

**FUNCTIONAL GENETICS OF CANCER AND CONGENITAL
DISORDERS**

JAROSLAV ZAK

A thesis submitted to the Board of the Faculty of Medical Sciences in partial
fulfilment of the requirements for the degree of

Doctor of Philosophy

at the

University of Oxford

ABSTRACT

The genetic architectures of cancer and congenital disorders are heterogeneous and incompletely mapped. Rare and low-frequency variants of incomplete penetrance are emerging as an important class of germline and somatic variation, but their contribution to disease remains poorly characterised. This thesis aims to identify and assess pathogenic mutations in the 1q41q42 microdeletion syndrome, neural tube defects, neuropsychiatric disorders and cancer. Rare microdeletions at the 1q41q42 locus cause a clinically heterogeneous syndrome characterized by developmental delay, characteristic dysmorphic features and brain morphological abnormalities. Examining new and published patients with 1q41q42 microdeletions, we found that *TP53BP2*, encoding ASPP2, is a strong candidate for being the gene responsible for brain morphological abnormalities of the syndrome. Mice deficient for *Trp53bp2* show multiple abnormalities overlapping the features of the 1q41q42 microdeletion syndrome such as dysmorphic lateral ventricles, heart and urogenital abnormalities. ASPP2 deficiency also causes neural tube defects, hopping gait, and male-specific motion hyperactivity in mice. We further identify candidate pathogenic *TP53BP2* duplications, implicating *TP53BP2* dosage sensitivity in the ganglionic eminences of the developing brain, manifested by structural abnormalities in the striatum and lateral ventricles of both deletion and duplication patients. ASPP2 controls neuroepithelial cell polarity via Par3 and genetic disruption of aPKC-Par3 interaction by rare missense variants was implicated in human neural tube defects. An integrative analysis of cancer genomic data revealed that *PPP1R13B*, encoding ASPP1, bears many hallmarks of a tumour suppressor gene, despite being mutated at a low absolute frequency. A subset of missense somatic mutations in ASPP genes genetically interact with

TP53 mutations, disrupting an autoinhibitory mechanism to modulate p53-dependent transcription. In summary, this work identified novel candidate pathogenic variants in developmental disorders and cancer, and explored the mechanisms underlying their respective genotype-phenotype links.

DEDICATION

This work is dedicated to my mother, in loving memory.

ACKNOWLEDGMENTS

I would like to thank Xin for her guidance and the scientific freedom she has given me, for which I am very grateful. Xin, thank you for being a great mentor. My thanks also go to John who taught me immunology from scratch and allowed me to dive into a risky project. It has been a great ride! Thanks to Ian for looking after us Skaggs-Oxford folk during our Oxford years. A big thanks goes to Ben SB for 'encouraging' me to learn R, and putting up with all the beginners' questions. Let's also not forget the lab meeting cakes. Thanks also to Richard Bryant, Marc, Celine and Kevin - it's been a pleasure collaborating with you. I'm grateful to Elena, Daniel, Dorota, Indi, Lucy, Liz, Shan, Melissa, Halley, Vincent, Ben Davies, Douglas, Khatoun, James, Carmella, Alex, Gay and Ivy for their hands-on help. To Yihua, Min, Ludo, Gopi and Namir - I have learnt a lot from you, thanks for your patience and all the interesting discussions. I am grateful to Mary for her writing assistance and her attention to detail. To Steffi and Isa, talented Master's students-turned-PhD students, thank you for your good work. A big thanks to Veronica, you are the lifeline of the Ludwig! Thanks to Anna, Mario, Luca, David, Mike, Richard Owen, Xiao, Jingyi and the whole Lu lab for making everyday lab life fun. You will be missed! A shout out to the Skaggs cohort, Anne, Keary, Owen, JL and Dan. Last but not least, I'm grateful to all my collaborators in Oxford, at Scripps, at hospitals and elsewhere; thank you for making the research possible.

CHAPTER 1: INTRODUCTION

1.1 Genetic architectures of human diseases

Genetic architecture comprises the relative contributions of alleles with varying frequency and effect on disease risk. Genetic architecture is a key part of the aetiology of diseases with a genetic component, and its understanding directly affects clinical management of the disease. For example, monogenic disorders with a dominant pattern of inheritance can be prevented by prenatal screening for the presence of the dominant allele. In contrast, developmental diseases caused by a dominant *de novo* germline mutation have a low chance of recurrence within the same family. In addition to aetiological implications, knowledge of the loci causally linked with the disease can lead to a molecular understanding of mechanisms underlying the disease, and development of targeted treatments.

1.1.1 Pathogenic variants in human disease

The origins of genetics as a scientific discipline are usually traced to Gregor Mendel who discovered the rules of heredity based on his observation of trait characteristics in pea plants. Dominant traits, such as yellow pea colour, can be distinguished from recessive traits, such as green pea colour, based on the predictable distribution of traits among individual plants or organisms within subsequent generations of progeny. These principles, published in 1866, still form the backbone of a conceptual framework for understanding the genotype-phenotype relationship today.

Humans as a diploid organism show multiple traits that conform perfectly or near-perfectly to the dominant and recessive models. Autosomal dominant diseases such as familial hypercholesterolemia, autosomal dominant polycystic

kidney disease or type I neurofibromatosis have a 50% chance of transmitting to offspring if a single parent carries a single copy of the pathogenic allele. Within medical genetics, variants underlying dominant Mendelian disorders are now understood to represent the upper bound of a continuous spectrum of effect sizes of disease-causing variants (**Figure 1.1**).

Figure 1.1 Genetic architecture of hypertension. Reproduced from Rossier et al. (1) with permission.

Unlike Mendelian disorders, many prevalent diseases do not show predictable segregation in families. Sporadic diseases and disease-associated traits such as hypertension, coronary artery disease or obesity have been shown to associate with genetic variants which modulate risk by a relatively small amount, typically <20% and often significantly less (2-6). These variants are however highly prevalent in the population, with allele frequencies typically ranging

from 5-90%. Together, dominant Mendelian and common low-risk variants form the opposite bounds of the genetic architectures of human diseases (**Figure 1.1**).

However, the binary classification of pathogenic variants as rare and dominant versus common and low-risk does not translate to a corresponding binary clustering of genetic architectures. Common genetic variation currently explains a small proportion of the heritable disease risk of most human diseases (7). Other diseases manifest as severe developmental phenotypes in the absence of any family history of the disease. Diseases such as type 2 diabetes, schizophrenia, autism spectrum disorder or rheumatoid arthritis affect a large number of individuals, and contain a genetic component in their aetiology, but possess a genetic architecture that has remained largely hidden from genetic studies. These observations demonstrate, firstly, that genetic architectures of most human diseases likely contain contributions from both common and rare variants, and secondly, that variants of other effect size-versus-frequency classes are likely to contribute, beyond Mendelian and common/small-effect variation (8).

1.1.2 Mendelian variants enable functional understanding of disease

Dominant Mendelian diseases have fuelled our understanding of the physiological and molecular aetiology of many disorders, including diseases in which the Mendelian form accounts for a small percentage of cases. This is because dominant alleles allow for a causal link to be established between a mutation in a single gene and the occurrence of the disease phenotype in all mutation carriers. For example, Mendelian forms of hypertension have converged on a narrow set of genes which control salt management in the kidney (**Figure 1.1**) (9, 10). Moreover, most Mendelian variants are nonsynonymous and thus

enable a direct functional analysis of the mutant/truncated protein. In contrast, genome-wide association studies (GWAS) identify disease loci which are incompletely penetrant, usually located in non-coding regions, and might not be directly involved in the pathogenesis of the disease by virtue of linkage disequilibrium.

Because of their defined pattern of inheritance, Mendelian diseases are reliably identified by linkage analysis which remains an important tool in the identification of causal genes in Mendelian disorders (11). An appreciable proportion of severe congenital diseases show a Mendelian pattern of inheritance. Neurofibromatosis type I (NF1), caused by mutations in the *NF1* tumour suppressor gene, is characterised by predisposition to tumours of neural origin, but also by behavioural, cognitive, motor, bone, cardiac and pigmentary abnormalities (12). The prevalence of NF1 is estimated at 1 in 3,000 births worldwide. This disease also represents a genetic overlap between cancer and developmental disorders which occurs with other familial cancer susceptibility syndromes (13). Other examples include Ataxia-telangiectasia (autosomal recessive, mutations in *ATM*), associated with neurological, immune and cancer phenotypes; Fanconi anaemia (typically autosomal recessive; most commonly caused by mutations in *FANCA*; *FANCC* or *FANCG*), characterised by bone marrow failure, irregular skin colouring, infertility and an increased risk of multiple cancer types; or Rothmund-Thomson syndrome (autosomal recessive, mutations in *RECQL4*), associated with skin abnormalities, reduced growth, vision abnormalities and susceptibility to bone and skin cancer (13). The observation that many of these syndromes are caused by mutations in DNA repair genes highlights the importance of DNA repair in both human development and cancer prevention.

1.1.3 The landscape of human functional genomic variation

1.1.3.1 Exonic variation

Until recently, the degree and frequency of variation at different positions in the human genome remained poorly characterised. The release of the Exome Aggregation Consortium (ExAC) catalogue significantly enhanced the degree of characterisation of exonic (and to some extent splice region) variation in the germline of the human population. ExAC pooled a total of 60,706 high-quality whole-exome sequences and analysed these using a common pipeline (14). Interestingly, 99% of the variants observed in ExAC showed a frequency <1% and 54% were singletons, i.e. observed only in a single ExAC individual. Encouragingly, 63.1% of all the possible synonymous CpG transitions within regions well covered by exome sequencing were observed in ExAC, although only 7.5% of synonymous variants overall were seen. This suggests that at least some classes of genomic variation (in this case the frequently mutating CpG nucleotides) are approaching saturation at this sample size. An interesting finding of ExAC was the observation of recurrence of rare variants in independent unrelated individuals. Genetic drift dictates that most rare variants are destined to disappear from the germline, however ExAC data suggest that these variants recur independently; for example, 43% of synonymous *de novo* mutations in an external set of 1,756 trios (15, 16) were also observed in ExAC participants.

Importantly, approximately 3,020 genes were classified as intolerant to monoallelic loss-of-function (LoF) variants, suggestive of haploinsufficiency. This number does not include genes whose haploinsufficiency causes milder and/or adult-onset phenotypes such as *BRCA1*. Therefore, damaging variants in a substantial fraction of human genes are under significant constraint. Conversely,

many genes were tolerant to LoF variants which rose to appreciable frequencies in some populations, for example 1-5% in Finland. Related to this, haploinsufficiency was significantly more prevalent on the X chromosome compared to autosomes, suggesting that wild-type alleles of autosomal genes play an important role in compensating for the effects of monoallelic LoF variants. Provocatively, the authors suggest that given the mutational rates of ca. 1×10^{-9} , the vast majority of non-lethal single-nucleotide variants probably exist in at least one living human. If so, by sequencing every human, it might be possible to map the complete genomic landscape of variant constraint and thus identify all genes and genomic regions necessary for development. However, given the explosive population rate, many damaging variants have undergone limited purifying selection (17-19). The increasing rate of population growth might also explain the very high percentage of singleton variants which includes nonsynonymous variants that should be subject to minimal purifying selection.

1.1.3.2 Coding versus non-coding variation

Genomic territory outside the protein-coding regions was probed by the 1000 Genomes Project and more recently the UK10K consortium which performed whole-genome sequencing (WGS) of 3,781 healthy individuals and whole-exome sequencing (WES) of approximately 6,000 individuals with rare disease, severe obesity or neurodevelopmental disorders (20). Contrary to expectation, the study showed no appreciable abundance of low-frequency (MAF 1-5%) variants of large effect ($\beta > 1$), at least in relation with the 31 traits examined. In contrast, focusing on rare variants (MAF $< 1\%$), sequence kernel association tests and burden tests

revealed a significant signal in 9, 70 and 196 genes examining LoF, functional (missense and LoF) and naïve (all exonic, untranslated region (UTR) and essential splice site) variants, respectively. Of these, LoF variants in *APOB* achieved experiment-wide significance and other genes were suggestive of real signal. This demonstrates that rare variants are likely to play an important role in modulating phenotypic traits in disease-free individuals, and suggests that purifying selection has reduced most penetrant exonic variants to low frequency. An alternative explanation is that rare variants acquired during recent explosive population growth are enriched in functional variants that have been subject to limited selection but are rare as a result of their recent origin.

Figure 1.2 Distribution of fold enrichment statistics for single-variant associations with 5 lipid traits. Low frequency (MAF 1-5%) vs common (MAF >5%). Reproduced from (20) under the Creative Commons license.

In a more focused association test with five lipid measures, low-frequency exonic variants showed the strongest enrichment for association (**Figure 1.2**). This confirms the notion that exonic variants, in particular rare and low-frequency variants, are most likely to be phenotypically functional. Interestingly, in contrast to

exonic variants, non-coding variants in the 3' UTR, transcription start site (TSS) and some further non-coding regulatory regions showed a significant enrichment that did not differ between common and low-frequency variants (**Figure 1.2**). Given that these low-frequency variants are present in 1-5% of the population, more frequently than the rare variants discussed above, the observed bias in enrichment of low-frequency variants specific to exonic versus non-coding variants is most likely due to purifying selection of nonsynonymous alleles, independently of their association with lipid measures.

A discovery of 13 associated markers in autism spectrum disorder (ASD) was reported by UK10K; however these only achieved statistical significance after patient samples were pooled with an autism consortium cohort, demonstrating that discovering pathogenic rare variation in some neurodevelopmental diseases (NDDs) requires particularly large sample sizes. Unfortunately, the UK10K consortium have not released data on burden tests in the UK10K-exomes part of the study, therefore the importance of a polygenic burden of rare variants in the diseases examined is uncertain.

1.1.3.3 Structural variation

Structural variation accounts for the majority of varying nucleotides among human genomes (21). Following earlier efforts (22-24), the most comprehensive insight into naturally occurring structural genomic variants in humans to date came from the 1000 Genomes Project (25, 26). The catalogue of structural variants identified in the project comprises 42,279 biallelic deletions, 6,025 biallelic duplications, 2,929 multi-allelic CNVs (mCNVs), 786 inversions, 168 nuclear

mitochondrial insertions (NUMTs), and 16,631 mobile element insertions (MEIs), including 12,748; 3,048 and 835 insertions of Alu, L1 and SVA (SINE-R, VNTR and Alu composite) elements, respectively (26). A combination of long-read Pacific Bioscience sequencing with short-read Illumina sequencing allowed the authors to improve breakpoint resolution with a mean boundary precision of 0-15 bp with the exception of inversions and duplications (32 bp and 683 bp, respectively).

Figure 1.3 Abundance and size distribution of SVs identified by the 1000 Genomes Project. Reproduced from Sudmant et al. (26) under the Creative Commons license.

The majority of SVs occur at a low frequency: 65% SVs have a variant allele frequency $<0.2\%$. Interestingly, biallelic duplications were significantly depleted among common SVs; duplications were instead dominated by multi-allelic CNVs, suggesting duplications are under-ascertained in current tag-SNP-based studies. These SVs could represent an important source of genetic variation underlying the missing heritability in complex diseases.

As expected, deletions are depleted in functional regions such as coding sequences, UTRs or transcription factor binding sites. SVs also seem to have a higher relative impact on gene expression than SNPs, probably owing to their affecting a larger sequence. In fact, a number of previous GWAS associations were shown to be in strong linkage disequilibrium with SVs, suggesting some significant GWAS signal might be attributable to SVs. Complex events

characterised by multiple breakpoints were also observed and ascertained by long-read sequencing. Strikingly, long-read characterisation of inversions revealed that 80% were complex, multi-breakpoint inversions; the majority of which were inverted duplications. This points to the importance of other mutational processes in addition to non-allelic homologous recombination, retrotransposition, and non-homologous end-joining.

Overall, the median SV density is estimated at 18.4 Mbp of SVs per genome, dominated by mCNVs (11.3 Mbp) and biallelic deletions (5.6 Mbp). This estimate excludes low-complexity regions and regions with poor coverage by Illumina reads, which can harbour additional SVs. Interestingly, somatic SVs also occur in humans, for example retrotransposition events in neurons of normal brains which result in mosaicism (27, 28).

1.1.4 Structural variation in disease

Large CNVs were initially discovered by cytogenetics in patients with Down syndrome (formerly called mongolism) and intellectual disability (29-31). Since then, CNVs have been causally implicated in multiple disorders, most notably neuropsychiatric disorders including autism spectrum disorder (32, 33), schizophrenia (34, 35), bipolar disorder (36, 37), and developmental diseases featuring intellectual disability (38-41). Both *de novo* and germline CNVs are overrepresented among neuropsychiatric and developmental disease patients (32, 36). Risk-associated germline CNVs were also found to affect cognition in disease-free carriers (42). Importantly, the penetrance is estimated to range from 10-100% and so disease-associated CNVs do not always reliably co-segregate with the disease (43). Moreover, many CNVs are undetectable by traditional

cytogenetics, necessitating the use of higher-resolution genomic analysis in ascertaining patient CNVs (44).

These studies led to an intimate understanding of the functional genetics of certain forms of NDDs, for example those associated with *SHANK3* CNVs which have been characterised in mouse models as well as patient-derived neuronal cultures (45, 46). Restoration of *Shank3* expression has even been shown to reverse some autistic-like phenotypes, suggesting the identification of pathogenic CNVs can potentially lead to new therapy (47). Moreover, CNV studies firmly implicated certain functional networks of genes in the aetiology of NDDs, notably genes involved in transcription (48), chromatin remodelling (48-50) and synaptic function (16, 48, 51).

A recent analysis of CNVs in ExAC yielded 126,771 CNVs among 59,898 individuals, with 2.1 high-confidence CNV intersecting at least one protein-coding gene observed per individual (52). CNV constraint, estimated by deviation from a linear regression model of CNV rate, significantly correlated with constraint of LoF and missense SNVs. Importantly, highly expressed genes had higher CNV intolerance scores in most tissues, with genes highly expressed in the brain being the most intolerant to CNVs. The 5% most CNV-intolerant genes were significantly enriched in the GO term neuron/axon development, which also comprised the largest enriched gene network. These results provide a rationale for the strong association of CNVs with neurodevelopmental diseases: brain-expressed genes are more dosage-sensitive than genes in other tissues and this effect might be particularly striking during brain development. Accordingly, analysing CNVs within a schizophrenia study showed that schizophrenia-associated CNVs were enriched in genes with higher constraint based on missense and LoF variants.

Given the strong association of CNVs with neuropsychiatric diseases and developmental delay, analysis of chromosomal abnormalities by chromosomal microarray has become the first-tier diagnostic test in patients with developmental disabilities or congenital anomalies (53).

