 females (54.7%) were evaluated, with a median age of 12.0 (Interquartile range 6.0, 23.5). Molecular confirmation was obtained for all patients (17 harbored pathogenic variants in *PCCA* and 25 in *PCCB*). Eight patients underwent organ transplants: 5 had isolated liver transplant (LT) (median age 1.5yo, range 1-20), 1 had an isolated kidney transplant (at age 42 years), 1 had a combined liver kidney transplant (21.5 years), and 1 had combined liver/heart transplant (7.8 years). POBT obtained in 29 (14 *PCCA*, 15 *PCCB*) patients showed a median 1-^{13}C-propionate oxidative capacity of 3.79% (IQR 2.0, 13.52). In comparison, 21 healthy volunteers had a median value of 32.9% (IQR 31.0, 34.2), and 3 post-liver transplant PA patients had a median value of 29.8% (IQR 18.1, 41.3). 1-^{13}C-propionate oxidization at 60 minutes negatively correlated with Full-Scale Intelligence Quotient ($p<0.001$), height Z score ($p=0.005$) and left ventricular ejection fraction ($p=0.016$) in untransplanted patients. Plasma concentrations of disease-specific metabolites, including 2-methylcitric and 3-hydroxypropionic acid, were measured (N=35 pre-transplant and 5 patients after LT), showing a reduction in levels post-transplant. Both metabolites negatively correlated with 1-^{13}C-propionate oxidization at 60 minutes ($r=-0.548$, $p<0.001$, and $r=-0.662$, $p<0.001$ respectively) and_correlated negatively with kidney function. ***Conclusion:*** Our study further elucidates the natural history of propionic acidemia and provides a basis for studying surrogate biomarkers that could serve as informative pharmacodynamic endpoints in future phase I/II clinical trials.

581. AAV Gene Therapy Corrects Metabolic Profile and Extends Survival in a Mouse Model of Argininosuccinic Aciduria

Yuchen Zhou, Jill Thaisz, Craig Smith, Christina Chang, Veronica Viramontes, Donald Chun, Yogendra Shrestha, Franziska Graf Leifer

Insmed Incorporated, Bridgewater, NJ

Argininosuccinic Aciduria (ASA) is a rare pediatric-onset urea cycle disorder caused by loss-of-function mutations in the argininosuccinate lyase (ASL) gene. ASL is one of five enzymes in the urea cycle, catalyzing the conversion of argininosuccinate to arginine and fumarate[1]. Reduction in or loss of ASL function leads to rapid buildup of ammonia in the blood stream that, left untreated, can cause coma and death[1]. The current ASA standard of care regimen of nitrogen scavenger therapy, low protein diet, and arginine supplementation may leave patients at continued risk for recurring hyperammonemic crises, and many experience long-term cognitive impairment[1]. Adeno-associated virus (AAV) gene therapy is a promising treatment modality for therapeutic targeting of the liver[2], however, the single-dose paradigm of current AAV gene therapy treatments is not suitable for early-onset pediatric ASA patients due to the expected loss in transgene expression in the growing liver over time[3]. To potentially overcome this limitation, Insmed is developing a redosable AAV gene therapy platform that could enable durable therapeutic benefit. As part of that work, we have developed a series of therapeutic AAV transgene constructs encoding the human ASL gene and evaluated their in vivo efficacy in ASA$^{neo/neo}$ mice, an early-onset mouse model of ASA. We delivered the hASL transgenes encapsulated in wildtype recombinant AAV particles via a single dose ranging from 1e13 vg/kg to 1e14 vg/kg. We monitored clinical outcomes and biomarkers including body weight gain, survival, blood ammonia, and urea cycle intermediates. Following treatment, blood ammonia levels of ASA$^{neo/neo}$ mice dropped from above 400 μM prior to treatment to the normal range below 100 μM and plasma argininosuccinate, the urea cycle intermediate metabolized by the ASL enzyme, was significantly reduced. At the same time, bodyweight gain of ASA$^{neo/neo}$ mice accelerated up to ten-fold from 0.046 g per day predosing to 0.460 g per day the week after dosing and the median survival of ASA$^{neo/neo}$ mice increased from less than 20 days to over 100 days. These results indicate that Insmed's ASA AAV gene therapy constructs can successfully ameliorate the metabolic state of ASA$^{neo/neo}$ mice and could be a promising treatment for ASA if delivered as a redosable AAV gene therapy. 582. Deep Phenotyping of a Cobalamin B-Type (*cblB*) Methylmalonic Acidemia Patient Cohort Guides the Selection of Biomarkers and Outcomes for AAV Gene Therapy Clinical Trials

Abigael Gebremariam, Camryn Hall, Samantha McCoy, Jennifer L. Sloan, Susan C. Ferry, Carol Van Ryzin, Carolina Galarreta-Aima, Oleg Shchelochkov, Irini Manoli, Charles P. Venditti

National Human Genome Research Institute (NHGRI), Bethesda, MD

Introduction: Cobalamin B-type (cblB) methylmalonic acidemia (MMA) is an ultra-rare autosomal recessive inborn error caused by pathogenic variants in the MMAB gene, which encodes for the enzyme ATP:cob(I)alamin adenosyltransferase (ATR). ATR catalyzes the synthesis and delivery of 5'-deoxyadenosylcobalamin (AdoCbl) to the methylmalonyl-CoA mutase enzyme (MMUT). MMAB-MMA results in life-threatening metabolic instability and progressive multisystem disease with limited therapeutic options outside elective liver transplantation offered to severely affected patients. In collaboration with NCATS via the Platform Vector Gene Therapy (PaVe-GT) project we aim to develop AAV9 gene therapy for MMAB-MMA. In this study, we document genotype-phenotype associations, biomarkers of disease severity and effects of liver transplant in MMAB patients in preparation for a future AAV gene therapy clinical trial. **Methods:** We evaluated 17 cblB patients, 12 male (70.5%), ranging from 2 to 46 years of age, including eight with a liver or combined liver and kidney transplant (LT/LKT) under a natural history protocol (NCT00078078). We examined genotype-phenotype correlations; measured canonical metabolites, including methylmalonic acid (sMMA) levels, and plasma FGF21, a marker of hepatic mitochondrial dysfunction; and conducted a 13C-propionate oxidation breath test (POBT), as a safe, non-invasive, indirect measure of MMAB enzymatic activity. In preparation for gene therapy, we evaluated AAV neutralizing antibody (NAb) titers measured using a Huh7 cell-based assay with a AAV-CMV-lacZ reporter after incubation with serially diluted serum

from 8 study participants (PMID: 19133809). **Results:** In our cohort, 58.8% of alleles (8 homozygous) were the c.556C>T p.(Arg186Trp) variant, which is associated with a severe phenotype. Five patients were compound heterozygotes for c.700C>T p.(Gln234Ter), a nonsense variant associated with a higher residual enzymatic activity and B12 responsiveness in vitro. Half of the homozygotes for the p.(Arg186Trp) variant presented in the neonatal period, while 80% of the patients carrying the p.(Gln234Ter) allele were late onset. The median age of chronic kidney disease stage 3 onset was 3 years old for severe patients compared to the median age of 31 years for the mild variant. The POBT test confirmed low enzyme activity in a patient homozygous for p.(Arg186Trp) (16% of the isotope dose oxidized in 120 min) in contrast to near normal enzymatic activity (47%) in a patient compound heterozygous for p.(Arg186Trp) and p.(Gln234Ter) variant. Mild patients and recipients of a liver or liver/kidney transplant maintained lower serum metabolites, including sMMA and plasma FGF21, than those with severe disease. The total seroprevalence of NAbs against AAV2 or AAV9 was 25% (n=2/8) and 37.5% (n=3/8), respectively, while 66% were co-seropositive. Seropositive patients were older than 18 years (n=2) or had received solid organ transplantation (n=2). All untransplanted pediatric individuals were seronegative for AAV9. **Conclusions:** Genotype-phenotype correlations have emerged from the study of patients with MMAB-MMA, and directly inform the generation of murine models for preclinical proof of concept studies to enable AAV9 gene therapy. We also document that the more severely affected, younger patients have a predictable pattern of biomarker changes and are seronegative against AAV9, which should help facilitate translation of gene therapy for these children.