1.1.5 Filling the gaps in the genomic catalogue of human disease

Despite the successes of linkage analysis, genome-wide association studies, next-generation sequencing, haplotype-resolved genome assemblies, and others, the diagnostic yield in many diseases with a strong genetic component remains under 50%. This problem is partly caused by our incomplete knowledge of the genetic architectures of human diseases, exemplified by type 2 diabetes: a recent large sequencing study of a total of 15,597 individuals and an associated genotyping and imputation-powered analysis of a further 111,548 patients and controls identified 126 variants commonly associated with T2D risk and concluded that common variation contributes much more to T2D heritability than rare ones do (54). Unfortunately, currently known common variation accounts for only about 10% of the genetic risk, and the authors concluded that nearly all common-variant associations detectable by whole-genome sequencing were previously found by GWAS. Therefore, it remains unclear which genetic factors determine the remaining and dominant fraction of the heritable risk of T2D.

Other, less robustly characterised diseases, also remain challenging to reliably genetically diagnose. A recent study, published as part of the WGS500 program to sequence 500 patient genomes of patients with a diverse genetic disorders, identified pathogenic variants in 21% of cases, despite taking multiple

steps to improve accuracy of variant calling, filtering and annotation across the pooled patient set (55). Among the challenges highlighted by the authors were the observations that multiple genetic factors likely contribute, and only very large patient cohorts are sufficiently powered for the identification of new variants with modest contribution. In addition, the authors noted that ultimate assignment of pathogenicity relies on the identification of the same variant in multiple patients for whom detailed phenotypic and clinical data are available. Clearly, in rare diseases, rare variants of incomplete penetrance will be very challenging to match, hampering the definitive proof of pathogenicity in many cases. Accordingly, Cooper et al. noted that ‘...the primary roadblock faced by the field is increasingly one of variant interpretation, rather than data acquisition’ (56). Therefore, with the decreasing cost of WGS, the number of patients ascertained and characterised in the public domain will likely become the major limiting factor to improving diagnostic yield.

Neural tube defects (NTDs), the second most frequent group of birth defects, are estimated to contain a strong genetic component to their aetiology, yet the genetic architecture remains incompletely characterised. In particular, there is a vast gap between the list of genes causing NTDs when mutated in mice, and those genes that have been linked with NTDs in humans (57, 58). The genetic architecture of NTDs is poorly understood.

Neurodevelopmental diseases such as autism spectrum disorders (ASD) and schizophrenia are also proving challenging to map genetically, owing to the significant heterogeneity of disease-associated genes. For example, all high-confidence pathogenic variants in ASD identified thus far, including SNVs, CNVs and syndromic causes, explain only a small fraction (<10%) of the genetic

contribution to ASD risk (59). Hence, NDDs are considered polygenic diseases with monogenic form accounting for a small percentage of cases. Mapping the remaining genetic architecture remains an important goal in NDD genetics (60).

Cancer has been the focus of intense genomic investigations, as all or virtually all cases of cancer arise from acquired genomic aberrations. The genetic architecture of cancer comprises germline and somatic components. Germline alleles influence cancer risk with a continuum of effect sizes (**Figure 1.4**) (13, 61), but further somatic mutations are required to develop malignancy. The somatic component is discussed in more detail in section 1.3.

Figure 1.4 Genetic architecture of breast cancer risk. Reproduced from Hindorff et al. (61) with permission.

Overall, future genetic work needs to meet three major challenges: 1) characterise all pathogenic variants of known classes (common low-risk alleles, rare large-risk alleles) amenable to existing genetic methods; 2) improve the

analytical tools for genetic variation outside the scope of current studies (e.g. rare variants of low effect; CNVs in low-complexity regions; mosaic somatic mutations); and 3) characterise their contribution to the genetic architectures of diseases, and identify pathogenic variants of those difficult-to-probe classes.

1.1.6 Discovery and assessment of candidate variants

Given the incomplete knowledge of the genetic architectures of human diseases, the identity of pathogenic variants, and uncertainty surrounding the relevance of many variants identified by WES and WGS, it is necessary to continue the process of discovery and assessment of candidate pathogenic variants across diseases. However, in addition to limited sensitivity, a problem faced by genome-wide variant searches is the rate of false positives. Indeed, The exome aggregation consortium (ExAC) found that on average, an ExAC participant harbours ~54 variants reported as disease-causing in the Human Gene Mutation Database (HMGD; <http://www.hgmd.cf.ac.uk/ac/index.php>) or ClinVar (14). A manual curation of 192 such variants with an ExAC allele frequency >1% found good evidence of pathogenicity for only 9 variants, and led to the re-classification of some of the remaining variants. This suggest the medical genetic literature is burdened with a relatively high rate of false positives. In order to improve the sensitivity and specificity of identification of pathogenicity, a common assessment framework is required that allows researchers and clinicians to understand the level of confidence surrounding the implication of a specific variant in a specific disease.

A working group of the US National Human Genome Research Institute have published guidelines for investigating causality of sequence variants in

human disease (62). The guidelines highlight a primary role for genetic evidence in supporting causality, noting that many protein-damaging variants are present in human genomes. At the gene level, a burden of rare or *de novo* variants in patients compared to a matched control cohort provides good evidence of gene involvement. Importantly, ethnicity and sequencing depth must be well matched between cases and controls, as rare variants are particularly sensitive to these types of bias.

At the variant level, single-variant enrichment in cases over controls provides convincing evidence of disease association, however most disease cohorts are underpowered to detect genome-wide significant associations for rare variants (63). Co-segregation of the variant with disease in multiple family members or in multiple families is also considered strong genetic evidence. However, an important caveat is that variants with moderate penetrance will not always co-segregate with disease. In fact, Bodmer and Bonilla specifically noted that 'neither common nor rare variants are familial', demonstrating in an example that for a susceptibility allele *D* with a penetrance of 20% (corresponding to an odds ratio of 3 or higher), heterozygous to wild type matings *Dd* x *dd* will result in only 5.2% families with four offspring having more than one affected offspring (64). A penetrance approaching 50% is necessary to start observing Mendelian-like familial segregation. Therefore, co-segregation evidence in a small number of families will only be available for variants with a relatively high penetrance.

Finally, important evidence is provided by population frequency: zero or low frequency of the variant in large population cohorts with ancestry similar to the disease cohort supports the potential pathogenicity of the variant. However singleton rare variants are observed in both patients and healthy individuals, as

robustly demonstrated by ExAC. Taken together, these observations show that genetic evidence for disease association of single variants is likely to be limited to high-penetrance rare variants in all but very large studies. Low- to moderate-penetrance rare variants can thus be uncovered by gene-level or gene set-level analysis.

Guidelines for variant interpretation have been recently formalised by the American College of Medical Genetics and Genomics (ACMG), and the Association for Molecular Pathology (65). These guidelines provide a useful framework for the classification and quantification of evidence surrounding pathogenicity of sequence variants across diseases (**Figure 1.5** and (**Appendix Tables S1-S3**)). The quantitative scale classifies variants as benign, likely benign, pathogenic, likely pathogenic, or of uncertain significance. In this thesis, the guidelines will be utilised to describe the evidence supporting the pathogenicity of the variants investigated in the following chapters.

ACMG guidelines also exist for the interpretation and reporting of germline CNVs (66). Although lacking a quantitative framework, the guidelines provide a useful reference for weighing the relative strength of different types of evidence in classifying CNVs.

	Benign			Pathogenic		
	Strong	Supporting	Supporting	Moderate	Strong	Very strong
Population data	MAF is too high for disorder BA1/BS1 OR observation in controls inconsistent with disease penetrance BS2			Absent in population databases PM2	Prevalence in affecteds statistically increased over controls PS4	
Computational and predictive data		Multiple lines of computational evidence suggest no impact on gene /gene product BP4 Missense in gene where only truncating cause disease BP1 Silent variant with non predicted splice impact BP7 In-frame indels in repeat w/out known function BP3	Multiple lines of computational evidence support a deleterious effect on the gene /gene product PP3	Novel missense change at an amino acid residue where a different pathogenic missense change has been seen before PM5 Protein length changing variant PM4	Same amino acid change as an established pathogenic variant PS1	Predicted null variant in a gene where LOF is a known mechanism of disease PVS1
Functional data	Well-established functional studies show no deleterious effect BS3		Missense in gene with low rate of benign missense variants and path. missenses common PP2	Mutational hot spot or well-studied functional domain without benign variation PM1	Well-established functional studies show a deleterious effect PS3	
Segregation data	Nonsegregation with disease BS4		Cosegregation with disease in multiple affected family members PP1	Increased segregation data →		
De novo data				De novo (without paternity & maternity confirmed) PM6	De novo (paternity and maternity confirmed) PS2	
Allelic data		Observed in <i>trans</i> with a dominant variant BP2 Observed in <i>cis</i> with a pathogenic variant BP2		For recessive disorders, detected in <i>trans</i> with a pathogenic variant PM3		
Other database		Reputable source w/out shared data = benign BP6	Reputable source = pathogenic PP5			
Other data		Found in case with an alternate cause BP5	Patient's phenotype or FH highly specific for gene PP4

1.1.7 The importance of rare variants in disease

Earlier studies of cancer and complex disease susceptibility predicted that rare and low-frequency variants would be important in completing the full picture of the genetic architecture (6, 61, 64). As discussed above, rare variants are now known to correlate with phenotypic traits in healthy individuals, and significantly associate with developmental diseases. Many significant associations between rare variants have been identified to date, including a burden of *SOD1* variants in sporadic amyotrophic lateral sclerosis (67), *CYP27B1* variants in multiple sclerosis (68), variants in 7 neuronal genes in bipolar disorder (69), RAS pathway gene

variant in Noonan syndrome (70), *IFIH1* rare variants in type 1 diabetes (71), polygenic burden of disruptive variants in schizophrenia (72), non-syndromic heart defects (73), colorectal adenomas (74), lung cancer risk (75), but also variants in complex adult diseases such as type 2 diabetes (76), irritable bowel syndrome (77) or hypertriglyceridemia (78). Rare SNVs and CNVs in various genes have also been linked with neural tube defects (79-82).

Based on the numerous studies that succeeded in identifying clinically relevant rare variants, and the extent of missing heritability in complex diseases once common variants have been accounted for, the contribution of rare variants to human disease is likely to be important. These variants represent an important class of genetic variation separating low-risk common variants identified by GWAS, and dominant variants with a Mendelian inheritance pattern. Exonic rare variants are particularly likely to exert significant effects. Approximately 88% of trait-associated variants of weak effect are non-coding (6). The majority of coding variants are rare (<1%) and nonsynonymous SNPs have the highest odds ratios as a class in GWAS (6). Low-frequency (1-5%) exonic variants are significantly more enriched in trait-associated loci than frequent exonic variants, and represent the most highly enriched class of variation in lipid level-associated variants (20). The ratio of non-coding to coding causal variation declines relative to increasing mutational penetrance and disease severity (83). In a recent WGS study of breast cancer, only 2 recurrent somatically mutated non-coding loci with suspected driver function were identified, in contrast to many coding driver mutations (84). In addition, due to the recent explosive human population growth, human coding variants are over-represented in deleterious variants compared with other species due to limited purifying selection (17, 19). Taken together, rare nonsynonymous

SNVs and genic CNVs have a high *a priori* probability of non-neutral effect on disease phenotypes.

Despite the strong rationale for the importance of rare variants in disease, the majority of causal rare variants still elude detection in most scenarios. This is because most genome-wide studies are under-powered to detect their association with disease, and small-scale sequencing studies are usually inconclusive on their importance because of incomplete penetrance and low recurrence rate of the same variant in unrelated cases. Therefore, current methods of uncovering pathogenic rare variants rely on burden tests, which identify gene-level and gene set-level associations, or on targeted hypothesis-driven sequencing (64, 72, 85).

In this thesis, the contribution of rare germline and *de novo* variants (both SNVs and CNVs) to developmental defects, and the contribution of rare somatic mutations to cancer are examined. We focus on the ASPP family of genes as proof of principle and discuss how the discovery methods developed throughout could be generalised genome-wide.

1.2 Congenital disorders of the central nervous system

A large number of congenital disorders affecting the central nervous system exist, ranging from lethal defects such as craniorachischisis, to mild developmental delay. In this thesis, we will focus on abnormalities associated with 1q4 CNVs, neural tube defects, childhood-onset schizophrenia, and autism spectrum disorder.

1.2.1 1q41q42 microdeletion syndrome

Structural variants in the human genome arise from a range of mutational mechanisms, including DNA recombination, replication- and repair-associated processes. CNVs and other structural abnormalities are associated with many developmental abnormalities (86, 87) which led to the adoption of the chromosomal microarray as the first-tier test for individuals with developmental disabilities or congenital anomalies, offering a diagnostic yield over 15% (53). A major source of CNVs is nonallelic homologous recombination (NAHR), which occurs between two paralogous low-copy repeats or segmental duplications (88, 89). Recurrent CNVs at these loci can be pathogenic, especially when spanning gene-rich regions (90).

The composition of non-recurrent rearrangements is more complex and includes compound mechanisms such as duplication-inverted triplication-duplication (87, 91). Breakpoint junctions in non-recurrent rearrangements generally vary in each individual, making the clinical interpretation more difficult (92). The distinct properties of non-recurrent rearrangements suggest they are

formed by a mechanism independent from NAHR, such as non-homologous end joining (NHEJ), and replication-based mechanisms such as break-induced replication, microhomology-mediated break-induced replication, serial replication slippage, and fork stalling and template switching (93, 94). Importantly, some of these repair mechanisms can introduce nucleotide changes such as point mutations and indels, concomitant with the structural variant. In addition, insertion of short <100 bp segments from nearby genomic regions is observed in up to 35% nonrecurrent structural variant junctions (95). Therefore, in addition to breakpoint heterogeneity, changes in genomic sequence associated with CNVs further increase the diversity of these structural variants, which is reflected in the phenotypic heterogeneity of CNV carriers. Moreover, these replication-based mechanisms are thought to occur during mitosis and so can contribute to somatic structural variation and mosaicism.

Chromosomal deletions that cause rare genetic disorders usually affect more than one gene and cause multiple phenotypic features. Deletions in the chromosomal 1q41-q44 region are significantly associated with central nervous system (CNS) defects including neural tube defects (NTDs), agenesis of corpus callosum, microcephaly and hydrocephalus (96, 97). Small interstitial deletions in the 1q41q42 region are implicated in the 1q41q42 microdeletion syndrome with features of severe developmental delay, intellectual disability, and brain morphological abnormalities. This syndrome was discovered by testing over 10,000 patients with developmental disabilities by chromosomal microarray and observing a subset of patients with shared features that harboured small (<10 Mb) deletions in the 1q41q42 region, otherwise undetectable by cytogenetics (44).

A critical region comprising the genes *FBXO28*, *TP53BP2*, *CAPN2* and *CAPN8* has been proposed for the 1q41q42 microdeletion syndrome based on the smallest region of overlap (SRO) (98). Virtually all 1q41q42 deletions causing the 1q41q42 microdeletion syndrome are *de novo*; a patient with a small inherited 1q41q42 microdeletion was diagnosed with an isolated congenital heart abnormality and the deletion does not span the critical region of the syndrome (98). Since then, a small inherited *DISP1* deletion (*DISP1* is located outside the SRO) has been reported in a patient with seizures that lacks most severe features of the syndrome (99). Among the genes within the SRO, *FBXO28* (encoding the F-box only protein 28, a ubiquitin ligase) has been proposed as a candidate gene responsible for seizures and intellectual disability in microdeletion patients (100, 101). However, the genes responsible for other phenotypes, in particular the brain morphological abnormalities, of the syndrome are unknown.

TP53BP2, which is located at the boundary of 1q41 and 1q42, encodes the Apoptosis Stimulating Protein of p53 2 (ASPP2). It is also an ankyrin repeat, SH3 domain and proline-rich containing protein (ASPP), originally identified as a positive regulator of p53-mediated transcription of apoptotic genes (102, 103). In mice, ASPP2, encoded by *Trp53bp2*, is essential for embryonic development (104, 105): an ASPP2-null genotype in mice is lethal prior to embryonic day E7 and mice with homozygous deletion of exon 3 exhibit loss of neuroepithelial cell polarity and hydrocephalus (106). ASPP2 is involved in regulating apoptosis through binding to p53 (and its sibling proteins p63 and p73) via its C-terminus and in regulating cell polarity through binding to the tight junction protein Par3 via its N-terminus (106, 107). Therefore, *TP53BP2* is a potential candidate gene for a causal role in the 1q41q42 microdeletion syndrome. Identification of causative

genes could extend our understanding of molecular pathways that are responsible for common diseases. In Chapter 2, the role of *TP53BP2* in the aetiology of 1q41q42 microdeletion-associated abnormalities is investigated.

1.2.2 Neural tube defects

Neural tube closure (NTC) is a key step of central nervous system (CNS) development. Neural tube defects (NTDs) stem from a failure of the neural tube, the structure that will give rise to the brain and spinal cord, to close during neurulation. NTD often results in death or severe disability and is among the most common birth defects worldwide ranging from 1 to 27 per 2000 pregnancies in the USA and China, respectively (108) (109). During neurulation, the neural plate bends upwards and eventually fuses to form a hollow tube. This process is evolutionarily conserved and occurs following a well-defined sequence of events along the embryonic axis (110). In mouse, initiation of closure starts at the future cervical-hindbrain boundary and goes bi-directionally into the hindbrain and along the spine (closure 1). Two additional closure sites occur at the midbrain-forebrain boundary (closure 2) and at the most rostral extremity of the forebrain (closure 3). NTDs are classified according to the region of the brain and spinal cord that are affected. Complete failure of closure 1 leads to craniorachischisis, the most severe NTD, in which almost the entire brain and spinal cord are open. If closure 1 remains incomplete in the cranial region, anencephaly occurs. In the spinal region, failure of closure at the posterior neuropore leads to spina bifida. The mildest form of spina bifida, myelomeningocele, is the most common NTD compatible with life.

NTDs have a complex aetiology involving both genetic and environmental factors with genetic factors contributing up to 70% (111). Over 250 transgenic

mouse models of NTD have been reported to date, spanning many classes of biological function including planar cell polarity (PCP), apoptosis, epigenetic regulation, metabolism and actin dynamics (58, 112). While homozygous disruption of many genes gives rise to NTD in mice, monogenic NTD in humans is unknown (113). A small number of common loci (114, 115) and rare variants associated with NTDs have been identified (57), limited by the small number of cases and the heterogeneity of the underlying aetiology. Only a very limited number of gene mutations were linked with similar phenotypes in both mouse and human NTDs. PCP genes *SCRIB* (116) and *CELSR1* (117, 118) are two examples. An important insight came recently from the identification of *de novo* *SHROOM3* truncating mutations in 2 independent NTD cases, highly significant given the cohort size of 43 trios (119). *Shroom3* mutant mice develop NTDs, confirming these *de novo* *SHROOM3* truncations as pathogenic in human NTDs. The same study identified truncating *de novo* mutation in *PAX3* in an unrelated case and a missense *de novo* mutation in *GRHL3*; mutations in the orthologous genes cause NTDs in mice.

To date, the gene mutations identified in human NTDs are mainly involved in PCP (e.g. in *VANGL1*, *VANGL2*, *CELSR1* or *SCRIB*) occur at low frequency, and account for a small proportion of cases (79, 117, 118, 120). Interestingly not all PCP genes behave the same. Although mutation in *VANGL1* gene has been detected (79) in human NTDs at a low frequency, *Vangl1*-null mice do not suffer from NTD. It is unknown whether mutations in other mouse NTD-related genes contribute to human NTDs.

Folic acid (FA) supplementation reduced the incidence of NTDs substantially. FA plays a key role in one-carbon metabolism that controls the

production of purine and thymidylate, building blocks of DNA and RNA biosynthesis as well as the production of methyl donor S-adenosyl-methionine (SAM) used in DNA, RNA and protein methylation. Thus FA may prevent NTD by affecting cell proliferation via multiple pathways including gene expression. Mutation status of FA metabolic pathways has been subject to intense study. However transgenic mice deficient in MTHFR and MTHFD1, two key enzymes of FA metabolic pathway, failed to develop NTD phenotype. Similarly *Dact1*-null embryos also do not suffer from NTD (121). Few functional mutations have been identified in human NTDs that involve the FA metabolic pathway. Consistent with this, around 30-50% of NTDs are not preventable by FA supplementation (122). Although polymorphisms in some genes (e.g. *GLUT1*, *HK1*, *LEP1* and *LEPR*) have also been associated with NTD risk (57), most mutation screens and case-control studies failed to find significant associations between the known polymorphisms (such as in folate genes *MTR* or *FOLR1,2,3*) and NTDs (57, 123). All these suggest that an unmet clinical need is the identification of pathogenic variants in human NTDs.

A key process in neural tube closure is apical constriction. Following convergent extension of the epithelial sheet, cells reduce the width of their apical surface while allowing the basal surface to enlarge, thus enabling the epithelial sheet to fold. Epithelial apical constriction is regulated in part by Par3 and Willin which prevent apical localisation of ROCK via regulating aPKC (124, 125). Junctional loss of aPKC is required to allow ROCK-mediated cytoskeletal changes leading to apical constriction. Mutations in apical constriction regulators *Shroom3*, *Abl* and *Mena* in mice result in well-defined NTDs comprising exencephaly and

caudally restricted spina bifida (58). Exencephaly is the mouse clinical equivalent of human anencephaly. As described above, truncating *de novo* mutations of *SHROOM3* were found in human NTDs, implicating the genetic disruption of apical constriction in the aetiology of NTDs (119, 126). The interaction of *SHROOM3* and *ROCK* is required for neural tube morphogenesis in mice (127). Interestingly, SNP variants in the gene *PARD3* that encodes Par3, a key component of apicobasal polarity complex, are associated with anencephaly in China (128). The convergence of these risk factors on apical constriction mediated by *ROCK* implicates the genetic disruption of this process in the aetiology of NTDs.

Recent studies suggested that *ASPP2*, a binding partner of Par3 and a regulator of apical basal polarity and adherens junctions, is required for CNS development. *ASPP2*-deficient mice exhibit loss of neuroepithelial cell polarity and hydrocephalus (106). *ASPP2* also inhibits the epithelial-to-mesenchymal transition (EMT), a process which has recently been implicated in neural tube closure downstream of *GRHL2* (129, 130). Therefore, it would be interesting to investigate whether *ASPP2* is disrupted in NTDs.

Interestingly, amongst mouse mutants exhibiting NTDs, a subset of p53-deficient embryos have been shown to develop NTDs, suggesting that p53-dependent transcription programs may be required during neural tube closure (131, 132). Those embryos exhibit exencephaly, consisting of an outgrowth of the neural tissue usually confined to the fore- and midbrain, but sometimes also affecting the hindbrain. Some mice with mutations in p53-target genes, such as *Gadd45a*-null mice, have been shown to develop NTDs, further suggesting that p53 transcriptional activity may be required during neural tube closure (133).

Moreover p73, a p53 sibling, is required for neural stem cell maintenance and its deficiency also causes hydrocephalus suggesting p73 might be involved in NTDs (134, 135).

Chapter 2 of this thesis investigates the role of ASPP2 deficiency in CNS abnormalities including NTDs in mice and humans. In Chapter 3, the role of rare variants in *TP53*, *TP73*, *TP53BP2* and *PARD3* in human NTDs is investigated.

1.2.3 Autism spectrum disorder and schizophrenia

Concordance rates in monozygotic versus dizygotic twins are an important source of evidence of heritability. In psychiatric disorders, twin studies estimate heritability at 0.80 for autism spectrum disorders (ASDs) (136), 0.81 for schizophrenia (137) and 0.75 for bipolar disorder (138) (**Figure 1.6**). These studies indicate a substantial genetic component in the aetiology of ASD and schizophrenia. In addition, *de novo* mutations have been shown to play a role. Taken together, understanding of the genetic basis of ASD and schizophrenia is an essential step towards a mechanistic understanding of these diseases, a pre-requisite for targeted therapy.

Figure 1.6 Heritability vs lifetime prevalence of psychiatric disorders. Adapted from Sullivan et al. (137) with permission.

No Mendelian forms of schizophrenia seem to be known (139). Therefore, the genetic architecture of schizophrenia comprises incompletely penetrant germline variants and *de novo* mutations. In addition to common loci, an increased burden of structural rare variants in neurodevelopmental pathways, and single-nucleotide variants in synaptic and chromatin remodeling genes have been demonstrated in schizophrenia patients (72, 140, 141). *De novo* mutations are also implicated in schizophrenia (35, 36, 142) and autism (32, 143, 144). These mutations span diverse genes, highlighting the polygenic nature of schizophrenia and ASD.

Estimates of the ASD gene target sizes are in the region of 250-1,800 genes (144). Understanding the function of all these causal genes is a great undertaking. However, some common pathways emerge, which allow us to generalise the likely modes of disruption to classes of genes. For example, synaptic signaling, chromatin remodeling, and protein translation are strongly implicated processes in the

pathophysiology of ASD and other psychiatric disorders (59). Importantly, there is a significant functional overlap between genes associated with multiple psychiatric disorders.

An interesting example of an ASD gene is *SHANK3*, a gene encoding a postsynaptic density scaffolding protein of excitatory synapses. A syndromic form of ASD called Phelan-McDermid syndrome arises from 22q13 deletions that span *SHANK3*. This syndrome represents a possible example of a monogenic form of autism. However, *SHANK3* point mutations have also been observed in both schizophrenia and ASD patients, and even in a Rett syndrome-like patient (145-148). Some of these mutations have been shown to modify dendritic spine morphology by an actin-dependent mechanism (149). *SHANK3*-deficient mice recapitulate some of the human phenotypes associated with *SHANK3* mutations such as deficits in social interaction (45, 150). This gene exemplifies the partial convergence of psychiatric disorders on common dysregulated gene networks and cellular processes.

1.3 Functional genomics of cancer

1.3.1 Tumour suppressor genetics

Cancer is driven by genetic dysregulation which allows cells to proliferate and migrate outside their physiological spatiotemporal bounds. The genetic architecture of cancer includes a major somatic component but also germline risk alleles of varying penetrance. Traditionally, tumours are thought to be driven by a small number (<8) of 'driver gene' mutations with the remaining somatic mutations considered 'passengers' which confer no selective growth advantage (151). However, defining driver gene mutation as a 'mutation that directly or indirectly confers a selective growth advantage to the cell in which it occurs' allows for a continuum of effect sizes. The traditional view of tumour suppressor genes, based on observations in retinoblastoma, portrays TSGs as recessive: an inactivating mutation requires a second hit in the same gene (such as another inactivating mutation or loss of heterozygosity) in order to cause cancer (152, 153). *RB1* conforms to this model, causing disease in germline mutation carriers who acquire a second, somatic mutation that triggers tumorigenesis.

However, not all TSGs are recessive, as Fearon and Vogelstein noted in 1990 based on the observations of adenomas in patients with familial adenomatous polyposis who did not show allelic losses of the chromosome linked to the syndrome : 'In some cases, mutant tumour suppressor genes appear to exert a phenotypic effect even when present in the heterozygous state; thus, some tumour suppressor genes may not be recessive at all.' (154). Since then, the 'two-hit paradigm' has been revised from a dogma to a model that applies to some but not all TSGs (155, 156). The remaining TSGs show evidence of dosage

sensitivity. For example, not all tumours in Li-Fraumeni syndrome patients, carriers of cancer-predisposing mutations in *TP53*, show loss of *TP53* heterozygosity. Many other haploinsufficient and dosage sensitive TSGs exist and were reviewed by Payne et al. (156). Notable examples include the cell cycle inhibitor *Cdkn1b* (p27); *Nkx3.1*; *Cdkn1a* (p21) or *Msh2*. *Cdkn1b*^{+/-} mice show an intermediate susceptibility to irradiation-induced tumours between wild type and p27-null mice but do not show deletion of the other *Cdkn1b* allele (157). Similar intermediate susceptibility phenotype in *Cdkn1b*^{+/-} mice was observed with 1,2-dimethylhydrazine induced tumorigenesis (158). Therefore, evidence of biallelic loss is not required for identification of TSGs. Another example of a haploinsufficient TSG is *Trp53bp2*: *Trp53bp2*^{+/-} and *Trp53bp2*^{Δ3/+} mice develop spontaneous tumours which include lung adenocarcinomas, squamous cell carcinomas, lymphomas and sarcomas (104, 105, 159). ASPP2 deficiency manifests itself at the cell-autonomous level by increased thresholds for apoptosis, and by defective cell cycle checkpoints in γ-irradiated primary cells (104). Hemizygous deletions occur frequently in human tumours and are thought to act as mini-drivers which optimise the proliferative potential of cancer cells (160).

Berger et al. introduced a concept of 'obligate haploinsufficiency', marking TSGs whose optimal inactivation is conditional on one allele being retained (155). For example, in prostate cells, full loss of *Pten* on a wild-type p53 background leads to senescence whereas hemizygous deletion can lead to prostate neoplasia and cancer. Other examples includes *Dicer1* in the lung or *Npm1* in haematologic malignancies.

1.3.2 Tumour mutations are context-dependent

An important concept in understanding tumour suppressor gene function is context dependence. The penetrance of TSG loss is influenced by tissue type and the presence of modifier alleles. For example, germline *BRCA1* mutations increase the lifetime risk of breast cancer and ovarian cancer by up to ~80% and ~50%, respectively, which is thought to be related to increased survival of oestrogen-induced *BRCA1*-deficient mammary epithelial cells (161). *BRCA1* is not somatically mutated at a statistically significant level across pooled cancer types but is significantly mutated in ovarian cancer (162). Another example is *WT1*, the Wilms' tumour gene. Deletions of *WT1* are associated with syndromic cases of Wilms' tumour, a childhood cancer of the kidney whereas frequent somatic mutations drive acute myeloid leukaemia (163, 164).

Modifier alleles can have a decisive effect on the penetrance of TSG mutations. Mice carrying the *Apc*^{min} mutation develop spontaneous polyps in strains positive for a mutation in *Pla2g2a* (originally named *Mom1*), such as C57BL/6, but are resistant to polyps in *Pla2g2a*-wild type strains such as AKR (165). Germline SNPs have been found to modify risk of *BRCA1* and *BRCA2* mutation carriers (166). In human cancers, many mutations are connected by functional networks and co-occur in tumours, for example in the condensin and CLASP and CLIP complexes (167). This suggests some gene networks have built-in redundancy that is broken by multiple mutations within the same network. Copy number variants also show co-occurrence patterns in tumours (168). Conversely, mutations showing mutual exclusivity often mark dominant driver mutations that make another mutation within the same pathway unnecessary or detrimental. It is well known that mutations within druggable pathways can underlie acquisition of

drug resistance. For example, expansion of tumour clones with *MEK1* or *MEK2* mutations occurs in some patients with *BRAF* resistance (169, 170). Only a handful of mutations are penetrant enough to be able to transform a wide range of cell types from non-malignant to malignant. The penetrance of most mutations is conditional on the tissue of origin and/or cooperating transforming genetic events. Therefore, mutations in cancer should be considered as being a function of their environment crucially including the tissue of origin and somatic genome of the cell.

A view of cancer as an evolutionary process incorporates much of the complexity discussed above. Cancer shows evidence of complex clonal dynamics including competition, predation, parasitism and mutualism between co-evolving clones (171). Interesting ecological phenomena have also been observed; for example cancer clones injected into opposite flanks of mice and rats can inhibit each other's growth, with only one clone sometimes being specifically affected (172, 173). In ecological terms this is known as an amensal interaction and shows that competition between different cancer clones can directly affect tumour growth. These features along with the empirical parameters that govern and constrain the evolution of each individual cancer determine the clinical course of the disease including its response to therapy. Importantly, understanding the evolutionary and ecological dynamics of cancer can present opportunities for manipulating the disease by applying methods known to affect populations with similar properties (e.g. by introducing a 'predator' such as CAR T cells, or restricting the tumour's resources). A comprehensive understanding of the process of tumorigenesis is needed to identify both stochastic and deterministic parameters that reduce clinical and molecular heterogeneity to predictable phenotypic variability.

A crucial step in building such a framework is linking specific genetic alterations to phenotypic changes and the resulting shift in clonal dynamics. This includes both strong driver mutations and passenger mutations whose collective effect might have a deleterious influence on cell fitness. Indeed, models have shown that the collective burden of passenger mutations is likely to exert deleterious effects (174). One implication of deleterious passengers is an increased requirement of the unfolded protein response which can be exploited therapeutically.

An invaluable insight into the dynamics of cancer has come from the colon in which tumour progression normally follows discrete stages that can be molecularly described and isolated from the preceding and following stages. Thus, genetic events have been reliably linked to the disease progression from normal colon tissue through the hyperproliferative, early to late adenoma, carcinoma, and ultimately metastatic stage (154). *Ras* mutations seem to mark the progression from an early to an intermediate adenoma (greater than 1 cm in size), appearing in over 50% of intermediate and larger adenomas but <10% of benign adenomas below 1 cm. *TP53* loss, for example through 17p deletions, seems to mark the transition from adenoma to carcinoma. However, despite this 'preferred order' for a pathway to malignancy, the authors stress that genetic alterations can be acquired in other orders, and it is the progressive accumulation of oncogenic mutations, not their precise order, that is most consistent between distinct colorectal tumours (154). Nonetheless, regularities in the order of acquisition of mutations can be informative with respect to gene function and their relationship to the hallmarks of cancer.

1.3.3 Mini-driver mutations in human cancer

Until recently, the continuous nature of effect sizes among cancer mutations has been underappreciated, with a black-and-white division of drivers and passengers prevailing in cancer research. However, next-generation sequencing of large cohorts uncovered exceptionally diverse sets of mutated genes in many cancer types. These 'long tail' distributions argue for the role of many genes in cancer, as they suggest multiple distinct combinations of mutations in multiple different genes can produce the same malignant phenotypes. Moreover, in a recent WGS study of 560 breast cancers, 5% of tumours had no high-confidence driver mutations and many showed only a single high-confidence driver (84). Given that breast cancer is probably the most comprehensively characterised tumour type by genomics to date, this observation underscores a clear gap between existing models of cancer genetics and our knowledge of the causal mutations. Therefore, more attention is being given to rare mutations of potentially large effect as well as small-to-medium-effect 'mini-drivers' (175).

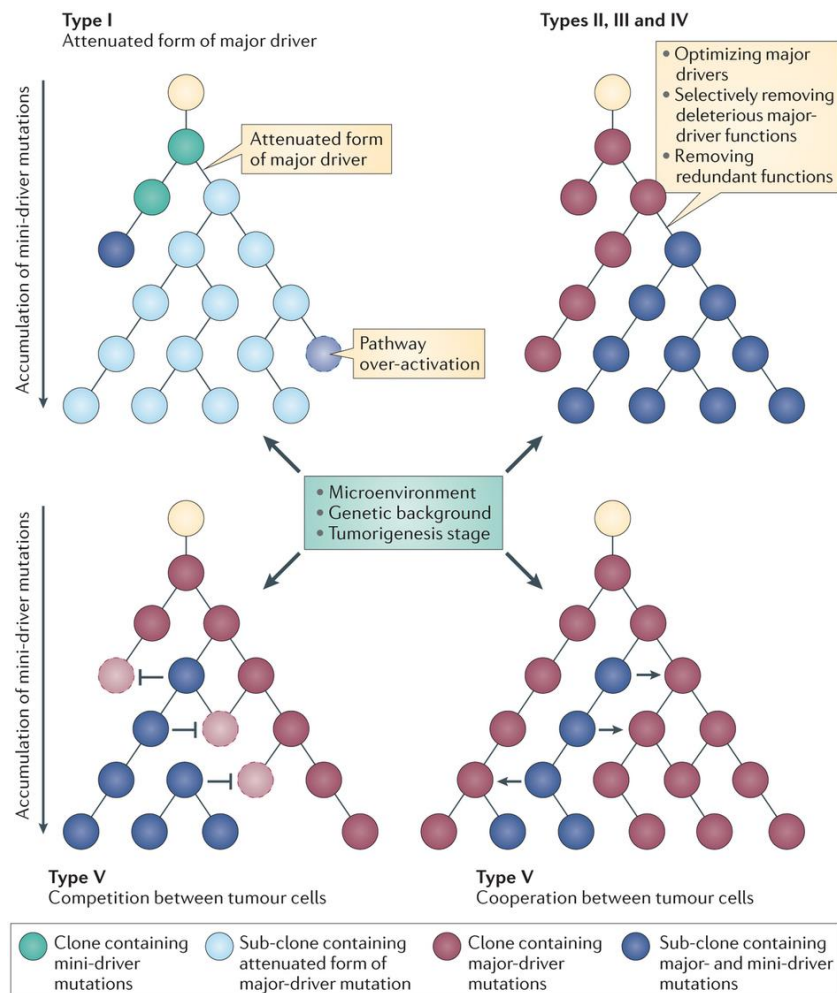

Figure 1.7 Predicted functional classes of mini-driver mutations. Figure reproduced from Castro-Giner et al (175) with permission.

Castro-Giner et al. provide a useful conceptual framework for classifying these mini-driver mutations, and thus help in defining an underappreciated component of the genetic architecture of cancer (**Figure 1.7; Table 1.1**) (175). They propose many cancers might in part follow a polygenic model in which a larger number of mutations with weak effect sizes can drive tumorigenesis. Studies of copy number variations already support this hypothesis (160, 176). Similarly, studies from transposon insertional mutagenesis in mice show that thousands of genes can promote tumorigenesis when disrupted (177, 178). The number of 'early stage drivers' is generally much lower than the number of later

stage drivers, indicating that the acquisition of the cancer phenotype requires the convergence on a number of key signalling pathways. Once the cancer has formed, the perturbation of many pathways can influence tumour growth. Hence the heterogeneity of driver mutation is much higher in later stages than in the early stages or *in vitro*. Recently, the *piggyBac* system was used to identify a non-coding regulatory region of *Cdkn2a*, confirming a functional role for non-exonic mutations in cancer, which can also act as mini-drivers (179).

Table 1.1 Summary of mini-driver mutation classes. APC, adenomatous polyposis coli; CNA, copy number alteration; CRC, colorectal cancer; HIF1A, hypoxia-inducible factor 1 α ; IDH1, isocitrate dehydrogenase 1; VHL, von Hippel–Lindau. Reproduced from Castro-Giner et al. (175) with permission.