583. Prevalence of Neutralizing Antibodies Against AAV2 and AAV9 Capsids in Propionic Acidemia (PA): Implications for Systemic Gene Therapy

Camryn S. Hall, Jennifer L. Sloan, Carolina I. Galarreta, Oleg Shchelochkov, Irini Manoli, Charles P. Venditti

National Human Genome Research Institute, Bethesda, MD

INTRODUCTION: Propionic Acidemia (PA) is a severe inborn error of metabolism marked by life-threatening metabolic instability, multiorgan involvement, and poor long-term prognosis. PA is caused by biallelic variants in PCCA or PCCB resulting in a deficiency of alpha or beta subunits of propionyl-coA carboxylase, respectively, which catalyzes the conversion of propionyl-CoA to methylmalonyl-CoA. The limited treatment options for the disorder, which may involve invasive procedures like liver transplantation in severe cases, underscore the need to develop systemic AAV gene therapy as a novel treatment approach. Studies have demonstrated the efficacy of systemic AAV gene delivery in mouse models of PA, and initiatives by the Platform Vector Gene Therapy (PaVe-GT) program and Bespoke Gene Therapy Consortium (BGTC) are underway to advancing systemic AAV9 gene therapy for the patients. Thus, our focus was on evaluating neutralizing antibody (NAb) titers against serotypes 2 and 9 in a well-characterized group of PA patients, aiming to assess the feasibility of future gene therapy clinical trials with AAV9 vectors. METHODS: Participants and biospecimens were accrued via NIH study "The Natural History, Physiology, Microbiome and Biochemistry Studies of Propionic Acidemia" (clinicaltrials.gov identifier: NCT02890342). NAb titers were measured using an Huh7 cell-based assay with a AAV-CMV-lacZ reporter after incubation with serially diluted serum from the patients (PMID: 19133809). One sample from a previous study that had been processed in identical fashion was included as a positive control (PMID: 26790480). RESULTS: Archived serum samples from 36 patients (16 PCCA, 20 PCCB) aged 2 to 53 years were analyzed. Four patients have had organ transplants (3 liver, 1 kidney). The total seroprevalence of NAbs against AAV2 or AAV9 was 22.2% (8/36) and 25% (9/36), respectively; 70% of patients were co-seropositive. Most individuals with AAV9 NAbs were either adults or had undergone solid organ transplantation (55.5%, n=5/9). In the cohort of PA patients under 18 years without solid organ transplants, 10% (1/10) PCCA patients and 30% (3/10) PCCB patients were seropositive against AAV9, however, seropositive patients had titers less than or equal to 1:40, and 16/20 (80%) were seronegative for AAV9. CONCLUSIONS: In our study, the prevalence of AAV NAbs in PA was lower than observed in historical controls where AAV9 seropositivity ranged from 31-47%, with a lower limit of detection of 1:30 in adults and 1:50 in pediatric participants (PMID: 20095819, 29064732). Of special note, in our cohort, the younger patients who had not been transplanted were largely seronegative (16/20, 80%). Whether this reflects an underlying immune irregularity is unknown but is unlikely caused by decreased exposure to AAV given the frequent hospitalizations experienced by the patients. The Nab profile against AAV, especially AAV9, has encouraging implications for the clinical development of systemic gene therapy, especially for pediatric patients with propionic acidemia.

584. Using Genomic Databases to Estimate Rare Disease Prevalence: Application to Disorders of Propionyl-CoA Oxidation

Jennifer L. Sloan[1], Camryn S. Hall[1], Irini Manoli[2], Charles P. Venditti[2]

[1]National Human Genome Research Institute, Bethesda, MD,[2]NIH, Bethesda, MD

Introduction: Inborn errors of propionate metabolism are a group of autosomal recessive, genetically heterogenous, severe and potentially lethal disorders detected via elevated propionylcarnitine on newborn screening (NBS). As part of public and private partnerships, including the PaVe-GT and Bespoke Gene Therapy Consortium efforts, the development of AAV-gene therapy is underway for isolated methylmalonic acidemia caused by variants in *MMUT* or *MMAB* and propionic acidemia due to deficiency of propionyl-CoA carboxylase, encoded by *PCCA* or *PCCB*. Data from NBS studies suggest these conditions should be classified as rare diseases however the exact prevalence of each disorder is unknown and complicated by genetic heterogeneity and the lack of a nationwide NBS registry. *Methods*: We first interrogated genome sequencing datasets, gnomAD v2.1.1 [125,000 exomes] and SVs 2.1 [15,000 genomes]. Variants in *MMUT, MMAB, PCCA* and *PCCB* were downloaded and pathogenic or likely pathogenic (P/LP) ClinVar variants were analyzed. Variants that were conflicting, of uncertain significance, or not annotated were further reviewed as well as those found in literature through the Human Genome Mutation Database (HGMD) Professional version 2022.3 to determine variant pathogenicity using expert curation informed by guidelines (PMID: 25741868). To augment classification of variants, we included additional disease-causing mutations present in participants

evaluated at the NIH Clinical Center (NCT00078078, NCT02890342). Gene carrier rate (GCR) was determined by the sum of the minor allele frequency (MAF) of all P/LP variants. Carrier frequency and predicted incidence were calculated using the Hardy-Weinberg equation. *Results*: For *MMUT*, 153 P/LP variants were identified with GCR of 0.0024, equating to an estimated carrier frequency of 1/209 and predicted incidence of 1/175,849. Variants were individually rare and missense changes accounted for about half. We identified 37 P/LP variants in *MMAB*, yielding a GCR of 0.0007. We calculated an estimated carrier frequency of 1/677 and prevalence of 1/1.8 million. The c.556G>T p.Arg186Trp, was the most common variant, consistent with observations that it accounts for ~30-40% of alleles in MMAB patients. For propionic acidemia, we identified 93 variants in *PCCA* and 85 variants in *PCCB* with similar GCRs of 0.0013 and calculated a combined prevalence of ~1/319,000. Most variants in *PCCB* were missense whereas 70% of variants in *PCCA* were loss of function. One commonly reported insertion/deletion variant in *PCCB* may be underestimated given poor alignment and incorrect annotation. *Conclusions*: To our knowledge, there is no official regulatory guidance on the use of genomic databases, which are massively expanding across the globe, to assist with population estimates of rare disease prevalence and incidence, which are required to report to the FDA during the development of rare disease therapeutics. Although genome-based analysis of the prevalence of *MMUT, MMAB, PCCA* and *PCCB* pathogenic variants represents a conservative estimate of disease allele frequency, the subsequent predicted birth incidence calculated using the Hardy-Weinberg equation closely agrees with the number of infants diagnosed with MMA and PA in a cohort of ~4.5 million babies who underwent NBS in California (PMID: 32778825). For example, we estimate a prevalence of *MMUT*-type MMA as ~1/175,849 while NBS data reports ~1/110,000. Extending this approach to other rare genetic disorders that lack data from newborn screening but have promising therapies under development is feasible. Whether genomic analysis may more widely be accepted by regulatory bodies as a primary data source to support orphan designation and ultrarare disease classification is supported by our analyses.

585. Precise Base Editing of Hyperlipidemia-Associated Genes by the Transformer Base Editor to Reduce Blood Lipid Levels

Lang Zhang[1], Lijie Wang[1], Peixue Li[1], Huanyu Li[1], Tao Wei[1], Jinyan Zuo[1], Yuchen Zhang[1], Jing He[1], Bingbing Wu[1], Jia Chen[2], Xiaodun Mou[1]

[1]CorrectSequence Therapeutics Co., Ltd, Shanghai, China,[2]ShanghaiTech University, Shanghai, China

Hyperlipidemia refers to abnormal elevated levels of low-density lipoprotein cholesterol (LDL-C), triglycerides and/or lipoprotein (a) in the blood, which is associated with increased risks of atherosclerotic cardiovascular diseases (ASCVDs). Gene editing of certain hyperlipidemia-associated targets provides a promising strategy for lifelong reduction of blood lipids. We have previously reported a novel transformer base editor (tBE), which was elaborately designed to eliminate both sgRNA-dependent and sgRNA-independent off-target editing. The tBE is a cytidine base editor which converts C•G to T•A pairs, and therefore, enables gene silencing by conversion of CAA (Gln), CAG (Gln), CGA (Arg), TGG (Trp) to stop codons. In this study, tBE was employed to knock out genes associated with lipid metabolism, including *PCSK9*, *Angptl3*, *ASGR1*, *ApoC3* and *LPA*. Different pairs of hsgRNA (helper single-guide RNA) and msgRNA (main single-guide RNA) were screened for each target gene in hepatic cell lines. The highest editing efficiency reached above 80% for all the target genes *in vitro*. Next, the candidate sgRNA pairs for each target gene were tested *in vivo*, with PCSK9 as an example here. The four components of tBE, including Locator (L) mRNA, Effector/Key (EK) mRNA, hsgRNA and msgRNA, were encapsulated into lipid nanoparticles (LNPs), and injected into mice via tail vein at a dose of 0.5-3.0 mg/kg (n = 5). Gene editing efficiency, plasma PCSK9 levels and LDL-C levels were determined 7 days after LNP administration. The whole hepatic *PCSK9* knockout efficiency increased in a dose-dependent manner, and reached a maximum of 57% as determined by next-generation sequencing (NGS). Compared with the vehicle group, the plasma PCSK9 protein levels were reduced by over 90%, while the LDL-C levels decreased by about 50%. No off-target editing was detected at the three potential off-target sites predicted by Cas-Offinder. Furthermore, *PCSK9* editing occurred specifically in the liver, while little editing was detected in other tissues. These results demonstrated the feasibility of hepatic delivery of tBE by LNP for efficient gene editing. Since certain patients showed a combined increase of LDL-C, triglycerides, or lipoprotein (a), gene editing of one single target may not be sufficient to eliminate all the risks of ASCVDs. We will evaluate multiplex editing of different hyperlipidemia-associated genes in future studies.

586. A New Class of Circulating Hepatic Biomarkers Derived from Aberrant Post-Translational Modifications in Isolated Methylmalonic Acidemia

PamelaSara Head[1], Lisa M. Jenkins[2], Tapan K. Maity[2], Charles P. Venditti[3]

[1]Metabolic Medicine Branch, NHGRI, National Institutes of Health, Bethesda, MD,[2]Mass Spectrometry Resource, Center for Cancer Research, NCI, National Institutes of Health, Bethesda, MD,[3]Metabolic Medicine Branch, NHGRI, NIH, Bethesda, MD

Background: Organic acidemias (OAs), such as methylmalonic acidemia (MMA), are a heterogeneous group of inborn errors of metabolism that largely arise from impaired catabolism of amino acids. OAs are difficult to treat and have multisystemic manifestations, leading to increased morbidity and mortality. Successful elective liver (LT), kidney (KT), and liver-kidney transplantation (LKT) can provide metabolic stability, but patients can still manifest significant metabolic perturbations, with massively elevated circulating methylmalonic acid levels despite total hepatic correction. Therefore, there is a need to define circulating biomarkers that might correlate with the extent of *in vivo* hepatic correction after liver directed mRNA, gene editing and/or AAV gene addition therapy. In previous work (PMCID: PMC10468269), we discovered that aberrant methylmalonylation characterizes the hepatic proteome in MMA mice and human patients, and therefore hypothesized that a differential pattern of modification(s) on a subset of circulating proteins would be present in MMA patients that have received a LKT compared to untransplanted patients or those that have received a KT. Methods: Affinity anti-methylmalonyllysine antibody columns were prepared

and used to enrich for methylmalonylated targets from liver, kidney, and brain extracts from *Mmut*$^{-/-}$;*TG*^{MCKMmut} mice, an animal model that recapitulates the hepatorenal cerebral syndromes of MMA. An expanded LC MS/MS discovery methymalonylome dataset containing >300 aberrantly acylated targets was generated and then subject to an *in silico* analysis to identify circulating proteins that could be routinely measured in a standard chemistry panel. Aspartate aminotransferase (AST) was nominated and studied after validation of methylmalonylation via immunoprecipitation (IP) from MMA mouse and human liver tissues. Enzyme activity of AST was also measured in MMA and control mouse livers. AST was then examined in plasma from *Mmut*$^{-/-}$;*TG*^{MCKMmut} mice, control *Mmut*$^{+/-}$;*TG*^{MCKMmut} mice, transplanted (LKT, KT) and untransplanted patients with MMUT type MMA, and healthy controls. Results: AST in *Mmut*$^{-/-}$;*TG*^{MCKMmut} mice and human patient liver tissues was heavily methylmalonylated as determined by LC MS/MS and by direct validation in liver extracts from mice and MMA patients. Despite an increased level of immunoreactive AST in MMA, enzymatic activity was not elevated in *Mmut*$^{-/-}$;*TG*^{MCKMmut} mice as compared to controls suggesting that methylmalonylation could inhibit AST activity. AST was methylmalonylated in plasma from *Mmut*$^{-/-}$;*TG*^{MCKMmut} mice but not *Mmut*$^{+/-}$;*TG*^{MCKMmut} controls. Patients with MMA also demonstrated methylmalonylation of plasma AST that was not seen in a healthy control. Methylmalonylation of plasma AST was absent in patients that received a LKT, but persisted after KT. Conclusions: Traditional biomarkers typically rely on protein abundance or measurement of enzymatic activity. This proof-of-concept study has identified a promising class of new biomarkers derived from a disease-associated aberrant PTM - methylmalonyllysine - which is readily detected on a routinely measured enzyme, AST. The complete correction of PTMs on AST in MMA patients who have received an LKT, but not KT, establishes the utility of directly measuring the PTM load as a dynamic hepatic biomarker to assay the *in vivo* response to liver-directed therapies in MMA. Extension of this approach to other IEMs, specifically organic acidemias and FOADs, is envisioned.

587. rAAV-Mediated Gene Therapy for Cytochrome C Oxidase 20 Deficiency

Peiyi Guo[1], NhatAnh B. Nguyen[1], TramAnh M. Nguyen[1], Morgan Mooney[1], Chuanjiang He[2], Guangping Gao[1,3,4], Dominic J. Gessler[1,4]

[1]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[2]Department of Laboratory Medicine, The First People's Hospital of Kashgar, Kashgar, China,[3]Li Weibo Institute for Rare Diseases Research, UMass Chan Medical School, Worcester, MA,[4]Co-corresponding Authors, Worcester, MA

Cytochrome c oxidase 20 (COX20) deficiency is a rare autosomal recessive genetic disorder resulting from mutations in the *COX20* gene. The encoded protein is a chaperone stabilizing the COX2 subunit on the inner mitochondrial membrane and, thereby facilitates the assembling of complex IV and the proper function of the mitochondrial respiratory chain. Twenty-seven out of the 30 documented cases of this newly described disease have been reported within the past five years, suggesting the existence of a potentially larger patient population. Individuals with COX20 deficiency exhibit clinical features including sensory neuropathy, early onset ataxia, dysarthria, hypotonia, dystonia, and ophthalmoplegia. Despite the growing awareness of this disorder, an effective therapeutic intervention for COX20 deficiency has yet to be established. In this study, we developed a recombinant adeno-associated virus (rAAV)-based gene therapy for the treatment of COX20 deficiency using the ubiquitously active chicken beta-actin (CB) versus endogenous human COX20 promoter. In a proof-of-concept study rAAV9.CB-hCOX20 was delivered intravenously in neonatal wild-type mice expressing one of the two isoforms of the human *COX20* gene (201 and 203). The chaperone activity of COX20 relies on its mitochondrial localization. Therefore, we examined the subcellular localization of the hCOX20 using co-immunofluorescence staining, and observed the co-localized of hCOX20 with mitochondria markers in the brain, liver, and heart, supporting the proper function of the expressed hCOX20. To assess the safety of the rAAV-based gene therapy for COX20 deficiency, we monitor mouse weights and blood markers. Interestingly, we found that although treated wild-type mice show significant body weight loss compared to untreated mice, no pathologic findings were observed in these mice using complete blood count (CBC) and basic metabolic panel (BMP) blood tests, as well as multiple tissue H&E staining conducted at 6 months after treatment, indicating a well-tolerated and minimal toxic response to AAV9-COX20 vectors. With western blot, we found that endogenous COX20 protein levels remain consistently low in both mice and human HEK293 cells. In contrast, hCOX20 driven by CB promoter exhibits high expression in mouse tissues, including the liver, muscle, and heart, as well as in HEK293 cells. This heightened protein level may contribute to additional energy consumption, potentially leading to weight loss of rAAV9.CB-hCOX20 treated WT mice. To avoid the risk of unintended side effects resulting from excessive protein expression, we generated the second generation of AAV9-COX20 vectors driven by the human COX20 promoter and conducted examinations of protein expression and toxicity of these vectors in WT mice. There is currently no Cox20 mouse model available. To overcome this gap, we generated a COX20 mouse model mimicking the human compound heterozygous variant and a conditional COX20 knockout mouse model, which enables the ongoing evaluation of our newly developed rAAV vectors for COX20 deficiency. In summary, our study supports the safety of rAAV-based gene therapy for COX20 deficiency but also suggests that improved specificity with an endogenous promoter might be advantageous. Additionally, this work will provide valuable in vivo efficacy information for this therapeutic approach.

588. Design of the Prospective Study and the Consideration of the Clinical, Laboratory, and Dietary Determinates of Outcomes in Purine and Pyrimidine Metabolism Disorders

Shannon Haines[1], Oleg Shchelochkov[2], Katharine Chaillet[1]

[1]Purine and Pyrimidine Unit, NHGRI, Bethesda, MD,[2]Purine and Pyrimidine Unit, National Institutes of Health, Bethesda, MD

Introduction: Disorders of Pyrimidine and Purine Metabolism (DPPMs) is a group of inborn errors of metabolism characterized by a range of clinical presentations and significant unmet need. The overall prevalence of DPPMs in the general population is not known. The purine and pyrimidine metabolism pathways encompass >29 and >12 genes, respectively, which are involved in their synthesis,

transport, and degradation. Manifestations of DPPMs can affect any system including skeletal, neurological, immune, hematological, and renal. Some DPPMs can shorten life expectancy and lead to severe disabilities. With few exceptions, there are currently no effective gene-specific therapies. The lack of established diagnostic biomarkers, surrogate endpoints and poor understanding of the natural history slows progress in the development of new biologics for DPPMs. **Methods**: To help close knowledge gaps and to develop strategy for the discovery and validation of predictive biomarkers, we initiated a natural history study of DPPMs at the National Human Genome Research Institute aims. The study aims to improve our understanding of genomic, metabolomic, and environmental correlates underlying outcomes of DPPMs and biobank blood, urine, and stool samples (ClinicalTrials.gov ID NCT06092346). To optimize our recruitment strategy, design the clinical protocol, and to delineate prevalence of DPPMs, we reviewed the pattern of inheritance, the range and severity of DPPM symptoms in the published literature and reviewed variant databases. **Results**: All twelve of the pyrimidine disorders are known to be inherited in an autosomal recessive manner. In contrast, 3/29 (10%) of the purine disorders are inherited in an X-linked recessive pattern, and 2/29 (6%) purine disorders are inherited in an autosomal dominant pattern. The remainder of the purine disorders 23/29 (79%) show an autosomal recessive pattern. Among disorders of synthesis, transport and breakdown of pyrimidines, neurological manifestations are seen in 4/12 (33%) conditions, skeletal/dysmorphic features in 4/12 (33%), hemolytic anemia in 3/12 (25%), disorders of inflammation 2/12 (10%), renal manifestations in 1/12 (8%). Among disorders of synthesis, transport, and breakdown of purines, neurological manifestations are seen in 14/29 (48%) conditions, renal manifestation 8/29 (27%), disorders of inflammation 5/29 (17%), hemolytic anemia 5/29 (17%). Two purine disorders, AMPD1 and IMPDH1, are known to have isolated disorders outside of the typical spectrum (isolated rhabdomyolysis and isolated retinitis pigmentosa, respectively). **Conclusions**: We anticipate this study will garner information to expand our understanding of the phenotypic spectrum of DPPMs as well as identify novel diagnostic biomarkers. The long-term aim is to support future clinical trials and development genomics therapies for this group of rare of disorders.