Type	Definition	Effect	Possible examples from sporadic human cancers(177)
I	Attenuated form of 'major-driver' mutation	Mutations in the same gene or pathway as the major driver	<i>KRAS</i> mutations at codons 146 and 117 (Ref. (180))
II	Optimize major-driver mutations	Keep signalling pathway levels at an optimum	Reduction of the effects of WNT activation, through CNA in <i>APC</i> (181) and inactivating mutations in <i>SOX9</i> (Ref. (182))
		Modulate the level of genomic instability	None known at this time
		Reverse the effects of deleterious 'hitchhikers'	None known at this time
		Amplify germline variation	Targeting a polymorphism that affected an enhancer that drives an oncogene, such as allelic imbalance at rs6983267 contributing to CRC somatic evolution (183)
III	Selectively remove disadvantageous major-driver functions	Remove growth-suppressing side effects of driver mutations	Renal cancers acquiring inactivating <i>HIF1A</i> mutations consistent with selection for removal of that specific consequence of <i>VHL</i> mutation (184)
		Remove a major-driver function that has become disadvantageous during somatic evolution	None known at this time
IV	Remove redundant or unnecessary functions	Loss of driver mutations that are no longer needed as cancers progress	Loss of <i>IDH1</i> from glioblastoma (although not in therapy-naive tumours) (185)

Type	Definition	Effect	Possible examples from sporadic human cancers(177)
		High frequency of inactivating somatic mutations in some genes with a role in differentiated cells and no plausible role in carcinogenesis	None known at this time
V	Competition or cooperation between tumour cells with minor overall effect	One cell population 'freeloading' or directly harming another	None known at this time
		Promote cooperation among tumour cells	None known at this time

Mini-drivers are predicted to mimic major driver mutations with a smaller effect; to adjust cellular impact of major drivers to optimise fitness; neutralise deleterious passenger mutations; streamline fitness by removing redundant functions; exert inhibitory effects on other clones (for example by secreting a factor the secreting clone is genetically insensitive to); communicate with non-malignant cells to adjust the microenvironment, and play other roles (**Table 1.1**).

Identification of these mutations along with a quantitative understanding of their effect sizes will be important in elucidating the somatic genetic architecture of cancer.

1.3.4 Approaches to the discovery and functional analysis of new driver and mini-driver mutations

Given the large number of rare mutations and potential mini-drivers, experimental and computational approaches are needed to aid in identifying these mutations and their effect on cancer growth. For the discovery of traditional Mut-drivers (somatic alleles of large penetrance), most analyses rely on the statistical evaluation of somatic mutation frequency per gene compared to background. As

somatic mutation frequency is not independent of genomic location, tissue type, gene length and other variables, methods such as MutSigCV have been developed to calculate somatic mutation burden corrected for independent confounders (186). Vogelstein et al. proposed a ratiometric method, termed the 20/20 rule, to identify 'Mut-driver genes' that is, cancer driver genes dysregulated through mutations (151). The method classifies oncogenes as those with >20% of mutations at recurrent positions and missense, whereas tumour suppressor genes as having >20% of their mutations inactivating. This approach identified 125 genes based on sequencing data from 3,284 tumours.

In a recent study, Kim et al subjected 474 patient-derived mutant alleles to an *in vivo* tumour formation assay in mice (187). They found that some somatic alleles, which were observed only once in a large pool of patients, and without having known oncogenic function, such as *POT1* G76V, were able to transform cells and cause tumour formation. In this way, mini drivers can be identified experimentally alongside rare major drivers.

Berger et al. took a different approach, screening 194 mutations from lung adenocarcinomas using an expression-based assay which quantified the mutant protein's effect on the transcriptome (188). Lentiviral transduction of mutant genes into lung adenocarcinoma cells followed by transcriptional profiling of 1,000 transcripts yielded transcriptional data that were used to compare the impact of each mutant with wild type and with reference driver alleles. 69% of the variants were characterised as impactful and many of those, including non-canonical mutations in known driver genes such as *KRAS* D33E, promoted tumour growth *in vivo*. Importantly, these newly identified oncogenic alleles were not always predicted to be impactful by *in silico* methods such as SIFT or PolyPhen2.

Although it is difficult to predict from this study what percentage of somatic mutations may be drivers due to the non-random selection of candidate genes, it is important in providing proof that rare somatic mutations can be drivers, irrespective of their statistical enrichment within patient cohorts.

A recently developed program called REVEALER (repeated evaluation of variables conditional entropy and redundancy) demonstrated the feasibility of systematically identifying genetic interactions between driver alterations correlated with functional phenotypes (189). As examples, application of REVEALER across 83 cell lines from the Cancer Cell Line Encyclopaedia (CCLE) found that *APC* mutations of 13q33 amplification can substitute β -catenin mutations. Analysis of 182 lung cancer cell lines from the CCLE revealed that *KEAP1* mutations and 15q22/26 amplification can act as alternative causes of *NRF2* activation. It would be interesting to see how many mutations in unclassified genes would show such correlations with major drivers across human cancers.

Another recently published tool called VIPER (virtual inference of aberrant protein activity) provides the means to estimate protein activity from transcriptional data (190). This can be useful in predicting chemosensitivity, as mutation status alone is a poor predictor of response, which limits precision oncology (191). Interestingly, the authors show that some tumours and cell lines without a mutation in a particular gene show a near-identical reduction in protein activity to samples with a driver mutation in the gene, as measured by VIPER's mutant phenotype score (MPS). This tool might be useful in analysing which rare drivers and mini-drivers substitute for canonical driver mutations – by analysing the genomic makeup of these tumours with wild-type driver genes but mutant-like

signature, it might be possible to discover sets of mutations in a related pathway. However, such application of VIPER remains to be investigated.

Multiple computational predictors of individual driver mutations exist, for example CHASM (192), FATHMM Cancer (193) and ParSNP (194). These methods score and rank somatic mutations based on their functional impact on protein function and likelihood to be involved in cancer. However, the application of their methodology in discovery of mini-drivers presents important caveats. Firstly, with the exception of ParSNP, the algorithms were trained using a set of curated driver mutations. This skews the predictions towards mutations that are most similar to currently known drivers such as *KRAS* G12D. Secondly, the benchmarking of the methods is often limited to the top 1% of candidates out of which only several mutations per tumour are discussed (top 5 in the ParSNP paper) (194). In fact, in developing ParSNP the authors specifically made use of the assumption that the proportion of mutations that are drivers decreases with mutation load. Therefore, while this approach might be successful in identifying rare drivers of large effect, mini-drivers may be less amenable to discovery by these methods because they are less impactful, by definition. Therefore, tools that are optimised for sensitivity in detecting driver mutations might overlook mini-drivers.

In summary, although encouraging progress has been made in the discovery and functional analysis of rare driver and mini-driver mutations in cancer, much more investigation is required before these mutation classes can be reliably and robustly identified. Of particular importance is the synergy between computational and experimental methods, in order to provide causal evidence of function for newly discovered mutations. Similarly, mechanistic studies focused on

individual genes will be important in characterising the landscape of effects of each mutation on gene function. Finally, cancer gene databases have to keep pace with the accelerating rate of cancer gene discovery by curating and synchronising gene lists discovered in multiple studies.

In Chapter 4.2, we discuss how mini-driver mutations can be discovered from cancer genomic data, using the ASPP gene family as an example.

1.3.5 Public databases of cancer driver genes

Thousands of genes have been implicated in the molecular and cellular processes relevant to cancer. Many of those have been shown to drive tumorigenesis in animal models, including unbiased transposon-mediated mutagenesis screens, shRNA screens in mice as well as targeted mutations and knock-in alleles, resulting in wealth of information on genes which have the potential to drive cancer in mice. However, it remains unclear which proportion of these genes drive tumorigenesis in clinically observed human tumours.

As a result, there is a clear gap between our knowledge of the functional genetics of cancer in model systems such as cell lines and mice, and the driver genomic landscape of human cancer. An important component in bridging this gap is a high-quality curated list of human cancer genes. Perhaps surprisingly, in contrast to public portals for cancer genomic data, an up-to-date comprehensive reference of this kind is still lacking. Arguably the most widely used list of cancer genes is the Sanger Cancer Gene Census (<http://cancer.sanger.ac.uk/census/>).

What are the empirical criteria for inclusion of genes in the Cancer Gene Census? In compiling the Census, Futreal et al. selected genes with 'at least two independent reports showing mutations in primary patient material', the most common alteration being chromosomal translocation at the time (195). To filter out likely passenger mutations, they excluded genes with fewer than five unambiguous mutations reported in primary neoplasms, low-penetrance cancer susceptibility genes, genes mutated primarily in mismatch repair-deficient tumours, genes located at fragile genomic sites (e.g. fragile histidine triad gene, *FHIT*) and genes altered by large copy number variants without high confidence of being the causal gene. Applying these criteria yielded 291 human genes in the first draft of the Census, many of these being recognised driver genes such as tyrosine kinases *RET* or *EGFR*.

However, application of these criteria in the era of whole-exome and whole-genome sequencing, when over 10,000 tumours have been sequenced by these techniques, would result in an order-of-magnitude higher number of genes. Because of the 'long-tails' distribution of somatic mutation frequency of most tumour types, hundreds of genes are mutated in independent samples (196, 197). This includes large genes such as *TTN* that are statistically most likely to accumulate somatic mutations by random chance due to their genomic size. Additional confounding factors such as genomic locus replication timing, GC-content, transcription-coupled repair also influence mutation rate (186). Therefore, more stringent methods are needed to increase the signal-to-noise ratio in detecting driver mutations. At the same time, as genomic studies continuously produce new evidence of causal role for genes in different cancer types, this stringency should be balanced by periodic updates of the database and the swift

inclusion of newly emerged data. Unfortunately, in the current version of the Census, little to no information is given on the source of current evidence supporting the membership of each gene.

Therefore, other platforms are being developed. One recent alternative is the DriverDBv2 (<http://driverdb.tms.cmu.edu.tw/driverdbv2/index.php>), a database collating ca. 13,000 exome-sequenced cancer cases and integrating 15 algorithms that analyse the mutation of each gene and call significantly mutated genes per study (198). The portal allows an interactive inspection and filtering of the statistical evidence for study type, for example by selecting the minimum number of algorithms that deem each gene significant. Unfortunately, the current implementation of DriverDBv2 does not allow for an easy access to driver gene lists compiled using specified criteria across all studies. These observations underscore the importance of data curation alongside high-throughput sequencing and data analysis.

As the number of sequenced cases and the quality of algorithms increase, we hope to approach saturation in the discovery of Mut-driver genes based on the over-representation of their somatic mutations. Currently, approximately 100,000 sequenced cancers are estimated to reach saturation, or 2,000 tumours for at least 50 tumour types (**Figure 1.8**) (162).

Figure 1.8 Number of tumour-normal pairs required to detect Mut-driver genes as a function of somatic mutation frequency. Reproduced from Lawrence et al (162) with permission.

Excluding mini-drivers, how many Mut-driver genes have been discovered?

The Cancer Gene Census currently (as of September 2016) holds 602 genes out of which 264 have mutational evidence other than amplifications, deletions and translocations assigned to them (i.e. putative Mut-drivers). Tamborero et al. reported a list of 291 high-confidence cancer genes from 3,205 tumours of 12 different cancer types (199). Applying a stringent false-discovery threshold, Lawrence et al. reported a list of 219 Mut-driver genes from 4,742 cancer exomes (162). An alternative analysis by Vogelstein et al. using the 20/20 rule yielded 125 Mut-drivers based on data from 3,284 tumours. From DriverDBv2 it is difficult to establish precisely because multiple algorithms are integrated with varying results and no single threshold is used. A resource named Network of Cancer Genes (<http://ncg.kcl.ac.uk/index.php>) states a considerably higher estimate of the

number of cancer genes: 1,571 in version 5.0 (200). However, this number includes genes dysregulated by amplification, translocation and other means. Taken together, current estimations of Mut-driver genes across human cancers range from 125-291 genes, and estimates of all driver genes from 602-1,571.

However, a closer inspection of the predicted sample sizes required for complete discovery of Mut-driver genes in various cancer types (**Figure 1.8**) reveals that saturation is unlikely to occur soon with rare Mut-drivers; for example in melanoma, lung squamous cell carcinoma and lung adenocarcinoma, over 10,000 tumour-normal pairs would be required to achieve 90% power for 90% genes mutated at >1% frequency. Given the existence of mini-drivers and rare Mut-driver alleles discussed above, significantly more sequencing is required before all relevant pathogenic alleles in the genetic architecture of cancer are uncovered. The need to identify these rare drivers has become a priority in cancer genomics (201). Based on this, approaches alternative to gene-level statistics of somatic mutation burden are necessary to accelerate cancer research and the discovery of cancer genes.

1.3.6 Reactivating CD8+ T cells to target diverse tumour-specific antigens

Cancer is a disease shaped by the somatic evolution of rogue cells at the expense of the host. Adaptive immunity in higher organisms is shaped by controlled somatic evolution of specialised cells that protect the host. Other tissues in the body do not undergo programmed somatic mutation or have no capability of exerting tumour-killing effects. The human repertoire of circulating $\alpha\beta$ -T cells is estimated at ca. 10^6 β chains, each pairing on average with ca. 25 different α

chains (202). Similarly, each human contains potentially up to 10^{11} unique antibody clones which can undergo further affinity maturation upon antigen stimulation (203, 204). Thus, antibodies and T cells can recognise a theoretically infinite number of antigens, including epitopes in mutant proteins expressed by cancer cells. Therefore, the interface between cancer and the immune system has an enormous potential to influence cancer progression. Given the high genetic diversity including the presence of mini-drivers, tumour heterogeneity, and the emergence of resistance to treatment observed in most advanced cancers, an exhaustive development of targeted therapies to combat each individual tumour may be beyond reach. A more realistic approach is to enlist the adaptive immune system with its vast clonal repertoire of killer T cells and antibodies to aid by selectively destroying tumour-antigen-expressing cells.

One challenge is to manipulate the immune response to cancer in a way that maximises tumour killing over undesired immunopathology. Although the field of tumour immunology dates back to the early 1900s, immuno-oncology has only reached the clinical mainstream in recent years, mainly due to the success of anti-PD1, anti-CTLA4 antibodies, frequently called immune checkpoint inhibitors, and CAR T cells. Following extraordinary results in clinical trials (205, 206), checkpoint inhibitors have transformed the clinical management of metastatic melanoma. Importantly, a subset of melanoma patients experience a durable response that leads to eradication of metastatic disease, which was unachievable with previous therapies, including BRAF inhibitors. BMS's anti-CTLA4 antibody ipilimumab became the standard of care in advanced melanoma following its FDA approval in 2011, however anti-PD1 antibodies nivolumab and pembrolizumab showed even more promising results and are now approved for melanoma as well (207, 208).

Nivolumab has gained FDA approval for advanced melanoma, advanced lung cancer, metastatic renal cell carcinoma, and most recently Hodgkin lymphoma (www.fda.gov). Merck's pembrolizumab (Keytruda) now holds FDA approval for advanced melanoma, advanced non-small cell lung cancer, and head and neck squamous cell carcinoma. In addition, clinical trials for multiple other cancer types are ongoing.

In order to realise the full potential of T cells in the fight against cancer, a deep understanding of the pathways controlling T cell proliferation, activation and dysfunction is needed. The role of PD1 in regulating the T cell response was originally discovered in the lymphocytic choriomeningitis virus (LCMV) experimental model of viral-induced immune suppression (209). PD1 is an inhibitory receptor which increases the threshold for effector CD8+ T cell activation upon binding of its ligand PD-L1. PD1 blockade enables tumour antigen-specific CD8+ T cells to elicit tumour cell killing by inhibiting PD-L1's binding to its receptor (210, 211). Effective checkpoint blockade typically relies on the presence of neoantigen-specific CD8+ T cells, and studies have indeed shown that neoantigen load correlates with checkpoint inhibitor sensitivity (212, 213). Despite the wealth of knowledge surrounding PD1 and T cell exhaustion, the precise molecular programme which induces PD1 expression and suppresses CD8+ T cell responses is not fully understood. Moreover, recent studies have shown that a durable response to PD1 blockade relies the proliferation of a subset of CD8+ CXCR5+ T cells with a distinct phenotype from exhausted terminally differentiated effector cells (214). Therefore, the molecular basis of T cell exhaustion, and the cell type dynamics of the CD8+ compartment in chronic viral infection are still incompletely understood.

Chapter 5 of this thesis explores a transcriptomic approach to assessing the viral-specific and total CD8+ T cells in chronic vs acute infection.

1.4 ASPP family

1.4.1 Discovery and members of ASPP family

The ASPP family, defined by functional and domain homology, are Apoptosis Stimulating Proteins of p53, and also Ankyrin repeat, SH3 domain and Proline-rich region-containing Proteins (**Table 1.2, Figure 1.9**) (103). The ASPP are not the only protein family characterised by this domain composition; SHANK proteins also contain multiple Ankyrin repeats, an SH3 domain, proline-rich region, in addition to PDZ and SAM domains (**Figure 1.10**) (215). Human ASPP family comprises 3 members: ASPP1, encoded by *PPP1R13B*; ASPP2, encoded by *TP53BP2*; and iASPP, encoded by *PPP1R13L* (**Table 1.2**). These names reflect the proteins' regulatory effects on apoptosis: ASPP1 and ASPP2 are activators of p53-dependent apoptosis whereas iASPP inhibits it.

Table 1.2 ASPP family members and their gene names. Alt, alternative exon.

Protein name	Human gene name	Human exon count	Human protein length	Mouse gene name	Mouse protein length
ASPP1	<i>PPP1R13B</i>	17 (+2 alt)	1090	<i>Ppp1r13b</i>	1087
ASPP2	<i>TP53BP2</i>	18 (+2 alt)	1128	<i>Trp53bp2</i>	1128
iASPP	<i>PPP1R13L</i>	13 (+1 alt)	828	<i>Ppp1r13l</i>	824

The first ASPP member to be discovered was ASPP2. In 1994, using a yeast two-hybrid assay on a B-cell cDNA library, Iwabuchi et al. identified 2 proteins binding wild type but not mutant p53; one of these proteins was named 53BP2, now understood to have been a fragment of full-length ASPP2 (216). Interestingly, 53BP2 specifically bound the DNA-binding domain of p53. This property connects ASPP2 with p53-inactivating viral proteins large T antigen from

the SV40 tumour virus, and E6 from human papilloma virus, which also specifically bind to the non-mutated DNA-binding domain of p53 (217, 218). Iwabuchi found a role for ASPP in stimulating p53-dependent transcription (219). 53BP2 was also shown to bind BCL2, although the function of this interaction is not well understood (220). These initial experiments identified fragments and isoforms of ASPP2 which are shorter than the full-length isoform comprising 18 exons, which is the dominant isoform expressed in human cells. A shorter isoform called Bbp (UCSC transcript name uc001hod) is generated from the *TP53BP2* gene by alternative splicing.