589. Gene Replacement Therapy Targeting the Root Cause for the Treatment of MPS IIID in Mice

Pratikshya Adhikari[1], Neil Sud[1], Xinyu Cao[1], Tierra Bobo[2], Haiyan Fu[2]

[1]The University of North Carolina at Chapel Hill, Gene Therapy Center, Chapel Hill, NC,[2]Division of Genetics and Metabolism, Department of Pediatrics, The University of North Carolina at Chapel Hill, Gene Therapy Center, Chapel Hill, NC

Mucopolysaccharidosis (MPS) IIID is a devastating ultra-rare neuropathic lysosomal storage disease caused by autosomal recessive defects in N-acetylglucosamine-6-sulfatase (GNS), a lysosomal enzyme crucial for breaking down Heparan Sulfate (HS), a biologically important Glycosaminoglycan (GAG). The disease manifests in all organs with severe progressive neurological impairment, leading to high mortality and premature deaths. There are no treatments currently available for MPS IIID. To address the unmet needs, we developed a self-complementary (sc) AAV gene replacement vector MPS IIID, employing the trans-BBB-neurotropic AAV9 vector to deliver the human GNS (h*GNS*) cDNA via the systemic route. The scAAV-h*GNS* vector construct mediated efficient expression and secretion of rGNS when tested *in vitro* in human MPS IIID skin fibroblasts. The scAAV9-h*GNS* vector was further tested in preclinical studies in 1-2-month-old MPS IIID mice via systemic delivery. As a result, a single IV injection of scAAV9-hGNS at doses of 5e12 vg/kg - 5e13 vg/kg resulted in the rapid restoration of functional rGNS enzyme and clearance of lysosomal GAG storage in the CNS and peripheral tissues in MPS IIID mice at 1m pi. Long-term experiments are ongoing, and animals are scheduled for behavior testing at age 8m. Given the highly reproducible efficacy and safety profiles of systemic AAV9 gene delivery, our preliminary data support the therapeutic potential of scAAV9-h*GNS* for the treatment of MPS IIID.

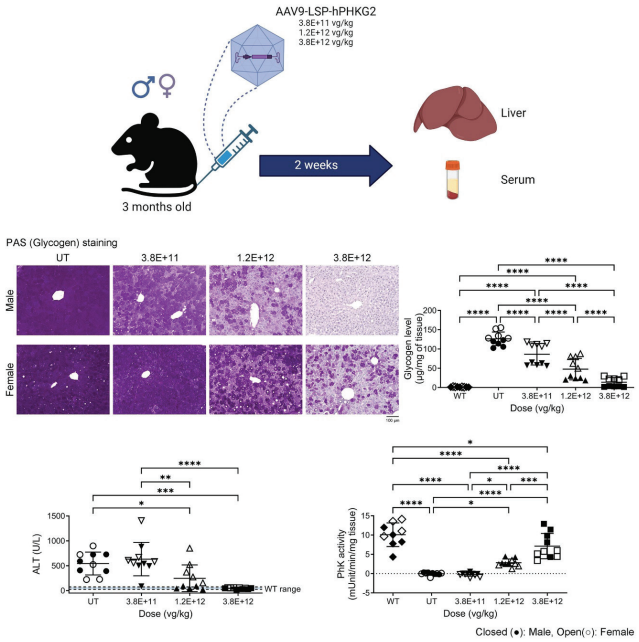
590. Delivery of scAAV9.co*SLC6A8* for Restoration of Creatine Transporter Function in a Creatine Transporter Deficient Mouse Model: A Dosage Study

Chiara E. Sawilla[1], Troy B. Webster[1], Robyn T. Binsfeld[1], Ilona Tkachyova[2], Melissa Mitchell[3], Andreas Schulze[2,4], Jagdeep S. Walia[1,3]

[1]Queen's University, Kingston, ON, Canada,[2]The Hospital for Sick Children, Peter Gilgan Center for Research and Learning, Toronto, ON, Canada,[3]Department of Pediatrics, Queen's University, Kingston, ON, Canada,[4]Departments of Pediatrics and Biochemistry, University of Toronto, Toronto, ON, Canada

Creatine deficiency syndromes describes inborn errors of creatine metabolism, impairing affected individuals' synthesis and transport of creatine. One such disease is creatine transporter deficiency (CTD). CTD, an X-linked disorder, results from mutations in the *SLC6A8* gene and renders creatine transporters in affected patients dysfunctional. Under normal physiological conditions creatine is synthesized endogenously and released into the blood stream to provide cellular energy. Creatine uptake is reliant on Na^+/Cl^- dependent creatine transporters as they deliver the synthesized creatine against a large concentration gradient into cells. Mutations in *SLC6A8* present clinically as intellectual disability, developmental delays, behavioural abnormalities, and speech and motor impairments. There are currently no treatments for CTD; creatine supplementation has shown limited success in restoring creatine levels in the brain of those affected. Thus, therapies focus on behavioural and seizure management strategies. The delivery of a codon optimized *SLC6A8* transgene via self-complementary adeno-associated virus 9 (scAAV9.co*SLC6A8*) has been proposed as a treatment for CTD. Previously, delivery of *SLC6A8* transgene via intracerebroventricular injection at 1 day of age in a *Slc6a8*$^{Y/-}$ murine model showed increased creatine levels in the brain, a decrease in hyperactivity, and an increase in muscle strength. This study aims to investigate the dose-response of the scAAV9.co*SLC6A8* using intrathecal route in a *Slc6a8*$^{Y/-}$ murine model. 5 cohorts (n=6 mice) received either vehicle, low dose ($3.5e^{11}$ vg/mouse), medium dose ($7.5e^{11}$ vg/mouse), or high dose ($1.1e^{12}$ vg/mouse), as well as a daily administration of immunosuppression with rapamycin and prednisone beginning at 5 weeks of age and injections at 6 weeks of

age. Both short term (13 weeks) and long term (24 weeks) cohorts undergo grip strength testing at 13 weeks. Long term cohorts will also undergo blood collection at 13 weeks, hyperactivity analysis in a digitally ventilated cage at 22-24 weeks, and a final grip strength test at 24 weeks. At the endpoint- serum, peripheral organs, and central organs will be collected for biochemical analysis. Data will be shown for short-term and long-term analysis. Our hypothesis is that the medium and high dose cohorts will show greater levels of creatine in the central nervous system, greater grip strength, and less hyperactivity when compared to vehicle control groups. Results of this study will provide important information for a future clinical trial.



Wednesday Posters: Liver Genetic Diseases

591. Assessing the Minimum Effective Dose of a Clinical Candidate AAV Vector in a Mouse Model of Glycogen Storage Disease Type IXγ2

Jeong-A Lim[1], Rebecca L. Koch[1], Su Jin Choi[1], Andrea Pappas[2], Priya S. Kishnani[1]

[1]Duke University Medical Center, Durham, NC,[2]Kriya Therapeutics, Research Triangle Park, NC

Glycogen Storage Disease type IX (GSD IX) is caused by a deficiency in phosphorylase kinase (PhK), which is responsible for initiating the breakdown of glycogen into glucose. In the liver, this complex enzyme is composed of four subunits, with α2, β, and δ modulating the activity of the catalytic γ2 domain. Deficiency of PhK in the liver disrupts glycogenolysis, leading to glycogen accumulation and subsequent metabolic complications observed in individuals affected by hepatic PhK deficiency. Pathogenic variants in *PHKG2* encoding the γ2 subunit cause GSD IX γ2, constituting approximately 25% of liver GSD IX cases. Patients with GSD IX γ2 typically exhibit symptoms such as hepatomegaly, fasting ketotic hypoglycemia, hypertriglyceridemia, and elevated serum ALT and AST levels. More than 95% of GSD IX γ2 patients develop liver fibrosis, which can progress to cirrhosis, elevating the risk of liver failure and death. Our research group recently characterized the GSD IX γ2 mouse model (Phkg2 KO), revealing its striking resemblance to clinical manifestations observed in patients. This mouse model recapitulates key symptoms and pathophysiological features, making it a valuable tool for studying the disease mechanisms and potential therapeutic interventions. Moreover, in our previous studies, we evaluated the efficacy of AAV gene therapy for GSD IX γ2. For this purpose, we delivered murine Phkg2 (mPhkg2) and human PHKG2 (hPHKG2) under a liver-specific promoter (LSP). We systematically treated Phkg2 KO mice with AAV9-LSP-mPhkg2 or AAV9-LSP-hPHKG2 at various ages and treatment durations to establish proof of concept. Both the short- and long-term treatments successfully reversed the disease phenotypes in Phkg2 KO mice. In this study, we assessed the minimum effective dose of the clinical candidate, AAV9-LSP-hPHKG2, in the Phkg2 KO mice. Male and female Phkg2 KO mice received intravenous injections of AAV9-LSP-hPHKG2 at three different doses (3.8E+11, 1.2E+12, and 3.8E+12 vg/kg) and were evaluated 2 weeks later. Liver tissue and serum were collected for assessment of disease indicators. The study results revealed that male and female mice responded differently to varying doses of AAV treatment. At the lowest dose (3.8E+11 vg/kg), male mice exhibited minor effects, whereas female mice demonstrated no noticeable impact. Alternatively, male mice treated with a dose of 1.2E+12 vg/kg displayed improvements in disease phenotypes, while the effects in females were minimal. Notably, treatment with a dose of 3.8E+12 vg/kg produced significant improvement across disease indicators in both male and female mice. These improvements included decreased liver size, normalized expression of PhK subunits, increased PhK enzyme activity, decreased liver glycogen levels, and normalized serum ALT and AST levels. Collectively, our findings suggest that the minimum effective dose of AAV9-LSP-hPHKG2 capable of producing positive effects in both male and female Phkg2 KO mice is 3.8E+12 vg/kg. These findings have significant implications for the development of definitive treatments for patients with GSD IX γ2.