Figure 1.9 Domain maps of ASPPs. Pro, proline-rich region (conserved part); SB, SH3-binding domain; PQ, proline- and glutamine-rich region. Numbers on the right indicate protein length of the full-length isoforms.

Figure 1.10 SHANK3 domain structure and splice forms. Reproduced from Sala et al. (215) with permission.

A fragment of ASPP1 was first reported in 1998 as a cDNA isolated from the brain with high homology to 53BP2 (221). The full-length and most abundant isoform of ASPP1 in humans is 1090 residues long. ASPP1 and ASPP2 show very high homology, in particular in the C-terminus, and an identical domain structure: both proteins share a C-terminal SH3 domain, 4 ankyrin repeats, a proline-rich region, an N-terminal coiled-coil sequence, and a ubiquitin-like/RAS-association domain at the very N-terminal end (**Figure 1.9**). Samuels-Lev et al. showed that ASPP1 and ASPP2 selectively enhance p53-dependent transcription on pro-apoptotic gene promoters (*BAX*, *BBC3* and *TP53I3*) but not cell cycle arrest gene promoters (such as *CDKN1A*, encoding p21) (103). A crystal structure of ASPP2's C terminus in the complex with p53 has been solved (102).

The third ASPP member, iASPP, was first reported in 1999 as a protein inhibiting the NK- κ B transcription factor p65 (222). The full-length isoform of iASPP, 828 residues long, is homologous to ASPP1 and ASPP2 in the C-terminal SH3 domain, Ankyrin repeats, and conserved proline-rich region, but not the preceding sequence which is also proline-rich (**Figure 1.9**). In fact, proline

represents 15.7% of human iASPP's sequence (compared with the total proline content of 6.3% among 18,666 human proteins) placing iASPP in the top 1.5% of human proteins by proline content (calculated using data from Morgan et al (223)). A crystal structure of iASPP's C terminus is available (224). In contrast to ASPP1 and ASPP2, iASPP inhibits p53 function by reducing its transcriptional activity on pro-apoptotic promoters (225). Thus, iASPP is differentiated from ASPP1 and ASPP2 not only by its protein sequence, but also by its opposing effect on p53-dependent apoptosis.

1.4.2 Evolution of the ASPP family

Most vertebrate genomes contain 3 distinct ASPP genes. Single ASPP orthologues have been found in *Drosophila melanogaster* and *C. elegans*. Early studies suggested that iASPP is the ancient member of the family, with ASPP1 and ASPP2 evolving at later stages (225, 226). The *C. elegans* ASPP orthologue inhibited apoptosis in germ cells, consistent with it being an orthologue of iASPP rather than ASPP1 or ASPP2 (225, 227).

However, a recent phylogenetic analysis by Song et al. suggests the issue might be more complicated (228). Song et al. identified an ASPP-like protein in the invertebrate *Branchiostoma belcheri* and showed it to be more homologous to human ASPP1 and ASPP2 than to iASPP. Moreover, a Bayesian analysis of individual ASPP proteins across species produced 4 distinct clusters: a vertebrate ASPP1 group, ASPP2 group, iASPP group, and an invertebrate ASPP-like group which contained proteins with motifs homologous to ASPP1 and ASPP2's ubiquitin-like and coiled-coil domains. These organisms do not seem to contain

another copy of ASPP, suggesting some lower organisms contain an ASPP1/2-like orthologue rather than an iASPP orthologue. The notion that iASPP might not have been the single ancient gene is also supported by the fact that some chordates seem to possess ASPP1 and ASPP2 orthologues but no iASPP orthologues (**Figure 1.11**). In contrast, no chordates seem to possess only iASPP in the absence of ASPP1 and ASPP2. Taken together, these insights present an alternative hypothesis: the ancient ASPP gene contained the N-terminal domains of ASPP1 and ASPP2 which in some invertebrates were retained, diversified, and in others (such as *C. elegans*) were lost. Thus, the ancient ASPP might have been duplicated in an ancestor of all vertebrates to produce ASPP1 and ASPP2, and in some vertebrates including humans, further duplicated to produce iASPP through a similar mechanism that led to the evolution of ASPP in *C. elegans*. The occurrence of an iASPP-like protein in humans and *C. elegans* would thus be an example of convergent evolution, rather than a manifestation of a common ancestor. An alternative hypothesis is that all 3 ASPPs were present in a common vertebrate ancestor, but iASPP was later lost in some vertebrates, for example birds and lamprey (**Figure 1.11**). A more detailed phylogenetic analysis is required to differentiate between these hypotheses.

Figure 1.11 A phylogenetic survey of ASPP family genes. Reproduced from Song et al. (228) with permission.

Vertebrate conservation scores support the hypothesis that ASPP2 is the most ancient ASPP protein: exons coding for N-terminal sequence of ASPP2 have much higher conservation scores among vertebrates than exons coding for N-terminal sequence of iASPP (UCSC Genome Browser). Song et al. also showed that among vertebrates, *TP53BP2* has experienced a slower rate of nonsynonymous/synonymous substitutions, suggesting a faster rate of adaptation of *PPP1R13B* and *PPP1R13L*, and their orthologues. This is consistent with a hypothesis that *PPP1R13B* and *PPP1R13L* were generated by duplication of *TP53BP2* during evolution, as the newly created genes would need to undergo a faster rate of evolution in order to diversify from ASPP2’s function, especially in

tissues where *TP53BP2* is dosage sensitive. In addition, the proline-rich region conserved between all three human ASPPs is a GC-rich sequence (Pro DNA codons are CCA/T/C/G), which undergoes a higher mutation rate than GC-poor sequence. Altogether, phylogenetic and genomic evidence support a more ancient role for ASPP2 as the common ancestor of the ASPP family, and suggest that vertebrate iASPP and its invertebrate orthologues evolved through loss of ASPP2's N-terminal domains.

1.4.3 Molecular function of ASPPs

As described above, ASPPs modulate p53-dependent apoptosis. In addition, ASPP1 and ASPP2 also directly stimulate pro-apoptotic transcription by the p53-family members p63 and p73 (107). Of note, the relative effect of ASPP1 and ASPP2 on p53/p63/p73 transcription at the *BBC3 (PUMA)* gene promoter is the inverse of the relative effect on the *BAX* and *TP53/3* promoters: the relative fold enhancement by ASPP1/2 on *BAX* and *TP53/3* is p53>p63>p73, whereas the *BBC3* promoter shows p73>p63>p53 (107). The molecular basis of this trend is currently unknown. ASPPs do not affect p53 family transcription factors' activity on the promoter of cell cycle inhibitor *CDKN1A*, suggesting ASPPs play a role in deciding the cellular response to stress by promoting apoptosis at the expense of cell cycle arrest (229).

The molecular interactions of ASPPs stretch far beyond the p53 family and apoptotic regulators. The BioGRID database indexed 110, 38 and 26 unique interactors for ASPP2, ASPP1 and iASPP, respectively (v3.4 checked on 2 October 2016). These figures are also consistent with a more ancient role for ASPP2 as the most highly interconnected protein. These relatively high numbers

of interactions also reflect the domain structure of the ASPPs: Ankyrin repeats, SH3 domain and ubiquitin-like domain all mediate protein-protein interactions. To date, no catalytic, DNA-binding, lipid-binding, membrane-binding, or chaperone activity have been reported for ASPPs, suggesting their primary role is that of protein-protein interaction hubs. This is also consistent with the domain structure being most similar to SHANK proteins, which serve as protein scaffolds.

Among the best characterised functions of ASPPs is modulation of PP1 activity; indeed, *PPP1R13B* and *PPP1R13L* bear their name owing to them being regulatory subunits of PP1, a feature of many Ankyrin-repeat proteins (230). However, all 3 ASPPs regulate PP1; therefore, *TP53BP2* is sometimes called *PPP1R13A*. ASPP2 has been shown to dephosphorylate TAZ to promote TAZ-dependent gene expression, thereby antagonising LATS kinase (231). We showed that another ASPP2-PP1 substrate is YAP which binds to a poly-proline motif in ASPP2 located prior to the Ankyrin repeats (232). Both YAP- and PP1-binding to ASPP2 is required for this process, and YAP's promotion of transcriptional activity is mediated by TEAD. Thus, ASPP2's control of YAP represents modulation of one transcriptional co-factor by another.

ASPP2 has been identified as a YAP-interacting protein in multiple proteomic experiments, suggesting this ASPP2-dependent regulation of YAP is a ubiquitous phenomenon (233, 234). Indeed, Hauri et al. identify the PP1-ASPP module as a key node in the regulation of the Hippo pathway in human cells (235). YAP, in turn, regulates ASPP2 stability by competing with the ubiquitin ligase Itch for the same binding site on ASPP2 (236). YAP is a regulator of cell proliferation and epithelial adhesion, playing a key role in cell contact inhibition (237). ASPP1 also regulates PP1 and the Hippo pathway, for example by binding LATS (238).

ASPP1 has been shown to bind PP1 in the testis and brain, tissues with high ASPP1 levels (239, 240). Interestingly, ASPP2 and SHANK3 were also detected as binding partners of PP1 in the brain (240). ASPP1 and ASPP2 also regulate chromosome segregation by enhancing the PP1-dependent dephosphorylation of kinetochores in mitosis (241).

In addition to cooperating with YAP, ASPP2 regulates apicobasal polarity by binding Par3 (106, 242). These observations suggest ASPP2 stabilises epithelial cell character by maintaining cell-cell junctions through Par3 and YAP. Indeed, we have shown recently that ASPP2 inhibits epithelial-to-mesenchymal transition by repressing ZEB1 expression through β -catenin (130). The integration of cell-cell junction maintenance with regulation of apoptosis also makes ASPP2 a target for pathogens, for example the toxin CagA, injected into epithelial cells by the oncogenic bacterium *Helicobacter Pylori*. CagA has evolved to bind a specific site within the Pro-rich region of ASPP2 and helps remodel tight junctions to allow for bacterial attachment (243, 244). At the same time, CagA hijacks ASPP2 in order to carry out p53 degradation. ASPP2 is also targeted by the core protein of hepatitis C virus to inhibit p53-mediated apoptosis (245).

ASPP2 also regulates the NF- κ B pathway by binding I κ B (159). Notably, ASPP1 and ASPP2 modulate the dominant oncogene RAS by promoting RAS-dependent senescence and inhibiting autophagy (246-248). In keeping with its role as a protein-protein-interaction hub, ASPP2 has since been shown to act as a pan-RAS nanocluster scaffold which steers cells towards RAS-induced senescence (249). This nanoclustering activity of ASPP2 is conditional on the presence of the coiled-coil N-terminal domain which is absent in iASPP. In liver cells, ASPP2 seems to promote autophagy as a means to trigger apoptosis via

DRAM (250). In oxaliplatin-treated colorectal cancer cells, ASPP2 inhibits autophagy, highlighting the context-dependent nature of ASPP2's functions (251).

1.4.4 Regulation of ASPP activity

Interestingly, we showed recently that all ASPPs, and some additional Ankyrin repeat proteins such as I κ B, use an alternative nuclear import pathway we named RanGDP/Ankyrin-Repeat complex-mediated nuclear import pathway (RaDAR) (252). This pathway enables nuclear import of specific Ankyrin repeat motifs into the nucleus without the need for importins by utilising direct binding of the GTPase Ran. Given that ASPPs perform important functions both inside and outside the nucleus, this pathway is important in mediating a nucleocytoplasmic shuttling of ASPPs, for example to integrate signalling at the cell-cell junction with regulation of gene expression.

Given the multitude of ASPPs' binding partners, regulatory mechanisms are needed to make the protein available for a subset of specific interactions. The intrinsically disordered Pro-rich sequence of ASPPs mediates the availability of the C-terminal Ankyrin repeat/SH3 domain (Ank-SH3) by an autoregulatory mechanisms. In ASPP2, the conserved Pro-rich region has been shown to bind to the Ank-SH3 domain which modulates its interaction with p53 (253, 254). A similar mechanism is suspected for ASPP1 although this has not yet been demonstrated experimentally. Since the Ank-SH3 domain is required for nuclear import via Ran, and for the interaction with p53/p63/p73, the Pro \leftrightarrow Ank-SH3 intramolecular interaction must be disrupted in order for ASPP2 to bind p53/p63/p73. Godin-Heymann et al. showed that phosphorylation of Ser827 of ASPP2 is required for

its pro-apoptotic function (255). S827 is located between the Pro-rich region and ASPP2's YAP-binding site, therefore it is plausible that phosphorylation of this residue promotes the 'open form' of ASPP2 (in the absence of Pro <-> Ank-SH3 interaction) which then translocates to the nucleus. In contrast, ASPP2 S698A was able to enhance p53-*BAX* transcription more significantly than ASPP2 wild type. S698 is located within the 'PRPLS' motif at the core of the conserved Pro-rich region; this motif is conserved between all 3 ASPPs and directly interacts with Ank-SH3 in ASPP2. Therefore, it can be speculated that phosphorylation of S698 might stabilise the 'closed form' of ASPP2 (with the Pro <-> Ank-SH3 interaction in place). This hypothesis is supported by the fact that the orthologous residue in mice is phosphorylated in the brain, kidney, liver, brown fat and spleen tissues (phosphomouse.hms.harvard.edu) which are expected to require the extranuclear functions of ASPP2 such as promoting epithelial cell-cell junctions. Notably, this autoregulatory mechanism is hijacked by CagA. CagA binds the more C-terminal segment of the Pro-rich region, which turns into an α -helix upon encountering CagA, in order to hijack ASPP2's C-terminus and degrade p53 (244, 256).

Although iASPP possesses a homologous Pro-rich region, its vast unique Pro-rich N-terminal domain presents other opportunities for autoregulation and therefore iASPP seems to have evolved a distinct mechanism of self-binding that utilises SPRKA motifs in the N-terminal region (residues 84-88) and in the sequence preceding the Ankyrin repeats (residues 616-620). This peptide is interacting with Ank-SH3 of iASPP in the published crystal structure (224), binding the cleft between the Ankyrin repeats and SH3 domain. Lu et al. showed that the phosphorylation of S120 by CDK1 promotes the dissociation of the N-terminal SPRKA from the Ank-SH3 domain, enabling iASPP to inhibit p53 in the nucleus

(257). This physiological mechanism is dysregulated in some melanomas with high CDK1 activity that keep constitutive iASPP in the nucleus as a means to inactivate wild-type p53. Taken together, studies show that autoregulation via Pro-rich sequences is important for directing ASPP2 and iASPP activity, and that this mechanism is disrupted by a bacterial toxin in the gut, and by aberrant kinase activity in melanoma.

1.4.5 The roles of ASPPs *in vivo*

Given a rich repertoire of molecular functions, it is not surprising that ASPPs are indispensable *in vivo*. Homozygous deletion of *Trp53bp2* in mice results in early embryonic lethality, demonstrated in two independent mouse lines (104, 258). Homozygosity for a hypomorphic allele (exon 3 deletion; *Trp53bp2*^{Δ3/Δ3}) results in prenatal or neonatal death, and is associated with severe brain abnormalities (106). *Trp53bp2*^{Δ3/Δ3} embryos show overgrowth of neuroepithelial cells, loss of cell polarity, abnormal cytoarchitecture of ganglionic eminences, impaired interkinetic nuclear migration and other abnormalities. Ganglionic eminences are a source of a population of neurons that migrate tangentially to the cortex, including GABAergic interneurons (**Figure 1.12**) (259). Most of the GABAergic interneurons are thought to originate in these subpallial structures, migrating tangentially over great distances, in contrast to the default and shorter mode of radial migration used by excitatory neurons (260). Striatal cells, predominantly radially migrating, are also derived from the ganglionic eminences.

Trp53bp2^{Δ3/Δ3} mice that survive birth have a 100% incidence of hopping gait, and virtually all males and many females develop hydrocephalus. This demonstrates ASPP2 is indispensable for central nervous system development, and points to a possible striatal disruption in the *Trp53bp2*^{Δ3/Δ3} mice that survive birth. ASPP2 is also a haploinsufficient tumour suppressor in mice (104, 105, 159).

Figure 1.12 Migratory routes of ganglionic eminence-derived cells during mouse brain development. Reproduced from Marin and Rubinstein (259) with permission. AEP, anterior entopeduncular area; Str, striatum; LGE, lateral ganglionic eminence; MGE, medial ganglionic eminence; NCx, neocortex; SVZ, subventricular zone; VZ, ventricular zone; PCx, piriform cortex; H, hippocampus.

ASPP1-deficient mice are born at a reduced rate and show defects in the lymphatic vasculature (261). The reasons for the reduced viability of *Ppp1r13b*^{-/-} mice are unknown.

The role of iASPP in mouse development was first studied in spontaneously arising mutants. Waved 3 mice (*wa3*) showed skin and heart abnormalities, with a rapidly progressing cardiomyopathy. The mice were born with precocious open eyelids, had disorganised hair follicles and wavy hair (262). The mutation was mapped to a 14 bp deletion in *Ppp1r13l* that removes a splice donor site, resulting in loss of iASPP expression in the homozygous state. Another spontaneous

mutation, deletion of exons 9-11 of *Ppp1r13l*, was reported by Toonen et al. (263). Named waved with open eyelids 2 (*woe2*), these mice shared the open eyelids at birth phenotype, cardiac abnormalities, and wavy coat, with *wa3*. In addition, *woe2* homozygous mice showed corneal opacities and absence of the Meibomian glands. A frameshift mutation in *Ppp1r13l* is also responsible for an autosomal recessive disorder in cattle called Cardiomyopathy and woolly haircoat syndrome (CWH) (264). This mutation was also associated with cardiac and haircoat abnormalities which usually resulted in death before 12 weeks of age. In addition, CWH homozygotes showed neonatal ocular keratitis. Later, iASPP was shown to be present in cardiomyocytes' intercalated discs, interact with desmoplakin and desmin, and to regulate desmosome integrity in mice (265). Taken together, iASPP is essential for heart, hair and skin development across species. The seemingly high occurrence of spontaneous truncating mutations also suggests that the *PPP1R13L* gene may be a region of genomic instability in some species. It would be interesting to investigate whether this putative instability may be related to *PPP1R13L*'s GC-rich sequence which is linked with polyglutamine expansion diseases such as Huntington's disease and ataxias, for which many causative genes are located on chromosome arm 19q.

However, despite the unequivocal evidence of the non-redundant role of ASPPs in development, the importance of ASPP genes in human disease is unknown. In Chapters 2, 3 and 4, the role of *TP53BP2* and *PPP1R13B* mutations in human disease is investigated.

1.4.6 ASPPs in cancer

As discussed above, ASPPs enhance the pro-apoptotic function of the most prominent cancer gene, *TP53*. ASPP1 and ASPP2 also stimulate the pro-senescence and pro-apoptotic activity of the most frequently mutated proto-oncogene, *KRAS*. Together with the *in vivo* data showing spontaneous tumours in *Trp53bp2^{+/-}* mice at a significantly increased rate over wild type mice (104, 105), *TP53BP2* is a candidate cancer gene. However, *TP53BP2*'s role as a driver gene has not been demonstrated in humans, with the single exception of a statistically significant somatic mutation frequency of *TP53BP2* in a recent genomic study of pancreatic cancer (266).