592. Exploration of Improvement Opportunities for Liver-Directed Gene Therapy in Glycogen Storage Disease 1a (GSD1a) through Protein Engineering and Sequence Optimisation

Robert Murren, Parisa Rahimnashat, Sophie Snow, Sid Sridharan, Erald Shehu, Su Kit Chew, Tihomir Dodev, Alex Dimokov, Nisha Nair Dastidar, Eliza Bujor, Sylvia Podda, Thangavelu Kaliyappan, Carlos Bueno Beti, Raquel Nunez Toldra, Dario Pilla, Mario Buono, Jaminder Khinder, Miriam Canavese, Rose Sheridan, Henning Stennicke, Eileen McNeill

Freeline Therapeutics, Stevenage, United Kingdom

Glycogen storage disease 1a (GSD1a) is a monogenic metabolic disease arising from the loss of functional glucose-6-phophatase protein (G6pase) expression in the liver. Lack of functional G6PC

leads to impaired gluconeogenesis leaving patients at risk of severe hypoglycaemia under fasting conditions. A successful gene therapy for GSD1a should offer widespread expression across liver hepatocytes as G6pase is an intracellular membrane protein. Current therapeutic efforts express wild-type G6Pase protein from a codon-optimised sequence driven by large portion of the endogenous promoter, placing the total transgene cassette outside the optimal transgene packaging size. In our approach, we sought to promote robust and regulated G6Pase expression, while reducing packaging size to 4kb. In addition to full sequence optimisation for optimal codon use with removal of CpGs and splice signals, we also carried out protein engineering to increase stability, thus increasing expression of G6Pase. Finally, we benchmarked basal and insulin-regulated expression of our novel promoter design using the proximal G6Pase gene promoter (2.86kb). Protein engineering approaches included homology and rational structure-based design. Compared to wild-type G6Pase, our novel protein variant showed a 2.5-fold expression improvement in liver cells. Screening of sequence-optimised variants yielded another 2.5-fold increase in expression compared to the natural human gene sequence. In addition, we also applied a bioinformatics approach to condense the endogenous promoter while retaining its activity. Candidate regulatory elements for G6PC were identified from epigenetic and transcriptional features in the wider G6PC genomic locus. These were combined with the core G6PC promoter to generate a condensed sequence of ~2.2kb. Our condensed promoter has similar basal expression to the large endogenous variant, and preliminary results indicate that it is sensitive to insulin treatment *in vitro*. Taken together, our AAV cassette engineering has yielded the optimised elements required for broad G6Pase expression in the liver of GSD1a patients, driven by an endogenous promoter within a 4.0kb transgene cassette.

593. Dissecting the Challenges of AAV-Mediated Liver Gene Transfer to Fibrotic Livers

Gemma Bruno[1], Rosa Ferriero[1], Agnese Padula[1], Iolanda Boffa[1], Marco Gargaro[2], Simone Pisano[1], Teresa Imperatore[1], Edoardo Nusco[1], Luigi Ferrante[1], Elena Polishchuk[1], Roman Polishchuk[1], Severo Campione[3], Nicola Brunetti-Pierri[1,4], Francesca Fallarino[2], Pasquale Piccolo[1]

[1]Telethon Institute of Genetics and Medicine (TIGEM), Pozzuoli, Italy,[2]Department of Medicine and Surgery, University of Perugia, Perugia, Italy,[3]Pathology Unit, "A. Cardarelli" Hospital, Naples, Italy,[4]Department of Translational Medicine, "Federico II" University of Naples, Naples, Italy

Liver fibrosis, characterized by the accumulation of scar tissue in response to various chronic insults, poses a significant challenge for liver-directed gene therapy. Patients with overt liver damage and fibrosis are currently excluded from gene therapy clinical trials based on the postulate that intact liver architecture is necessary for safe and efficient gene transfer to hepatocytes using adeno-associated viral vectors (AAV), currently the platform of choice for in vivo gene therapy. While preliminary evidence suggests a potential hindrance to AAV-mediated gene transfer in the presence of liver fibrosis, further investigations are needed. In this study, we explored the biodistribution and hepatocyte transduction of AAV-based vectors in the context of liver fibrosis. Analysis of three mouse models, representing induced and genetic liver fibrosis and characterized by different fibrosis patterns, revealed that fibrotic livers exhibit reduced transduction efficiency by AAV vectors. This reduction primarily arises from diminished vector uptake by the liver rather than vector genome loss due to hepatocyte proliferation. Additionally, liver fibrosis led to alterations in blood vector clearance and vector biodistribution in extra-hepatic organs, with a model-specific impact on increased viral particle uptake by the spleen, lung, and kidney. At the cell-type level, fibrosis resulted in decreased vector genome content in hepatocytes and increased content in non-parenchymal liver cells, splenic macrophages, and dendritic cells. Ongoing investigations are focused on understanding the implications of these changes on the innate and adaptive immune response against AAV. These findings underscore that liver fibrosis impedes AAV-mediated gene transfer to hepatocytes, emphasizing the need to overcome fibrotic barriers for the successful implementation of safe and effective gene therapy to fibrotic livers.

594. Use of an Oversized AAV8 Vector for CPS1 Deficiency Results in Long-Term Survival and Ammonia Control

Wesley Zhou[1], T. Diep[1], M. Nitzahn[1], I. Day[1], P. Patel[1], G. Makris[2], L. Lueptow[3], I. Zhuravka[3], J. Gangoiti[4], H. Padaon[4], B. Barshop[4], J. Haberle[2], Gerald S. Lipshutz[1]

[1]Surgery, Pharmacology, UCLA, Los Angeles, CA,[2]Metabolism, Univ Children's Hospital Zurich, Zurich, Switzerland,[3]Psychology, UCLA, Los Angeles, CA,[4]Metabolism, UCSD, San Diego, CA

Background: Carbamoyl phosphate synthetase 1 (CPS1) is the 1st enzyme in the urea cycle (UC), utilizing ATP to catalyze the reaction of bicarbonate & ammonia to carbamoyl phosphate, the 1st intermediate in the UC. CPS1 deficiency, a UC disorder, defined as the partial or total loss of the CPS1 enzyme, reduces ureagenesis & alters nitrogen metabolism, leading to hyperammonemia, initiating a sequence of adverse events that can lead to coma & death if not intervened upon rapidly. The development of an AAV-based gene approach for CPS1 deficiency is challenged by the large cDNA size (4.5 kb) & high protein requirement (~20% of mitochondrial matrix). Methods: We utilized an AAV 8 vector as a gene therapy approach to treat CPS1 deficiency. In order to constrain the AAV genome size, we used a small active liver specific promoter (LSP) & enhancer with a minimal synthetic polyA; this resulted in an ITR-to-ITR genome size of 5.3 kb. Using a murine conditional knockout model of Cps1, AAV-CPS1 was injected IV into 2-month- old male & female mice; controls received a null vector. Starting on day 14, n-carglumic acid & dextrose were added to their water along with carbohydrate to their cages; no nitrogen scavengers though were given. Blood was sampled monthly for amino acid profiling & $NH4^+$ determination. Surviving animals underwent behavioral testing at 8 months & $NH4^+$ challenging at 9 months after AAV-CPS1 administration. Ureagenesis was measured by ^{13}C-acetate administration. Results: Alkaline gel electrophoresis of the oversized AAV-vector demonstrated a dominant band at ~5.2 kb with some evidence of fragmentary genome packaging. Long-term survival (9 months, end of study) with $NH4^+$ control was achieved in AAV-CPS1 administered floxed Cps1 mice while null vector-injected controls all died by day 36. When compared with untreated knockouts, treated females demonstrated improved survival ($p < 0.0001$) over treated males ($p = 0.0020$). While plasma glutamine was elevated compared to wild type controls in both sexes, plasma $NH4^+$ was well-controlled

in surviving animals. Mice maintained their body weights & were not sarcopenic. Male mice (not females) exhibited a significant weight difference from controls; at necropsy this was revealed as lack of obesity in treated Cps1 male mice where controls had intra-abdominal adiposity that was often abundant. To test the physiologic response to exogenous $NH4^+$, mice were challenged with 3mM/kg ammonium chloride. In general, wild type mice had a controlled response (i.e., plasma $NH4^+$ peak at the 20-minute time point with subsequent decline) while AAV-treated mice had an exaggerated response at 20 minutes followed by declining plasma ammonia at 60 minutes; no seizures occurred. Behavioral phenotyping of treated Cps1-deficient mice demonstrated no statistically significant differences compared with controls. Plasma transaminases between AAV-CPS1 treated mice & controls exhibited no statistically significant differences between the two groups. At necropsy, livers appeared normal without evidence of fibrosis or malignancy. Conclusion: The development of an oversized AAV serotype 8-vector expressing CPS1 can be achieved & is functional. While the dominant genome size present is ~5.2 kb with this single vector, there is some evidence of vector fragmentation. Nevertheless, administration to a Cps1-deficient murine model results in long-term survival, $NH4^+$ control, normal behavior, & an appropriate response to an exogenous ammonia challenge. These findings demonstrate the utility of a gene therapy approach for a very challenging urea cycle disorder where high-level hepatic protein is necessary for survival.

595. Restoration of Ornithine Transcarbamylase Function with Endless RNA (eRNA)

Inbal Rahamin, James Sefton, Alexander Garruss, Jack Kwon, Richard Wilson, Ki Young Paek, Jason Wade, Russell Miller

Sail Biomedicines, Somerville, MA

Ornithine transcarbamylase (OTC) is an essential hepatic enzyme in the urea cycle, a metabolic pathway crucial for detoxifying ammonia in the liver. Patients with a mutation in the OTC gene causing deficiency in OTC enzymatic activity can present with an inability to produce urea and hyperammonemia, resulting in neurological issues and even death. Genetic approaches to restore hepatic OTC protein and enzymatic activity with AAV-based OTC gene delivery and exogenous OTC mRNA delivery are being developed for therapeutic treatment of OTC-deficient urea cycle disorders. mRNA-based protein replacement therapy has the potential to address the cause of disease but is hampered by several challenges, including the short half-life of exogenously administered mRNA and subsequent protein production. Endless RNA™ (eRNA™) has emerged as a promising platform due to its unique covalently closed, circular structure, which confers resistance to exonuclease degradation, and an extended half-life as compared with traditional mRNA. In this study, we demonstrate that eRNA-expressing human OTC (hOTC) with optimized lipid nanoparticles (LNPs) can be used to treat OTC deficiency successfully in mice, thereby restoring the impaired urea cycle. To select eRNA sequences yielding maximal OTC protein expression, we conducted comprehensive screens optimizing coding and non-coding sequence elements. We identified novel combinations of optimized open reading frames (ORFs) and diverse untranslated regions (UTRs), which resulted in significantly higher OTC expression levels compared to both endogenous protein and control mRNA. These optimized eRNAs were delivered intravenously with LNPs to OTC-deficient Spf^{ash} mice and resulted in a lowering of urinary orotic acid to wild-type animal levels, consistent with a rescue of the OTC deficiency. Collectively, our findings present a promising new therapeutic approach for OTC deficiency, demonstrating the potential of hOTC eRNA as an effective strategy to restore urea cycle function.

596. Using a Semi-Mechanistic Model to Predict Efficacious Dosing Regimens and Optimal Drug Design Properties for a LNP-Delivered mRNA UGT1A1 Replacement Therapy in Crigler-Najjar Syndrome Type 1 Patients

Jamie Nosbisch, Marc Presler, Saheli Sarkar, David Bassen, Carter Johnson, Diana Marcantonio, Joshua Apgar, David Flowers

Applied BioMath, LLC, Concord, MA

PURPOSE: Crigler-Najjar syndrome type 1 (CN1) is an autosomal recessive disease where bilirubin accumulates to toxic levels in the blood as a result of the reduced enzymatic activity of glucuronosyltransferase family 1 member A1 (UGT1A1). With no approved drugs for CN1, patients are often treated with blue light, but as they age, this is insufficient to control bilirubin levels. While liver transplants can be used to restore UGT1A1 activity, an alternative approach considers using gene therapy to restore UGT1A1 activity by delivery of mRNA encoding UGT1A1 protein via lipid nanoparticle (LNP). Utilizing a semi-mechanistic model, we explored the feasibility of dose amounts and frequencies that could sustain reductions in bilirubin levels over time and what properties could be optimized. METHODS: A semi-mechanistic model was developed to describe an mRNA therapy delivered to the liver via a LNP. The model includes LNP delivery to the liver, endosomal escape of the mRNA, translation of the target protein UGT1A1, and UGT1A1 catalysis of bilirubin to bilirubin monoglucuronide. To illustrate the usage of the model for a feasibility assessment, no parameters were derived from clinical or preclinical studies, but rather from the literature. RESULTS: Model simulations predict that prohibitively large doses are required to maintain the bilirubin reduction target of 25% of baseline over time. The model predicts that doses larger than 0.07 mg/kg achieve sustained reduction in bilirubin concentration at Q1W dosing frequency; however, increasing the dosing interval requires increasing doses, and at Q3W doses need to be prohibitively high to maintain desired bilirubin levels throughout the dosing period. This is because the mRNA is cleared at an exponential rate inside the cells, creating a nonlinear relationship between dosing frequency and sustaining the reduction. To understand requirements to the desired bilirubin reduction at 0.5 mg/kg dosed Q3W, 3 drug parameters were scanned over a realistic range. The efficiency of mRNA escape from endosomes is known to be a major bottleneck in intracellular drug delivery. The model predicts that optimizing endosomal escape efficiency may provide some benefit, but not enough to attain the feasibility criteria at 0.5 mg/kg dosed Q3W. Similarly, optimizing translation does not result in enough benefit to reach feasibility. The stability of the mRNA, on the other hand,is a key design variable that impacts the feasibility for

UGT1A1 replacement and its pharmacology. The model predicts that as the mRNA half life increases, the dose required for a given amount of bilirubin reduction is reduced substantially. With an mRNA half life of 30 hours, the drug achieves 25% reduction at all times at 0.5 mg/kg. Increasing the half life to 40 hours reduces the required dose five-fold to 0.1 mg/kg. CONCLUSIONS: A semi-mechanistic model was developed and parameterized to predict efficacious dose and dosing intervals and to help prioritize optimization of liver-targeted mRNA enzyme design to treat CN1. Using this model, we determined that it is feasible for liver UGT1A1 to restrict bilirubin to non-toxic levels at frequent (Q1W-Q2W) dosing intervals, but dose amounts would be prohibitively high at less frequent intervals (Q3W). With further model analysis, we identified UGT1A1 mRNA stability as the primary design variable that may be modified to enable a longer dosing interval at reasonable dose amounts. This case study highlights how mechanistic modeling can be used for making early feasibility assessments for novel gene therapy treatments and how modeling can help inform the drug design targets for optimal efficacy of these therapeutics.

597. RNA Gene Writers Drive Therapeutically Relevant Levels of Correction of Monogenic Disease Mutations Expressed in the Liver

Anne Bothmer, Luciano Apponi, Xiaolong Dong, Zsanett Jancso, Raed R. Ibraheim, Mugdha Bedekar, Annie Chivatakarn, Alan Mendoza, Florence Caro, Daniella Lu, Selina Sun, Elizabeth English, Rahul Nair, Gulen Tonga, Erin Spofford, Carol Cai, Jeff An, William Querbes, Cecilia Cotta-Ramusino, Michael C. Holmes

Tessera Therapeutics, Somerville, MA

Monogenic diseases are caused by mutations in a single gene, and although most monogenic diseases are rare, together they affect millions worldwide and result in high morbidity, mortality, and economic burden. RNA Gene Writers are designed to introduce a broad range of alterations to the genome, from writing in a transgene, inserting an exon, or introducing single nucleotide changes, providing an attractive toolkit for the treatment of monogenic diseases. RNA Gene Writers are inspired by the biology of non-LTR retrotransposons, a class of mobile genetic elements that can edit the genome through target-primed reverse transcription, or TPRT. RNA Gene Writers are designed to be delivered as all-RNA composition, which is intended to facilitate *in vivo* delivery by lipid nanoparticles, or LNP. Here we explored the application of RNA Gene Writers to correct mutations leading to various monogenic diseases expressed in the liver, including classic phenylketonuria (cPKU), alpha-1 antitrypsin deficiency (AATD), and Wilson's disease (WD), at therapeutically relevant levels *in vivo*. We developed an RNA Gene Writer designed to target the R408W mutation in the *PAH* gene causing cPKU and observed an average of 47% rewriting efficiency after a single dose in the liver of a novel humanized PKU R408W mouse model. We observed this level of correction led to normalized blood Phe levels. We also developed an RNA Gene Writer intended to correct the PiZ allele of *SERPINA1* carrying the E342K mutation that causes AATD. We observed LNP-RNA delivery of an RNA Gene Writer corrected this mutation in an existing high copy transgenic mouse model (*NSG-PiZ*). Separately, we engineered a humanized mouse model where the PiZ allele was inserted into the Rosa26 locus to better approximate humans with the homozygous PiZZ genotype. LNP-RNA delivery of an RNA Gene Writer achieved an average of 47% correction after a single dose in this diploid mouse model, and a corresponding increase in serum AAT was observed. We next developed an RNA Gene Writer designed to correct the H1069Q mutation in the *ATP7B* gene leading to WD. We engineered a humanized mouse model containing the human H1069Q mutation with its flanking sequence in the analogous mouse *Atp7b* gene. Through LNP-RNA delivery of an RNA Gene Writer, we achieved dose dependent levels of correction of the H1069Q mutation and observed a substantial reduction in copper accumulation at the highest dose tested. Taken together, we demonstrated that our RNA Gene Writing platform can be applied to efficiently correct disease-causing mutations expressed in the liver at therapeutically relevant doses with a single administration of LNP formulated RNAs. Through optimization of the template and RNA Gene Writers, we observed efficient editing *in vivo* across three different monogenic disease targets, supporting our belief that the potential therapeutic applications of our RNA Gene Writers may be broad and wide-ranging.