Other studies were limited by small patient sizes, such as the report of a truncating mutation in *TP53BP2* in gastric cancer (267), or were performed in cell lines or model organisms. Studies in cell lines have mostly reached a consensus of a tumour suppressive function for ASPP2, usually attributed to activation of apoptosis (247, 250, 268-273). Studies with human patient samples observed mostly decreased ASPP2 levels (274-280), but occasionally increased expression, for example in endometrial cancer (281, 282).

PPP1R13B promoter is hypermethylated in acute lymphoblastic leukaemia and hepatocellular carcinoma (277, 283). ASPP1 has also been shown to suppress tumorigenesis in the haematopoietic lineage in mice by restricting the self-renewal capacity of haematopoietic stem cells (HSCs), and inducing apoptosis in DNA-damaged HSCs (284). Concomitant deletion of both *Trp53* and *Ppp1r13b* resulted in significantly more aggressive malignancies than the deletion of either gene alone (284). Interestingly, despite this evidence of ASPP1's tumour

suppressive function *in vivo*, and its role in enhancing p53-dependent apoptosis, ASPP1 was reported to limit apoptosis in human cell lines by inhibiting YAP phosphorylation by LATS1 (238). Activation of YAP by ASPP1 also lowers levels of LATS2, reducing p53's ability to induce p21 expression (285). LATS2, in turn, promotes nuclear localisation of ASPP1 under oncogenic stress, and ASPP1-dependent activation of apoptosis (286). This suggests that under steady-state conditions, ASPP1 promotes cell survival via control of the Hippo pathway, whereas under oncogenic stress, ASPP1's pro-apoptotic nuclear function is activated by LATS2. Taken together, although ASPP1 shows hallmarks of a tumour suppressor in mice and patient samples, it appears to have both pro-survival and pro-apoptotic functions at the molecular level. It is currently unknown which of these is the dominant function of ASPP1 in human cancers.

iASPP, being an inhibitor of p53, is a candidate oncoprotein. A study aimed at refining the association of the 19q13.3 chromosomal band with cancer has linked the *PPP1R13L* locus with breast cancer risk (287). A missense polymorphism in *PPP1R13L* (encoding A67T) has been linked with lung cancer in China (288), and another SNP linked with rectal cancer (289). The lung cancer association of a haplotype containing the iASPP SNP rs1970764(G) has been reproduced in another study (290). Lack of association with *PPP1R13L* SNPs and the associated haplotype have been reported for colorectal cancer (291, 292).

Increased iASPP levels have been observed in colorectal cancer (293), acute leukaemia (294), lobular breast carcinoma (295), head and neck squamous cell carcinoma (296), and cervical cancer (297, 298). Cellular studies support a role for iASPP in inhibiting apoptosis, preventing senescence, and conferring chemoresistance on cancer cell lines (299-307). In melanoma, CDK1-

phosphorylated nuclear iASPP mediates inhibition of wild-type p53 (257). Taken together, iASPP shows hallmarks of an oncogene, and has been linked with human cancer through GWAS. However, it remains unclear whether driver mutations in *PPP1R13L* exist in human cancer, and whether iASPP acts as an oncogene across all tumour types.

Chapter 4 of this thesis employs an unbiased approach to assessing the role of ASPP genes in human cancer, then explores the possible mechanisms of ASPP dysregulation in tumours.

**CHAPTER 2: ASPP1 AND ASPP2 VARIANTS IN HUMAN
CONGENITAL DISORDERS**

RESULTS AND DISCUSSION

Figures 2.1-2.39 and the associated text were part of the following publication:

A., Pretorius P., Rosenfeld J. A., Mohun T. J., Lu X. ASPP2 deficiency causes features of 1q41q42 microdeletion syndrome. *Cell Death Differ.* **2016**, 23(12):1973-1984.

The content has been reproduced in accordance with Nature Publishing Group's guidelines.

2.1 *TP53BP2* deletions are associated with brain abnormalities in 1q41q42 microdeletion syndrome

To identify the gene(s) responsible for structural brain abnormalities in 1q41q42 microdeletion syndrome, we first established the smallest region of overlap (SRO) in 1q41q42 microdeletion cases with structural brain abnormalities. To date there are 31 reported 1q41q42 microdeletion cases and 26 of them have brain MRI/CT recorded. Among the 26 cases with deletions in the 1q41q42 region for which neuroradiology reports and/or MRI scans were available, 19 were from published reports and 7 are newly identified cases (**Tables 2.1, 2.2**) (ref. 44, 98, 100, 308-314). Of these 26 cases, 19 patients showed detectable structural brain abnormalities and their SRO (chr1:223 828 382-224 034 322; hg19) contains the entire coding regions of *CAPN2* and *TP53BP2*, plus exons 1 and 2 of *CAPN8* (**Figure 2.1**) whereas in 4 of the remaining 7 cases without brain abnormalities the *TP53BP2* locus is not affected (**Figure 2.1a and 2.1b**).

CAPN2 and *CAPN8* encode Ca²⁺-dependent proteases of the calpain family (315). Mice deficient in the orthologous genes *Capn2*, *Capn8* and *Trp53bp2* have been generated previously: *Trp53bp2*-deficient mice exhibit abnormalities in the

central nervous system (106), whereas *Capn2*-deficient and *Capn8*-deficient mice show no abnormalities in the brain or nervous system (316-318). Publicly available data also show that *TP53BP2* is expressed more highly in the brain than all other examined tissues, whereas *CAPN2* is expressed at very low levels in the brain compared to other tissues, and *CAPN8* expression is restricted to the stomach (**Figure 2.2**, www.gtexportal.org, (319)). Additionally, *TP53BP2* is most highly expressed in the ventricular and subventricular zones in the human embryonic brain throughout gestation, consistent with it having a key role in embryonic brain development (**Figure 2.2**) (<http://brainspan.org>, <http://human.brain-map.org>) (320, 321). We also found no deletions of *TP53BP2* in publically available copy number data from 2 large cohorts of healthy individuals (19,584 healthy individuals (41, 322); or in an independent pediatric control group of 2,026 (ref. 323)), suggesting that *TP53BP2* deletions may be pathogenic. In contrast, 2 deletions, nsv520609 and nsv521758, spanning multiple exons of *CAPN2*, were detected in the cohort of 2,026 disease-free individuals (323). These observations suggest that *TP53BP2* is the strongest candidate for being the causative gene responsible for brain morphological abnormalities associated with 1q41q42 microdeletions.

Figure 2.1 *TP53BP2* is deleted in 1q41q42 microdeletion patients with brain abnormalities. (a) Genomic locations of 1q41q42 deletions from new and published patients. Red indicates brain morphological abnormalities were reported for the patient, green indicates absence of reported brain abnormalities. The positions of the *CAPN8*, *CAPN2*, *TP53BP2* and *FBXO28* genes are marked with black arrows; black line further marks the position of *TP53BP2*. **FBXO28* is not contained in the smallest region of overlap (SRO) of patient deletions with brain abnormalities. Panel generated using UCSC genome browser (<http://genome.ucsc.edu>), hg19 assembly. (b) The proportions of cases with and without *TP53BP2* deletion with and without brain abnormalities. (c) Focus on the SRO of patient deletions with brain morphological abnormalities. Patients with abnormal ventricles are marked purple.

Figure 2.2 Spatial expression patterns of genes in the critical region for brain abnormalities. (a) Gene expression of *CAPN8*, *CAPN2* and *TP53BP2* across human tissues. Data exported from the Genotype Tissue Expression project (GTEx). Brain regions are coloured yellow and highlighted by the red line. RPKM, reads per kilobase of transcript length per million mapped reads. (b) Regions of the prenatal human brain with the highest *TP53BP2* expression. Data mined from the Allen Human Brain Atlas, z-scores shown. **Right:** bar plot of z-scores from regions of the developing brain, combining the data from all sub-regions for each region.

2.2 Brain MRI reveals common ventricular abnormalities among patients with *TP53BP2* deletions

We compared structural brain phenotypes among 1q41q42 microdeletion patients with and without heterozygous *TP53BP2* deletions. Among the 22 *TP53BP2* deletion cases, the most frequently observed brain abnormalities, seen in 16 out of 22 patients (73%) with heterozygous *TP53BP2* deletions, were dilation of ventricles and/or ventricular dysmorphism, frequently associated with hypoplasia or agenesis of corpus callosum (**Table 2.2**). All 4 1q41q42 microdeletion patients without *TP53BP2* deletions showed normal ventricles (**Table 2.2, Figure 2.1b**). Corpus callosum defects were observed in 10/22 (45%) of *TP53BP2*-deletion patients (5 with agenesis and 5 with hypoplasia) but in none of the patients without *TP53BP2* mutations. Cerebellar hypoplasia, encephalocele, hypomyelination, plagiocephaly, holoprosencephaly and malformations of sulcation were also observed in some *TP53BP2* deletion patients at a lower frequency (**Table 2.2**).

For the identified 26 cases of 1q41q42 microdeletion patients, only 14 brain MRI scans were available to us and 12 of them had morphometry-compatible MRI scans (9 with *TP53BP2* deletion and 3 without) (**Figure 2.3a**). We used probabilistic morphometry to quantify the lateral ventricle (LV) volume of the 12 1q41q42 microdeletion patients (**Figure 2.3b**). 28 normal children's brain MRIs from the NIH Paediatric MRI Data Depository were used as controls (**Figure 2.3b**). As expected, LV volume was significantly larger in the *TP53BP2* deletion group (mean 33.4 ml) (**Figure 2.3b**) compared to control group (mean 10.0 ml, SD = 4.5 ml) ($p < 0.001$) and the LV volumes of microdeletion patients without *TP53BP2* deletions were within normal range (**Figure 2.3b**).

We observed defects in the ventricles of cases with *TP53BP2* deletions but not in microdeletion cases without *TP53BP2* deletions. For example, in 4 cases with *TP53BP2* deletions the bodies of the lateral ventricles appeared more parallel due to hypoplasia of the corpus callosum (**Figure 2.3c**, Supplementary Table 2: patients Case 4; Shaffer 3; Rosenfeld 8; Rosenfeld 13). This is similar but more subtle than the ventricular dysmorphism seen in association with agenesis of corpus callosum. In 3 cases the LVs were asymmetric with one side larger than the other (**Figure 2.3c**: patients Shaffer 3; Rosenfeld 12 and Wat et al 2011). These data show that *TP53BP2* deletions are associated with ventricular abnormalities that are frequently accompanied by hypoplasia of corpus callosum and/or cerebellum.

months. For statistical comparison of LV volumes in patient groups, values were first tested for normality by the D'Agostino and Pearson omnibus test, then compared to NIH controls using two-tailed student's t-test and corrected for multiple hypothesis testing by multiplying the p-value by the number of tests. Mean \pm s. d. shown. (c) Axial and sagittal MRI images of brains of 1q41q42 microdeletion patients. T1 non-contrast images are shown, except for cases where only T2 scans were available (Rosenfeld Subject 14, Spreiz et al, 2014 and Case 7). Double white arrowheads: hypoplasia of corpus callosum; single white arrowheads: asymmetry in lateral ventricle size; yellow asterisk: mega cisterna magna.

Table 2.2 **Neuroradiological description of patient's brain MRI scans.**

Patient	DECIPHER number	TP53BP2 deleted?	Brain MRI description
Case 1	263059	deleted	Ventricles are obviously dysmorphic with absent corpus callosum. There is a monoventricle, thalamic fusion and holoprosencephaly with a grey matter bridge extending from the frontal lobe towards the occiput. Posteriorly there is some midline differentiation into 2 occipital lobes; microcephaly
Case 2	279742	deleted	N/A
Case 3	257458	deleted	N/A
Case 4	271297	deleted	Lateral ventricles more parallel appearance at their superior aspect; relatively hypoplastic corpus callosum
Case 5	266948	deleted	Generalised cerebral atrophy, especially over the frontotemporal region with large ventricles, thin corpus callosum
Case 6	257256	deleted	Occipital encephalocele
Case 7	-	deleted	Agenesis of corpus callosum, prominent midline interhemispheric fluid, minor cerebellar hypoplasia
Jun 2013	-	not del.	Normal
Au 2014	-	not del.	Normal
Rosenfeld 10	-	not del.	Normal
Rosenfeld 11	-	not del.	N/A
Rosenfeld 14	-	not del.	Normal
Shaffer 1	-	deleted	Normal
Shaffer 2	-	deleted	Mild prominence of lateral ventricles (2y); The ventricular system is top-normal in size, shape and configuration (9y)
Shaffer 3	-	deleted	1992: nonspecific increase in ventricular size; 2006: lateral ventricles somewhat prominent for age; restricted diffusion identified to suggest acute ischemia. Dysmorphic lateral ventricles with left LV being slightly larger than right; The trigones and posterior parts of the bodies of both lateral ventricles are more parallel than usual and slightly more bulbous, this appearance resembles minor colpocephaly which is a configuration associated with agenesis of the corpus callosum. The more lateral aspects of the posterior part of the body of the corpus callosum may be somewhat hypoplastic, leading to the observed ventricular dysmorphism.
Shaffer 4	-	deleted	Malformation of lateral ventricles, pointed frontal horns, fourth ventricle larger than normal; small cerebellum (CT), gyral malformations; malformations of sulcation, particularly around central sulcus
Shaffer 5	-	deleted	Normal
Shaffer 6	-	deleted	Enlarged ventricles prenatally
Shaffer 7	-	deleted	N/A
Rosenfeld 8	-	deleted	Dysmorphism of lateral ventricles, hypoplastic corpus callosum; retrocerebellar and prepontine arachnoid cysts; displacement of the pons away from the clivus by CSF material, mild cortical atrophy, prominent peripapillary atrophy, mega cisterna magna
Rosenfeld 9	-	deleted	Prominent subarachnoid space; Inferior right parietal lobe punctuate focus of abnormal susceptibility; slightly hypoplastic corpus callosum
Rosenfeld 12	-	deleted	Mild thinning of the periventricular white matter, ventricle size mildly prominent; Delayed myelination
Rosenfeld 13	-	deleted	Wide cisterna magna; mild cerebellar atrophy or hypoplasia; dysmorphic appearance of lateral ventricles with a relatively parallel configuration and slight effacement of the supra and lateral aspects of the bodies of the lateral ventricles; somewhat hypoplastic brainstem
Rice	-	deleted	Hypomyelination
Mazzeu 1	-	deleted	Left brain hemiatrophy with cortical dysplasia, possible microgyria at right
Mazzeu 2	-	deleted	Agenesis of corpus callosum, delayed myelination
Slavotinek	-	deleted	N/A
Filges 2010	-	deleted	Agenesis of corpus callosum, colpocephaly
Spreiz 2014	-	deleted	Normal; common incidental anatomical variant of the ventricles in the form a cavum septum pellucidum.
Christensen 2012	-	deleted	Agenesis of corpus callosum, somewhat small cerebellar vermis
Wat 2011	-	deleted	Severe asymmetrical cerebral atrophy with <i>ex vacuo</i> dilation of the lateral ventricle

Figure 2.4 Location of chromosomal deletions and duplications of newly described patients. Genomic location of copy number change in patient DNA ascertained by chromosomal microarray. Position of *TP53BP2* is shown with a black arrow. The data are shown are for the following:

- i. Case 1 (DECIPHER 263059) – location of deleted region indicated by a yellow line.
- ii. Case 2 (DECIPHER 279742) – location of deleted region indicated by probes outside of the marked diploid region.
- iii. Case 3 (DECIPHER 257458) – location of deleted region indicated by a yellow line.
- iv. Case 4 (DECIPHER 271297) - location of deleted region indicated by red shading.
- v. Case 5 (DECIPHER 266948) – location of deleted region indicated by probe positions (red markers unmatched by blue markers).
- vi. Case 6 (DECIPHER 257256) - location of deleted region indicated by orange shading.
- vii. Case 7 - location of deleted region indicated by probe positions outside the diploidy interval delimited by two lines.

2.3 ASPP2 deficiency in mice causes CNS abnormalities with similar features to 1q41q42 microdeletion patients

We used mice with deletion of *Trp53bp2* exon 3 (*Trp53bp2*^{Δ3}) to examine how ASPP2 deficiency affects CNS development. We showed previously that the *Trp53bp2*^{Δ3/Δ3} genotype results in severe developmental defects in a strongly background-dependent manner: BALB/c *Trp53bp2*^{Δ3/Δ3} mice are born at the expected rate but most develop severe hydrocephalus before weaning, whereas only 30% of mixed C57BL/6-129Sv background (further referred to as 'mixed') *Trp53bp2*^{Δ3/Δ3} mice survive post-natally (106). On a pure C57BL/6 (referred to as B6) background, which we established by back-crossing over 10 generations, no homozygous *Trp53bp2*^{Δ3/Δ3} mice survived after birth. The surviving BALB/c *Trp53bp2*^{Δ3/Δ3} mice have a 100% incidence of hop gait. Most severe cases of neonatal hydrocephalus develop prior to birth and likely result from early defects in brain development.

To provide direct evidence that ASPP2 deficiency causes structural abnormalities in mouse embryonic brain, we used micro-computed tomography (microCT) and high-resolution episcopic microscopy (HREM) to examine *Trp53bp2*^{Δ3/Δ3} embryos. These methods allow reconstruction of 3-dimensional images as well as individual sections, showing the morphology of anatomical defects (324). At embryonic stages E13.5 and E14.5, ~50% of *Trp53bp2*^{Δ3/Δ3} BALB/c embryos exhibited enlargement of brain ventricles (**Figure 2.5a**). Subcranial and intraventricular haemorrhage were also visible by naked eye and micro-CT in 50% of *Trp53bp2*^{Δ3/Δ3} BALB/c embryos (**Figure 2.5a, Figure 2.6a, b**). Brains of virtually all *Trp53bp2*^{Δ3/Δ3} embryos examined by HREM had absent or

severely hypoplastic pineal gland (**Figure 2.5b**). The spinal canal of all *Trp53bp2*^{Δ3/Δ3} embryos was abnormal with stenosis (**Figure 2.6c**), the presence of blood or small cyst-like structures in the caudal part of the neural tube. All *Trp53bp2*^{Δ3/Δ3} embryos examined had abnormalities in the cerebrospinal fluid space with blockage and/or haemorrhage in at least one part of the ventricular system and/or spinal canal. Heterozygous (*Trp53bp2*^{Δ3/+}) embryos showed CNS abnormalities, such as spinal canal stenosis or asymmetric lateral ventricles, but with lower penetrance (**Figure 2.5d**). 25% of BALB/c *Trp53bp2*^{Δ3/+} embryos showed localised abnormalities in the distribution of neuroepithelial brain tissue associated with small patches of subcranial haemorrhage (**Figure 2.5d**) This shows that ASPP2 is required for early stages of CNS development. Interestingly, surface rendering of lateral ventricles of *Trp53bp2*^{Δ3/Δ3} embryos showed a similar shape to the dysmorphism observed in patients with *TP53BP2* deletion, with bodies of the lateral ventricles being more parallel and bulbous (**Figure 2.5c**). This suggests that ASPP2 deficiency in the *Trp53bp2*^{Δ3/Δ3} mice might mimic effects of ASPP2 deficiency in humans resulting from the heterozygous deletion of *TP53BP2*.

Figure 2.5 *Trp53bp2*^{Δ3/Δ3} and *Trp53bp2*^{Δ3/+} mice have CNS defects. (a) Gross dilation of lateral ventricles is visible in *Trp53bp2*^{Δ3/Δ3} embryos, resulting in bulging foreheads. Intraventricular haemorrhage is frequently seen (white arrows). (b) Present and absent pineal gland (red arrows) in wild type and *Trp53bp2*^{Δ3/Δ3} embryos, respectively as seen in a single HREM section. (c) Surface rendering of lateral ventricles in 1q41q42 microdeletion patients (left, constructed from MRI scans) and *Trp53bp2*^{Δ3/Δ3} vs wild-type embryos (right, constructed from microCT scans). (d) Brain abnormalities in heterozygous *Trp53bp2*^{Δ3/+} embryos. Left: Asymmetry of lateral ventricles in heterozygous *Trp53bp2*^{Δ3/+} embryo caused by a structural abnormality (red arrow). MicroCT image shown. Right:

asymmetry in neuroepithelial tissue distribution in the brain (red arrow) and the associated subcranial haemorrhage (white and red arrows) in a BALB/c *Trp53bp2*^{Δ3/+} embryo.

Figure 2.6 Details on CNS phenotypes of *Trp53bp2*^{Δ3/Δ3} embryos. (a) Exencephaly in E14.5 *Trp53bp2*^{Δ3/Δ3} BALB/c embryo: lateral ventricular zone tissue protrudes outside the head, axial (top) and sagittal (bottom) views. MicroCT images shown. (b) Gross opening of the neural tube as seen in E14.5 *Trp53bp2*^{Δ3/Δ3} embryo with spina bifida (black arrow). MicroCT images shown. (c) Gender genotyping of *Trp53bp2*^{Δ3/Δ3} embryos with NTD phenotype. Embryos positive for *ZFY* are male.

2.4 ASPP2 deficiency causes neural tube defects in mice

ASPP2 was reported previously to control the cell polarity and cell proliferation of neural epithelial cells (106). These are two important biological processes involved in neural tube closure, an early event in CNS development the disruption of which causes NTDs. To further investigate the effect of genetic

background on phenotype severity in ASPP2-deficient mice, we compared *Trp53bp2*^{Δ3/Δ3} embryos in mixed, B6 and BALB/c backgrounds. NTDs were detected in 15% (n=127) of embryos on the mixed background, 46% (n=13) on the pure B6 background and 8% (n=12) on the BALB/c background (**Figure 2.7, Table 2.3**). The only NTD observed in BALB/c embryos was exencephaly (**Figure 2.7, 2.6a**). On the mixed background, NTDs were small at the early stages (E9.5-E10.5) but progressed to larger lesions at >E13.5, and featured mainly exencephaly and rostral spina bifida (**Figure 2.7**) but rarely craniorachischisis (**Figure 2.7-middle panel**). In contrast, NTDs in *Trp53bp2*^{Δ3/Δ3} B6 embryos have a broad spectrum of phenotypes, ranging from spina bifida to craniorachischisis with some spina bifida phenotypes affecting a large section of the neural tube (**Figure 2.7, 2.6b**). MicroCT and HREM inspection of *Trp53bp2*^{Δ3/Δ3} embryos with NTDs revealed occasional overgrowth of neural tissue (**Figure 2.6a**). The spinal column of the neural tube was often wrinkled, even in embryos without NTDs.

Given the association of *TP53BP2* deletions with brain structural abnormalities, we wondered whether *TP53BP2* deletions might also be associated with NTDs in humans. We compared the genomic location of human genes orthologous to genes which have been implicated in NTDs in mice with chromosomal bands reported by Tyshchenko et al. (96) as associated with NTDs in humans. Interestingly, *TP53BP2* is one of only 16 human genes that lie in these significantly associated bands (**Figure 2.8**). Deletions of the 1q41-q44 locus encompassing *TP53BP2* are significantly associated with posterior encephalocele, generally considered a NTD (96, 325, 326). This suggests that *TP53BP2* deficiency might also play a role in a subset of human NTDs.

Notably, we found no bias towards females in *Trp53bp2*^{Δ3/Δ3} embryos presenting NTDs, whereas NTDs in p53-null mice occur preferentially in females (**Figure 2.6c**) (ref. 131). This suggests ASPP2 contributes to NTDs via a p53-independent mechanism. In summary, these results demonstrate that 100% of *Trp53bp2*^{Δ3/Δ3} mice have CNS defects but their phenotypic characteristics vary substantially with the genetic background.

Figure 2.7. *Trp53bp2*^{Δ3/Δ3} mice have neural tube defects. Strain dependence of NTD penetrance in *Trp53bp2*^{Δ3/Δ3} mice: Embryo phenotypes in pure C57BL/6 (left), mixed 129Sv - C57BL/6 (middle), and BALB/c (right) background embryos range in severity from small exencephaly (right, white arrow) to severe craniorachischisis (left upper panel, white arrows). Spina bifida is also observed in the mixed (middle panels, white arrows) and B6 (left lower panel, white arrow) backgrounds.

Table 2.3. Genotype and NTD frequencies of mice derived from *Trp53bp2* heterozygous matings in mixed 129Sv-C57BL/6 ('mixed') and pure C57BL/6 ('B6') backgrounds. +/+ denotes *Trp53bp2*^{+/+}, Δ3/+ denotes *Trp53bp2*^{Δ3/+}, Δ3/Δ3 denotes *Trp53bp2*^{Δ3/Δ3}. Distribution of +/+, +/Δ3 and Δ3/Δ3 genotypes does not differ significantly from a 1:2:1 ratio among embryos ($\chi^2 = 1.78$, $p > 0.05$, Chi-squared test), whereas there is a significant deviation from this ratio among postnatal mice ($\chi^2 = 198.9$, $p < 0.001$, Chi-squared test).

^aPercentage of *Trp53bp2*^{Δ3/Δ3} embryos amongst all genotypes.

^bPercentage of NTDs amongst *Trp53bp2*^{Δ3/Δ3} embryos only.

Figure 2.8 Few genes that cause NTDs in mice lie in regions whose deletion is associated with human NTDs. (a) Positions of genes in the human genome that are orthologous to genes that cause NTDs when mutated in mice. Each gene is indicated as a black line; coloured dots mark the associated NTD phenotype in mice. Cytogenetic chromosomal bands are marked in grey and white; regions with heterochromatin in light blue. The location of bands the deletion of which is associated with NTDs in humans marked with red lines and labelled. (b) Focus on the 1q4 region, which is significantly

associated with NTDs in humans. Genes are marked that cause NTDs when deleted in mice.

2.5 Non-CNS phenotypes overlap between *Trp53bp2*^{Δ3/Δ3} embryos and 1q41q42 microdeletion syndrome patients

Visual inspection of *Trp53bp2*^{Δ3/Δ3} embryos also revealed craniofacial and eye abnormalities (**Figure 2.9a, b**). We reported previously that ASPP2-deficient embryos have highly penetrant retinal abnormalities (106). Some B6 *Trp53bp2*^{Δ3/Δ3} embryos lacked one or both eyes (**Figure 2.9a**) while others showed coloboma (incomplete eye tissue) or microphthalmia (abnormally small eye(s)) (**Figure 2.9b**).

We used microCT and HREM to examine *Trp53bp2*^{Δ3/Δ3} embryos comprehensively for developmental abnormalities. At E13.5 and E14.5, 67-100% of B6 and 33-56% of BALB/c *Trp53bp2*^{Δ3/Δ3} embryos had abnormal heart position involving a 30-45° twist along the coronal axis (**Figure 2.9c**) and 67% B6 and 33% BALB/c of *Trp53bp2*^{Δ3/Δ3} embryos had ventricular septal defect (VSD, **Figure 2.9d**). Heart function and chamber volumes of adult BALB/c *Trp53bp2*^{Δ3/Δ3} mice were normal (**Figure 2.10a**). *Trp53bp2*^{Δ3/Δ3} embryos in B6 and mixed backgrounds showed various craniofacial abnormalities including dolichocephaly (an elongation of the head), micrognathia (smaller lower jaw) (**Figure 2.9a, Figure 2.11**) and cleft palate (**Figure 2.9e**). A high percentage of embryos also showed gonadal abnormalities resulting in unclear gender at E14.5 (**Figure 2.9f**), urethral abnormalities (**Figure 2.9g**), abnormal trigeminal nerve and spinal ganglia (**Figure 2.10b**) and multiple other defects of varying penetrance (Figure 6). Notably, 33% of BALB/c *Trp53bp2*^{Δ3/Δ3} embryos lacked a visible abducens nerve.

Embryos with heterozygous deletion of exon 3 (*Trp53bp2*^{Δ3/+}) examined by microCT had 30% incidence of cleft palate in the B6 background, and 30% and 13%

incidence of VSD in B6 and BALB/c backgrounds, respectively. Recently, the International Mouse Phenotyping Consortium (IMPC, www.mousephenotype.org) – who are performing broad phenotyping for 20 000 mouse genes (3 154, to date) - released phenotypic data on mice with a *Trp53bp2*-exon4-deletion genotype, termed *Trp53bp2*^{tm1b(EUCOMM)Hmgu} (327). Our analysis of this publicly available data showed that the homozygous deletion of *Trp53bp2* exon 4 (*Trp53bp2*^{Δ4/Δ4}) is lethal, with 100% penetrance prior to embryonic day 9 (**Figure 2.12a**). *Trp53bp2*^{Δ4/+} mice were viable and males showed a significant hyperactive phenotype in the open field test (**Figure 2.12b**). The *Trp53bp2*^{Δ4/+} males showed no difference in the percentage of time spent in the centre of the open field, indicating the phenotype is highly specific to locomotor activation (**Figure 2.12b**). Of note, these mice also showed lower grip strength normalized by body weight, short tibia, higher bone density and an abnormal glucose response (**Figure 2.12c-e**). These data from the heterozygotes demonstrate that ASPP2 is haploinsufficient in mouse development.

There is substantial overlap in the phenotypic spectrum – including brain, neurological, craniofacial, eye, heart and urogenital defects - of ASPP2-deficient mice and patients with deletions involving 1q41q42. 50% of patients with *TP53BP2*-deletion had cleft palate, which was observed in 33% and 67% of BALB/c and B6 *Trp53bp2*^{Δ3/Δ3} embryos, respectively. Heart abnormalities, including VSD, were reported for 31% patients with *TP53BP2*-deletion, and 30% B6 *Trp53bp2*^{Δ3/+} embryos had VSD. 1q41q42 microdeletion patients also frequently present with hypotonia and hypoglycemia with hypoglycemic seizures, representing phenotypic overlap with the reduced grip strength and abnormalities in glucose response in *Trp53bp2*^{Δ4/+} mice (see above). Overall, the relative penetrance of defects in *Trp53bp2*^{Δ3/Δ3} embryos also broadly corresponds to the frequency of their

occurrence in 1q41q42 deletion patients: virtually all diagnosed cases with 1q41q42 deletions have intellectual disability and/or brain structural abnormalities and there is high penetrance of CNS abnormalities in *Trp53bp2*^{Δ3/Δ3} mice, with lower proportions of 1q41q42 deletion patients and *Trp53bp2*^{Δ3/Δ3} mice having the other phenotypes. These results suggest that *TP53BP2* haploinsufficiency might be implicated in additional abnormalities associated with the 1q41q42 microdeletion syndrome and 1q41q42 deletions more generally.

Figure 2.9 ASPP2-deficient mice have non-CNS phenotypes. (a) Craniofacial abnormalities in *Trp53bp2*^{Δ3/Δ3} E14.5 embryos include dolichocephaly and hypoplasia or agenesis of the lower jaw (white arrows) (b) Eye abnormalities observed in *Trp53bp2*^{Δ3/Δ3} mice feature coloboma (top, missing tissue indicated by red arrow) and microphthalmia (bottom) in E14.5 embryos. (c) Abnormal heart position is seen in all B6 embryos examined. The microCT-based 3D reconstruction shows the heart is twisted approximately 45 degrees along the coronal axis (top panel), sometimes resulting in an altered direction of the ductus arteriosus with respect to the aorta (axial view, white arrow). Colour coding: yellow – right ventricle; pink – left ventricle; blue trachea; red – aorta; light green – ductus arteriosus. (d) Ventricular septal defect in *Trp53bp2*^{Δ3/Δ3} E14.5 embryonic heart (red arrow); shown on a representative HREM section. (e) Palate (red arrows) showing cleft palate in *Trp53bp2*^{Δ3/Δ3} E14.5 embryo. (f) Largest-area HREM section of gonads (red arrows) showing abnormalities and unclear gender in a *Trp53bp2*^{Δ3/Δ3} E14.5 embryo vs male E14.5 wild-type embryo. (g) Single vs double ureter (red arrows) in wild type vs *Trp53bp2*^{Δ3/Δ3} E14.5 embryos, respectively as visible by HREM.

Figure 2.11 Summary of phenotypes in *Trp53bp2*^{Δ3/Δ3} and *Trp53bp2*^{Δ3/+} embryos

Abnormalities detected by naked eye (visual inspection), microCT and HREM in E13.4 and E14.5 ASPP2-deficient embryos. Frequency and the number of embryos evaluated for each phenotype are given. Wild-type littermate embryos were used as reference controls. In the case of BALB/c embryos, eye abnormalities were difficult to determine visually and therefore quantified for a small number of embryos.

Figure 2.12 Abnormalities shown by adult *Trp53bp2^{Δ4/+}* mice. (a) Birth rates of wild type, *Trp53bp2^{Δ4/+}* and *Trp53bp2^{Δ4/Δ4}* mice and embryos in heterozygous-heterozygous matings. (b) Results from the Open field test performed on *Trp53bp2^{Δ4/+}* mice (denoted *Trp53bp2^{+/-}*) vs wild type controls (*Trp53bp2^{+/+}*): distance travelled in the peripheral part of the arena (left), average speed in the periphery (centre) and % time spent in the centre of the arena. P values were obtained by IMPC's Mixed Model framework, linear-mixed effects model. N. s., not significant. (c) Forelimb and hindlimb grip strength normalised by body weight for *Trp53bp2^{Δ4/+}* mice (denoted *Trp53bp2^{+/-}*) vs wild type controls (*Trp53bp2^{+/+}*). P values were obtained by IMPC's Mixed Model framework, linear-mixed effects model. *, $p < 0.05$. (d) Tibia length (left panel) and bone density (right panel) as determined by X-ray and Dual Energy X-ray Absorptiometry, respectively, in *Trp53bp2^{Δ4/+}* mice (denoted *Trp53bp2^{+/-}*) vs wild type controls (*Trp53bp2^{+/+}*). P values were obtained by IMPC's Mixed Model framework, linear-mixed effects model. *, $p < 0.05$; **, $p < 0.01$; n. s., not significant. (e) Glucose tolerance

measured by the Intraperitoneal glucose tolerance test in *Trp53bp2*^{Δ4/+} mice (denoted *Trp53bp2*^{+/-}) vs wild type controls (*Trp53bp2*^{+/+}). P values were obtained by IMPC's Mixed Model framework, linear-mixed effects model; **, p < 0.01; ***, p < 0.001; ****, p < 0.0001.

2.6 *TP53BP2* duplications associated with developmental abnormalities have breakpoints overlapping the deletion SRO

Recently, an ExAC study estimated the sensitivity of protein-coding genes to copy number variation based on a linear-regression model of expected CNV frequencies. No high-confidence *TP53BP2* duplications were observed across the 59,898 human exomes examined, which resulted in *TP53BP2* ranking within the top 1% of protein-coding genes based on the likelihood of duplication-sensitivity (z-score = 1.66) (52). Interestingly, this was higher than *TP53BP2*'s and *FBXO28*'s estimated sensitivity to deletions (z = 0.50 and 0.47, respectively), despite the fact that *FBXO28* was called as likely haploinsufficient by ExAC based on its SNV profile. We therefore asked whether *TP53BP2* duplications could be pathogenic.

Table 2.4 CNV frequencies of ASPP genes in selected studies.

Study	No. deletions (patients)	No. deletions in controls	No. duplications (patients)	No. duplications (controls)
Coe 2014: <i>PPP1R13B</i>	9 (n=29085)	5 (n=19584)	7 (n=29085)	9 (n=19584)

ALS Wain 2009: <i>PPP1R13B</i>	7 (n=575)	0 (n=621)	0	0

Large studies focused on CNVs in various developmental diseases found no *TP53BP2* deletions among controls but found multiple deletions in patients (**Table 2.4**). Interestingly, *TP53BP2* duplications were also found exclusively in patients. This supports the notion that *TP53BP2* is sensitive to both copy number gain and loss in human development.

A DECIPHER search identified several cases with small interstitial duplications that include some *TP53BP2* sequence, the smallest one spanning merely 256 kb (**Figure 2.13a**). This small duplication includes entire coding sequence of *TP53BP2* and *CAPN2* plus two exons of *CAPN8*. Intriguingly, the duplication breakpoints are in the close vicinity of the smallest region of overlap of 1q41q42 deletion patients with brain structural abnormalities (**Figure 2.13c**).

Figure 2.13 Genomic locations of 1q41q42 microduplications in new patient cases. (a) Snapshot of probe-level aCGH data depicting the 255-kb duplicated region in DECIPHER258598. The entire coding sequence of *CAPN2* and *TP53BP2* is included, along with a fragment of *CAPN8* (region highlighted by violet shading). (b) Genomic locations of three cases with <2 Mb duplications involving *TP53BP2*. The distal breakpoint of duplication detected in DECIPHER267784 ends within the coding sequence of *TP53BP2* suggesting the gene might be truncated by the duplication. (c) Comparison of the regions of overlap of duplications (blue) vs deletions (red) with brain abnormalities. Both regions of overlap spans the same 3 genes as shown in the RefSeq track. Images exported from UCSC Genome Browser, hg19 build.

We examined the patient in collaboration with Prof. Charlotte Brasch-Andersen (University of Odense, Denmark). The patient (DECIPHER 258598) is a female with a history of status epilepticus. EEG showed paroxysmal changes in the left temporo-occipital region and right occipital region. She has dysmorphic features, microcephaly (head circumference 2 s. d. below mean), vision

abnormalities and delayed psychomotor development. Initial report of the brain MRI scan at 11 months noted the high-normal depth of 0.6 cm subarachnoid space around the frontal lobes, suggesting frontal atrophy which may be related to the microcephaly. The 95th percentile upper bound in healthy infants was proposed as 0.4 cm for craniocortical width (CCW) (328). However, a later ultrasonographic study estimated a higher 95th percentile value of ca. 8 mm for CCW 11 months (329).