598. Expressing AAT from Circular RNA-Encoding Vectors as a Promising Gene Therapy Approach for Alpha-1 Antitrypsin Deficiency

Eoghan T. O'Leary[1,2], Sara Vikberg[1,2], Juan Zhang[1,2], Daisy Hjelmqvist[1,2], Erik D. Wiklund[1], Victor Levitsky[1], Thomas B. Hansen[1]

[1]RnD, Circio AB, Huddinge, Sweden,[2]Clintec, Karolinska Institutet, Huddinge, Sweden

Alpha-1 antitrypsin deficiency (AATD) is a genetic disorder that manifests in the lung and liver. The deficiency is driven by pathogenic mutations in the SERPINA1 gene which typically impairs production of the protein in the liver reducing its serum levels and leading to lung emphysema. Despite greater than 100 pathogenic variants of SERPINA1 being described, the most common mutations known to cause AAT deficiency are the Z (Glu342Lys) and S (Glu264Val) variants. Moreover, 95% of individuals with severe AAT deficiency are homozygous for the Z allele mutation. Z-AAT proteins are prone to aggregate and accumulate in hepatocytes, resulting in liver cirrhosis through a toxic "gain of function" mechanism. Except for liver transplantation, there are no curative therapies available for alpha-1 antitrypsin deficiency, and current treatment options are focused on reducing the disease progression. Several gene therapies are in development that aim to elevate the serum alpha-1 antitrypsin level and prevent the progression of lung emphysema, while other approaches aim to deplete the accumulation of toxic Z-AAT in the liver. Circio is developing an alternative therapeutic technology based on our proprietary vectorized circular RNA (circRNA) expression platform, circVec. CircRNA is known to have superior intra-cellular stability compared to mRNA due to resistance to exo-nucleolytic decay, and is rapidly emerging as a promising novel therapeutic modality for disorders where persistent transgene expression is required, such as AATD. Here, we demonstrate that AAT expression from our circVec vector system achieves superior accumulation and out-competes conventional mRNA expression in terms of durability and absolute protein expression over time. Additionally, we demonstrate that our

circVec expression cassette is vector agnostic, facilitating expression from both viral and non-viral DNA-based vectors. Furthermore, we have developed a remove-and-replace system in which the mutant ZZ allele is specifically targeted and significantly depleted using a primary miRNA-like element (PME) while circVec-encoded wild-type AAT remains unaffected in vitro. Based on these results, we propose circVec vector-based circRNA expression as an alternative gene therapy technology for the treatment of AATD. The potential of combining long-term therapeutic protein expression with a mutant-specific depletion element enables the combined treatment of both lung and liver associated AATD pathologies, which has not previously been achieved with conventional expression systems. We foresee deployment of circular RNA-based platforms in the treatment of a variety genetic diseases, and expect that circular RNA will replace mRNA as the expression platform of choice for vector-based therapies.

599. An Improved AAV Vector with High Expression Efficiency for HAE Treatment

Yong Wang, Zhou Yang, Fenglan Wu, Tenghui Yu
Gritgen Therapeutics Co., Ltd., Suzhou, China

Background: Hereditary angioedema (HAE) is a rare autosomal dominant disorder most commonly caused by pathogenetic variants in the SERPING1 gene, resulting in reduced C1-INH function in plasma. HAE is typically characterized by reoccurring swelling in the limbs, the face, the airways, and the intestinal tract, among which upper airway angioedema (UAE) has a lifetime mortality rate up to 40%. Pharmacological management of HAE consists of on-demand treatment aiming to lessen both the severity and duration of symptoms during an HAE attack and prophylaxis to prevent HEA attacks. While different drugs have been approved for prophylaxis, they all require routine administration. C1-INH is expressed mainly in hepatocytes and secreted into blood and thus treatable by restoration of stable C1-INH function through AAV-mediated liver targeted SERPING1 gene transfer. So far there is only one AAV-mediated HAE therapy in clinical trial at a relatively high dose. we aim to develop an AAV vector for HAE treatment at a lower dose. Results: After multiple rounds of screening in different species, we have developed GS1196, an AAV8-based vector expressing human C1-INH for HAE treatment. In mouse models, supraphysiological activity of plasma C1-INH was detected after a single intravenous (IV) injection of GS1196 at a dose of 3e12vg/kg and maintained for at least 28 weeks. We observed a dose and sex dependent effect in mice. GS1196 was specifically distributed and expressed in liver. In NHP, single IV injections of GS1196 at a dose of 1e13vg/kg could produce C1-INH activity at therapeutic concentrations. Toxicological studies indicated that GS1196 was safe and well-tolerated in both species. Conclusion: Our data have shown efficient expression of GS1196 in mice and NHP. Preclinical studies have demonstrated the safety of GS1196 and provided support for its clinical studies.

600. Correction of the Human Wilson's Disease Mutation in an Engineered Disease Mouse Model Using RNA Gene Writers

Raed Ibraheim, Mugdha Bedekar, Luciano Apponi, Elizabeth English, Selina Sun, Mae Caldwell, Carol Zuhua Cai, Gang Sun, Ana Maria Jaimes Castillo, Anne Bothmer, William Querbes, Cecilia Cotta-Ramusino, Michael C. Holmes
Tessera Therapeutics, Somerville, MA

Wilson's Disease (WD) is an autosomal recessive disease characterized by the inability to excrete excess copper due to an inherited mutation in the transmembrane copper-transporting ATPase 2, ATP7B. The predominant WD mutation in North America and Europe is the missense (c.3207C>A) mutation, with a histidine to glutamine amino acid change at position 1069. We estimate that there are approximately 12,000 WD patients in the United States and Europe carrying the H1069Q mutation. Homozygotes or compound heterozygous carriers of this mutation experience ATP7B protein misfolding, abnormal phosphorylation, decreased ATP-binding affinity and abnormal localization to the trans-Golgi network. In WD, the proper transport of copper to the other body parts through ceruloplasmin and the trafficking of excess copper to the bile are dysregulated. This results in toxic accumulation of copper in the liver, brain, and other organs, leading to progressive liver disease and neuropsychiatric symptoms. The disease is primarily managed by copper chelators and/or zinc salts to promote copper excretion in the urine and reduce copper absorption from diet, respectively. Multiple barriers to compliance and adherence exist, including significant side effects, cumbersome dosing schedules, high pill burden, and the requirement of life-long therapy. RNA Gene Writers are inspired by the biology of naturally occurring non-LTR retrotransposons, a class of mobile genetic elements that can edit the genome through target-primed reverse transcription, or TPRT. We have engineered non-LTR retrotransposon proteins that are designed to introduce a broad range of edits to the genome, from writing in a transgene, inserting an exon, or introducing single nucleotide changes. We believe RNA Gene Writers could potentially be applied to WD to restore the H1069Q mutation to wild-type in the *ATP7B* gene. We deployed a high throughput screening approach to identify and engineer an RNA Gene Writer designed to correct the H1069Q mutation in model cell lines *in vitro*. We then developed a new mouse model engineered to contain the human H1069Q mutation with its flanking sequence in the analogous mouse *Atp7b* gene. We observed that this model recapitulated the phenotype of WD, such as elevated copper accumulation in the liver and brain, and increased levels of copper detected in the urine. We tested an RNA Gene Writer formulated in lipid nanoparticle, or LNP, *in vivo* in this humanized mouse model to evaluate correction levels of the H1069Q mutation as well as levels of hepatic copper and urinary copper compared to untreated animals. In summary, we developed a humanized H1069Q murine model of WD and were able to demonstrate correction of this mutation through the *in vivo* delivery of an LNP-RNA.

Wednesday Posters: Heart, Lung, and Kidney Diseases

601. Enhanced Therapeutic Efficacy of Embryonic Stem Cell-Derived Macrophages with Heterozygous Deficiency in PHD2 for the Treatment of Murine Hindlimb Ischemia

Sang W. Han[1], Patricia Alves[2], Sayone Moura[1], Helen Tayor[3], Antonella Fidanza[3], Cristiane Gil[1], Leonardo Martins[4], Alex Nasare[1], Andre Lengert[1], Bianca Garcia[1], Gabriel Guarache[1], Gustavo Pereira[1], Ivan Koh[1], Lesley Forrester[3]

[1]Federal University of Sao Paulo, Sao Paulo, Brazil,[2]University Federal of Sao Paulo, Sao Paulo, Brazil,[3]University of Edinburgh, Edinburgh, United Kingdom,[4]Institute of Medical Biology of Polish Academy of Science, Łódź, Poland

Background: Macrophages are pivotal immune modulators capable of reshaping the ischemic microenvironment by releasing factors that enhance arteriogenesis and facilitate tissue repair. Prolyl hydroxylase domain-containing protein 2 (PHD2) functions as a critical oxygen sensor and regulates hypoxia-inducible factors (HIFs), which are central transcription factors that adapt to decreased oxygen availability within the cellular environment. Previous studies on Phd2+/- mice have indicated that modulation of this pathway may offer therapeutic benefits in treating ischemia. However, studies for the translation of this approach to patient-specific treatments has been hampered by the difficulty of acquiring Phd2 haplodeficient macrophages. This study aimed to overcome such barriers by producing Phd2+/- macrophages from E14IV mouse embryonic stem cells (ESCs) modified to acquire the Phd2+/- genotype and evaluating their therapeutic value in a mouse model of hindlimb ischemia.Methods: The precision of CRISPR-Cas9 genome editing was utilized to establish a mouse embryonic stem cell line with a heterozygous deficiency in Phd2 (E14IV+/-). These E14IV+/- cells were then differentiated into macrophages, designated as C22-E14IV-MØ. Detailed phenotypic characterization was conducted using flow cytometry and RT-qPCR to ascertain cellular marker expression. Functional analyses were carried out, including Western blotting for PHD2 levels, phagocytosis assays, and angiogenesis evaluation through immunoassays and the HUVEC tube formation assay. The interaction between these macrophages and myoblasts was investigated using C2C12 cells. *In vivo* assessment of macrophage therapeutic efficacy was carried out in a murine model of hindlimb ischemia, with perfusion and tissue recovery measured via laser Doppler and histological evaluations.Results: The study revealed that C22-E14IV-MØ macrophages expressed more than a 50% reduction in PHD2 levels and showed an upregulation of specific cell surface markers indicative of an M0-like phenotype, such as CD206 and MHCII. These cells exhibited superior phagocytic function compared to wild-type counterparts. *In vitro*, the macrophages demonstrated a unique angiogenic profile and significantly enhanced capillary structure complexity in cocultured HUVECs. Additionally, the conditioned medium from M2-polarized C22-E14IV-MØ macrophages substantially increased proliferation rates in C2C12 myoblasts compared to control media. *In vivo*, the application of these macrophages into ischemic limbs led to observable improvements in blood circulation, indicated by increased perfusion and the formation of larger arterioles, as documented by laser Doppler and histological studies (Figure 1).Conclusion: The study presents strong evidence of the therapeutic potential of Phd2+/-MØ macrophages for the treatment of limb ischemia. The macrophages derived from Phd2+/- ESCs not only exhibit enhanced functional capabilities *in vitro* but also translate into significant therapeutic benefits *in vivo*.

602. Exosome-Targeted MiR-33a Antagomir is Present in Vascular Medial Cells After *In Vivo* Endothelial Transduction

Goren Saenz De Pipaon Echarren, Brad Wacker, Lianxiang Bi, David A. Dichek

University of Washington, Seattle, WA

Introduction: Atherosclerosis is driven by cholesterol accumulation in cells below the luminal arterial endothelium (i.e., macrophages and smooth muscle cells). MiR-33a is a micro-RNA that downregulates mRNA encoding the cholesterol transporter ATP-binding cassette subfamily A, member 1 (ABCA1; a key mediator of cholesterol efflux from artery wall cells). Antagomir-mediated inhibition of miR-33a can de-repress ABCA1 expression and increase cholesterol efflux in vitro and should reduce vessel wall cholesterol and prevent atherosclerosis in vivo. However, delivery of antagomir-expressing vectors to cells below the luminal endothelial layer is challenging. Here we test whether in vivo transduction of rabbit carotid artery endothelium with vectors expressing exosome-targeted miR-33a antagomirs can deliver the antagomirs to cells below the luminal endothelium. **Methods:** We transduced rabbit carotid endothelial cells in vivo with helper-dependent adenoviral vectors (HDAd) encoding miR-33a-directed antagomirs. The vectors expressed antagomirs either with (n=2 arteries) or without (n=2 arteries) the "X-motif" (an oligonucleotide sequence that directs small RNA preferentially to exosomes). Contralateral carotids in the same rabbits (n=4) received HDAd that express scrambled oligonucleotides (HDAdScr). 3 days after transduction, we used RT-qPCR to measure levels of antagomirs, miR-33a, and ABCA1 mRNA in extracts of FACS-sorted carotid endothelial cells (CD45-CD31+) and non-immune medial/adventitial cells (CD45- CD31-). We also measured levels of antagomirs, miR33a, and ABCA1 mRNA in extracts of laser-microdissected carotid endothelium and media and we measured miR-33a in arterial sections using fluorescence in-situ hybridization (miRNA-scope). **Results:** We detected miR-

33a antagomirs—both with and without the X-motif—in carotid endothelial cells and in medial/adventitial cells sorted from HDAd-anti-miR33a-transduced—but not HDAdScr-transduced—carotids. Analysis of laser-microdissected samples confirmed the presence of antagomirs in both the intimal and medial cells of all HDAd-anti-miR33a-transduced carotids. No antagomir-related changes in miR-33a or ABCA1 expression were detected. **Conclusions:** These preliminary results indicate that HDAd-mediated in vivo transduction of carotid endothelium reliably achieves accumulation of miR-33a antagomirs within both endothelial and sub-endothelial cells. In the coming weeks we will complete this study by increasing "n" (to 11 for both of the antagomir-expressing HDAds; to 22 for HDAdScr). We will measure vector DNA in endothelium and subendothelium to test our assumption that transduction is largely limited to endothelial cells. These new data will also allow us to test our hypotheses that addition of the X-motif promotes antagomir accumulation in vascular media and that downregulation of miR33a and upregulation of ABCA1 in cells below the endothelium can be achieved via HDAd transduction of endothelium.

603. Engineering the CRISPR-Cas13 System for Efficient PHD2 Enzyme Downregulation to Enhance *In Vitro* Angiogenesis

Sara Carolina Vieira Terra

Department of Physiological Sciences, Santa Casa School of Medical Sciences of São Paulo, São Paulo, Brazil

Peripheral Arterial Disease (PAD) arises from the stenosis of blood vessels in the upper or lower extremities. Hypoxia-inducible factor (HIF) plays a pivotal role in the stimulation of angiogenesis, constituting a critical component of cellular response to hypoxia. HIF-1α is degraded by the PHD2 enzyme. The CRISPR-Cas13d system offers a compelling avenue for gene editing. Consequently, we propose the utilization of CRISPR-Cas13d to downregulate PHD2, fostering angiogenesis through HIF-1α augmentation in endothelial cells (HUVEC) under hypoxia (H) and normoxia (N). Firstly, guide RNA (gRNA) design was performed, targeting the EGLN1 gene (encoding PHD2 enzyme). Subsequently, cloning of guide PHD2-KI (knock-in) and guide NTG (non-targeting genome) was carried out, followed by lentivirus production and endothelial cell transduction (HUVEC PHD2-KI and HUVEC NTG). Finally, a hypoxia assay, cell proliferation by MTT, and sprouting assay were conducted.The integration of the Cas13d cassette and its gRNA (NTG or PHD2-KI) was confirmed through RT-qPCR, with Cas13d expression observed in NTG and PHD2-KI groups under N and H. EGLN1 gene knock-in was confirmed by RT-qPCR, showing a 37.5% (N) and 34% (H) reduction in its expression in the PHD2-KI group, compared to the control (CTL) group.The Hypoxia Assay, followed by RT-qPCR, revealed in the PHD2-KI group a 7x (N) and 5.4x (H) increase in VEGFA; a 7.5x (N) and 30x (H) reduction in HIF-1α; and a 3.3x (N) and 4.4x (H) increase in MMP2 expression, all compared to CTL. VEGF ELISA showed a 4x (24h) and 5x (48h) higher expression in the PHD2-KI group, compared to CTL, in both N and H. TNF-α ELISA revealed 26x lower expression in the PHD2-KI group at 24h, in N and H, and no expression in the PHD2-KI group in both conditions at 48h. HIF-1α ELISA for showed a 280% increase in its expression in group PHD2-KI, in N, 24h, compared to CTL. Cell proliferation assessed by MTT over 5 days showed that, starting with 2000 cells, the PHD2-KI lineage exhibited an increase in proliferation on day 4, ending with 1.7x higher absorbance compared to CTL. Finally, to verify whether PHD2 downregulation would lead to an increased angiogenesis, a sprouting assay was performed. Under N, the PHD2 group, compared to CTL, showed approximately 2.4x, 3.4x, and 3.9x more sprouts per bead, respectively, in EGM-All, EGM without VEGF, and EGM SFB medias. Under H, the response was more pronounced, with 4.6x, 5.5x, and 2.1x more sprouts per bead in the PHD2-KI group, in the same medias, respectively. Regarding the length of the sprouts, the PHD2, compared to CTL, exhibited 1.4x and 1.6x longer sprouts, in EGM-All and EGM SFB medias, in N; 1.6, 2.5x and 1.6x longer sprouts, in EGM-All, EGM without VEGF, and EGM SFB medias, in H. In conclusion, this study demonstrated that the CRISPR-Cas13d system was able to downregulate the EGLN1 gene, consequently reducing PHD2 expression and endogenous HIF-1α. There was an increase in angiogenic factors and a decrease in inflammatory cytokines, indicating an anti-inflammatory action of this therapy. Additionally, there was an enhancement in the proliferative and angiogenic capacity of modified endothelial cells.

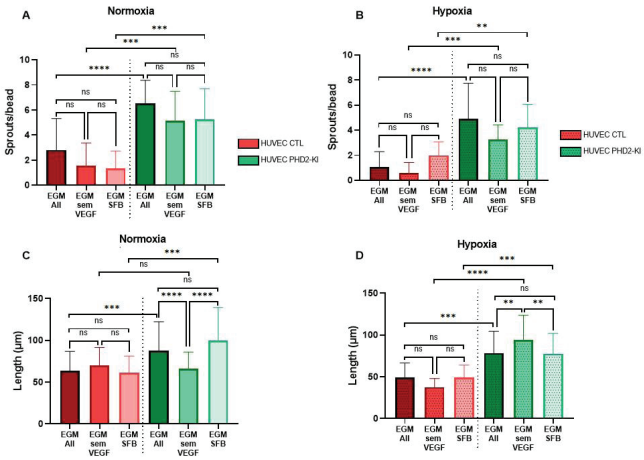

Figure 2 - Sprouting Assay. (A) and (B) number of sprouts per bead. (C) and (D) length of each sprout. EGM: Endothelial Growth Media. EGM-All: EGM media containing all the growth factor. EGM withou VEGF: EGM media containing all growth factors, but VEGF. EGM SFB: EGM media without growth factors, supplemented with FBS only.