Reassessment of the brain scan revealed a slightly unusual configuration of the bodies of the lateral ventricles in the form of effacement of the supero-lateral aspect of the ventricular lumens, limited to the bodies of the lateral ventricles (**Figure 2.14** – coronal scan, red arrowheads). This abnormality is likely congenital. Ventricular volume analysed by ALVIN was not significantly increased compared to age-matched controls.

Figure 2.14 Brain MRI images of patients with triploid (top) vs diploid (bottom) *TP53BP2* in the germline. MRI of DECIPHER258598 taken at 11 months and Jun et al at 5 months of age as a normal control. White arrowheads – prominent subarachnoid space; red arrowheads – effacement of superolateral aspects of ventricular lumens.

Patient DECIPHER 267784 was examined in collaboration with Dr Kristina Aubell (Medical University of Graz). The patient is female and presented with postnatal microcephaly (at 6 years 11 months: head circumference 48.4 cm, <3rd percentile; weight 26.8 kg, 90th percentile; height 123.3 cm, 50-75th percentile). Head MRI was not performed; EEG was normal. She shows mild intellectual disability and requires special schooling.

Patient DECIPHER 288114 was unavailable for contact at the time of submission. However, a history of seizures was reported for this patient on DECIPHER.

Taken together, these data suggest that duplications in the 1q41q42 region involving *TP53BP2* (with or without truncating potential) are associated with developmental delay, neurological abnormalities and microcephaly. Given that 1q41q42 deletions associated with structural abnormalities of the brain converge on the same critical region, it is possible that *TP53BP2* and/or *CAPN2* are sensitive to both deletion and duplication. However, we cannot exclude the possibility that disruption of a regulatory element within the intergenic region that separates *TP53BP2* and *FBXO28* also plays a role. Additionally, we cannot rule out that other pathogenic variants, such as single-nucleotide variants, are responsible for the phenotype. Therefore, DNA samples collected from the patients and parents will be subjected to whole-genome sequencing in order to scan for known pathogenic SNVs including *de novo* SNVs.

2.7 Dosage sensitivity of *TP53BP2* in the ganglionic eminences and basal ganglia correlates with structural abnormalities of lateral ventricles of CNV patients

As a regulator of neural tube closure and proliferation of neuroepithelial cells, ASPP2 controls the early stages of CNS development. What role ASPP2 plays in the developed brain is unknown. We observed that *TP53BP2* is highly expressed in the cerebral nuclei in mice and humans (**Figure 2.15, Figure 2.16**).

Figure 2.15 In the adult human brain, *TP53BP2* expression dominates within the cerebral nuclei. Expression data for a Representative adult brain; data retrieved from the Allen Institute's Brain Atlas.

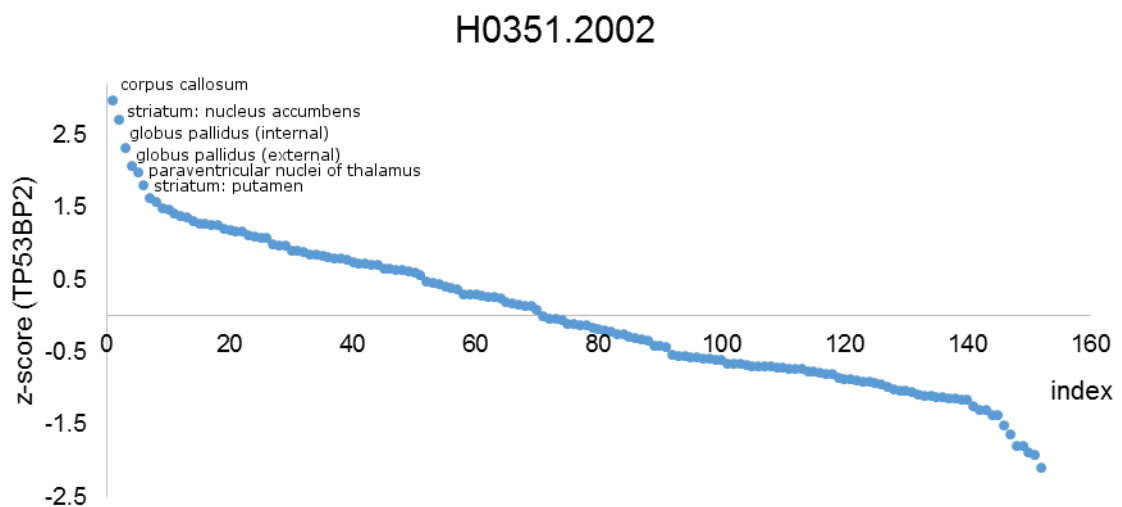

Figure 2.16 *TP53BP2* is highly expressed in the corpus callosum and basal ganglia in the developed brain. Data from donor H0351.2002; top 6 regions annotated. Data retrieved from Allen Institute's Brain Atlas.

Figure 2.17 Position of the head (left) vs body (centre and right) of the caudate nucleus with respect to the lateral ventricles. Violet surface marks the entire caudate nucleus. Dots signify tissue samples analysed by microarray; colour coding indicates mRNA z-score of *TP53BP2*, ranging from green (negative) to red (positive).

Because copy number changes affect gene expression levels, dosage sensitivity is most likely to affect areas in which *TP53BP2* levels are tightly regulated. As shown in **Figure 2.20**, globus pallidus shows very consistent and high *TP53BP2* levels. Within the basal ganglia, *TP53BP2* is most consistently expressed in the head of the caudate nucleus between individuals (**Figure 2.17**). The relative level of expression with respect to other regions (z-score) is the same for male and female brains. *TP53BP2* is still very consistently expressed within the tail of the caudate nucleus, however at lower levels than the head and body of the caudate. This spatial gradient of *TP53BP2* might play a role in regulating caudate development and/or function. Therefore, among the striatal regions, the caudate is most likely to exhibit *TP53BP2* dosage sensitivity.

Inspecting the position of the caudate nucleus with respect to the lateral ventricles (**Figure 2.17**) revealed a striking correlation with the dysmorphic regions in patients with *TP53BP2* deletions and duplications. The head of the caudate nucleus lies adjacent to the frontal horns of the lateral ventricles; this region is hypoplastic in 1q41q42 microdeletion patients who show wider frontal horns of the lateral ventricles. In contrast, patient DECIPHER258598 who carries a *TP53BP2*

duplication, showed an effacement of the superolateral aspects of the lateral ventricles, suggesting the head of the caudate nucleus might be increased in size (**Figure 2.18**). The body of the caudate nucleus runs parallel to the bodies of the lateral ventricles. *TP53BP2*-deletion patients frequently showed more parallel and bulbous bodies of the lateral ventricles (**Figure 2.18, Figure 2.3**), suggesting a hypoplastic body of the caudate nucleus might have led to the expansion of LVs *in vacuo*. Taken together, these results suggest that *TP53BP2* gene dosage controls the size of the caudate nucleus in humans, and *TP53BP2* copy number variants lead indirectly to lateral ventricle abnormalities by reducing (deletions) or increasing (duplications) the size of the caudate nucleus.

Figure 2.18 *TP53BP2* germline copy number correlates with caudate nucleus size, and lateral ventricle size and morphology in patients. Red arrowheads = anterior horns of lateral ventricles (caudate nucleus adjacent); yellow arrowheads = bodies of lateral ventricles

Figure 2.19 Opposing temporal gradients of *TP53BP2* levels in the developing and aging brain: global decrease vs increase of *TP53BP2* in the striatum.

Figure 2.20 Standard deviation vs mean *TP53BP2* expression per brain region across multiple male adult brain specimens. Regions with high *TP53BP2* expression and low s. d. labelled.

The correlation between consistent *TP53BP2* levels in the caudate nucleus with structural abnormalities associated with *TP53BP2* dosage in humans prompted us to investigate the spatiotemporal pattern of *TP53BP2* expression in the human brain (**Figure 2.19**). Interestingly, whereas *TP53BP2* levels show an overall decreasing trend in most brain regions, consistent with a strong foetal developmental role of *ASPP2*, *TP53BP2* levels increase in the striatum (which includes the caudate nucleus) during development and throughout adulthood (**Figure 2.19**-bottom panel). This opposing temporal gradient suggests *ASPP2* might play a role in controlling striatal development.

Analysing the standard deviation of *TP53BP2* levels in brain regions between different donors versus mean *TP53BP2* z-scores (**Figure 2.20**, **Figure 2.21**) revealed that in the adult brains, globus pallidus and caudate nucleus are

among the brain regions with the highest and most consistent *TP53BP2* levels (**Figure 2.20**). In the developing brain, the medial and caudal ganglionic eminences strikingly show the highest *TP53BP2* mean level and the lowest standard deviation between donors (**Figure 2.21**). These observations were validated in an independent dataset of high-resolution microarray analysis of 4 foetal brains (**Figure 2.22**, LMD microarray). Given that ganglionic eminences give rise to striatal cell types and cortical interneurons, these data suggest *ASPP2* promotes the differentiation of glial cells from the ganglionic eminence into the striatum. This model is consistent with the observation of hypoplastic caudates among *TP53BP2*-deletion patients and a hyperplastic caudate nucleus in a *TP53BP2*-triploid patient. In addition, a premature differentiation of ganglionic eminence progenitors can lead to decreased populations of other ganglionic eminence-derived cell types including cortical interneurons, the loss of which may underlie the observed microcephaly and prominent subarachnoid space in the *TP53BP2*-triploid patient (**Figure 2.18**). Consistently, defects in GABAergic interneurons have been linked with epilepsy.

Figure 2.21 *TP53BP2* is highly and consistently expressed in the medial and caudal ganglionic eminence in the developing human brains. Span of brain ages: 8 pcw – 40 years. NB: low sample numbers will influence this but the absolute expression levels not influenced, neither is the overall shape of regression line. Prominent outliers: upper (rostral) rhombic lip; cerebellum.

Figure 2.22 *TP53BP2* levels are highly regulated in the ganglionic eminences during prenatal development. Source: Human prenatal LMD microarray; 3 female brains aged 15, 21 and 21 pcw; 1 male brain aged 15 pcw. LGE-VZ, lateral ganglionic eminence – ventricular zone.

2.8 Sexually dimorphic expression of *TP53BP2* in the basal nuclei may underlie male-specific phenotypes

TP53BP2 is highly expressed in the caudate nucleus (part of striatum) in both genders, but dominates in the amygdala in females and the globus pallidus in males. This separation was very consistent across different male brains (**Figures 2.23, 2.24**). This dimorphism suggests *TP53BP2* might play a male-specific role in the globus pallidus and a female-specific role in the amygdala. Strikingly, *Trp53bp2*^{Δ4/+} male mice discussed above (official allele name *Trp53bp2*<tm1b(EUCOMM)Hmgu>) showed a significant male-specific increase in voluntary movement in the open-field test (**Figure 2.27**). They travelled at greater speeds and covered more distance than wild-type males, but no difference was observed between *Trp53bp2*^{Δ4/+} vs wild-type females. *TP53BP2* is also highly expressed in the nucleus accumbens which plays a role in encoding new motor programs. These observations suggest ASPP2 controls movement activation specifically in males and that this function might involve ASPP2 expression in the basal ganglia. It would be interesting to test whether caudate nucleus and/or globus pallidus size and function is affected in *Trp53bp2*^{Δ4/+} males.

Figure 2.23 *TP53BP2* expression is spatially dimorphic in human adult brains. The top region in males (M, blue) is globus pallidus, whereas in females (F, beige) *TP53BP2* is higher in the amygdala. Some nuclei such as caudate nucleus show very similar *TP53BP2* levels in both genders.

Figure 2.24 Sexual dimorphism of *TP53BP2* expression in the adult human cerebral nuclei. Blue dots represent data points for male brain regions; red dots for female brain regions. Source data retrieved from the Allen Institute; M, males; F, females; **, $p < 0.01$; *, $p < 0.05$; Student's two-tailed t-test.

Figure 2.25 *TP53BP2* is very consistently expressed within the caudate nucleus compared with other striatal regions. Data from Allen Institute's Human developed brain transcriptome.

Trp53bp2^{Δ3/Δ3} males die earlier and show more severe hydrocephalus phenotype than *Trp53bp2*^{Δ3/Δ3} females. In fact, virtually all the long-surviving (<3 months) adult *Trp53bp2*^{Δ3/Δ3} mice are female. This suggests *Trp53bp2* is developmentally less redundant in males and explains why heterozygous exon 4-deletion is also more penetrant in males. In addition, all *Trp53bp2*^{Δ3/Δ3} mice that survive birth show hopping gait, regardless of gender. Given the observed expression pattern of *ASPP2* in the basal ganglia, it is likely that *ASPP2* deficiency in the basal ganglia causes the hopping gait phenotype in mice.

The phenotypic and expression dimorphism has another interesting connotation. In breast cancer cells, *TP53BP2* levels are repressed by the addition of oestradiol (Broad compound database) and *TP53BP2* is strongly associated with the basal subtype of breast cancer in which it is significantly upregulated

compared with normal tissue and compared with ER⁺ breast cancers. Moreover, *TP53BP2* is induced during decidualisation in the mammalian human endometrium which occurs in a low-oestrogen phase of the menstrual cycle. *Trp53bp2* deficiency also causes gonadal abnormalities (data above) and ASPP2 protein is expressed on sperm and regulates sperm development (Zak et al., manuscript in preparation). All these suggest that *TP53BP2* is physiologically negatively regulated by oestrogen in selected tissues, which could play a role in the observed dimorphism in the brain.

Figure 2.26 *TP53BP2* shows polarity in expression in the putamen and claustrum (violet surface) vs hippocampus (brown surface). Red = $z(TP53BP2) > 0$; green = $z(TP53BP2) < 0$.

Interestingly, the lowest *TP53BP2* levels are found in the hippocampal formation which is immediately adjacent to the putamen and claustrum (**Figure 2.26**). This sets up a sharp spatial polarity of *TP53BP2* expression delineated by the contact surface between the putamen, amygdala and the hippocampal formation. In females the contact surface between the amygdala and hippocampus separates the region of highest and lowest *TP53BP2* expression in the brain. Given ASPP2's role in controlling promoter selectivity of various

transcription factors, it is possible this spatial pattern of expression reflects ASPP2's role in specification of the cerebral nuclei during development.

Figure 2.27 *Trp53bp2-Δ4/+* heterozygous mice have multiple male-specific phenotypes. Statistical tests used: panel Response amplitude – Mann-Whitney-U test; whole-arena resting time: Mann-Whitney U; Fat/body weight – Mann-Whitney-U; area under glucose – Mann-Whitney U; fat mass – Mann-Whitney U.

Potassium – Mann-Whitney U. *, $p < 0.05$

To determine the extent of sexual dimorphism in ASPP2 function in mice, we mined all datasets from IMPC's Δ exon4 line that showed a dimorphic phenotype. Numerous parameters showed a statistically significant difference in $Trp53bp2^{\Delta 4/+}$ males but not females (**Figure 2.27**). In comparison, only a handful of parameters had a female-specific phenotype; one example being blood potassium levels (**Figure 2.28**). Non-brain phenotypes of $Aspp2$ -deficient mice are also of interest. For example, $Trp53bp2^{\Delta 4/+}$ male have a significant increase in haemoglobin levels (**Figure 2.27**). A SNP within the $TP53BP2$ gene has been linked with levels of glycosylated haemoglobin ($p = 0.000683$) (330).

Figure 2.28 Circulating blood potassium levels are decreased in $Trp53bp2^{\Delta 4/+}$ females but not in males. Raw data extracted from Phenoview, data release v4.3; Mann-Whitney U test.

Taken together, these results demonstrate that caudate nucleus and lateral ventricles are sensitive to $TP53BP2$ dosage in humans and mice, and that

Trp53bp2 controls locomotor activation in male mice. The observation of specifically high expression of *TP53BP2* in the basal ganglia of adult brains suggests the gene might play a general role during CNS development and then assume a more specialized role in the basal ganglia of developed brains. It remains to be determined whether structural changes in the basal ganglia and lateral ventricles cause the observed neurological symptoms in patients with *TP53BP2* CNVs, such as seizures or intellectual disability. Due to *ASPP2*'s multiple roles in CNS development it is difficult to decouple effects caused by early events, such as neural tube closure or proliferation of early neuroepithelial cells, from later events such as development of the caudate nucleus.

The observation of higher *TP53BP2* levels in the globus pallidus of males vs females, the impact of *TP53BP2* copy number on basal ganglia size, the male-specific increase in locomotor activation upon exon4 deletion in mice, together with the 100% penetrant hopping gait in *Trp53bp2*^{Δ3/Δ3} mice demonstrate that *ASPP2* is required for the development of full motor function in mice and that the basal ganglia, especially the caudate nucleus and globus pallidus, are likely to play a role in this process. Indeed, hyperkinetic disorders such as Parkinson's disease have been connected with the impairment of striatal neurons projected to the lateral globus pallidus (331). In monkey models of Parkinson's disease, firing rates of globus pallidus external (GPe) neurons are reduced (332, 333).

These results also have potential relevance in schizophrenia. Studies have shown that schizophrenia patients smaller absolute and relative volumes of white matter in the caudate nucleus relative to healthy subjects (334). *TP53BP2* might play a role in the pathology of schizophrenia as a neighbouring SNP has been

linked with the disease in a GWAS study (rs7539624; $p = 8 \times 10^{-6}$) (335).

Interestingly, another GWAS link came in a study of MMR vaccine-related febrile seizures: the SNP rs140084787 with an odds ratio of 3.25 ($p = 6 \times 10^{-6}$) (336). Both of these SNPs lie within the introns of *CAPN2*, suggesting *CAPN2* might also be involved. This gene is also expressed in the caudate nucleus although unlike ASPP2, the *CAPN2*-deficient mice have no neurological phenotypes.

Multiple questions remain. Firstly, why are both *TP53BP2* deletions and duplications associated with microcephaly? Secondly, what are the dominant deficiencies in the brain in these CNV patients that cause the clinically relevant symptoms, and which (if any) changes are benign? Thirdly, does ASPP2 actively regulate motor functions in the basal ganglia? More mechanistic studies are necessary to answer those questions.

2.9 *PPP1R13B* shows a distinct expression profile from *TP53BP2* during development and in adults

PPP1R13B, the most homologous gene to *TP53BP2* in the human genome, encodes ASPP1. Like ASPP2, ASPP1 contains a C-terminal SH3 domain, 4 Ankyrin repeats, a proline-rich region, a coiled-coil domain and an N-terminal ubiquitin-like/RAS-association domain. In humans, the gene is most highly expressed in the thyroid, followed by testis and cerebellum (**Figure 2.29**)

Figure 2.29 mRNA levels of *PPP1R13B* across human tissues. Data retrieved from GTEX Portal v6p.

ASPP1-deficient mice are born at less than the expected rate and show abnormalities in lymphatic vasculature (261). Therefore, damaging variants in *PPP1R13B* might also play a role in human developmental diseases. At present, the relationship between genetic variation at the *PPP1R13B* locus and human disease is not known. Interestingly, according to ExAC, *PPP1R13B* is very likely to be haploinsufficient in humans ($pLI = 0.98$) due to its lower-than-expected number of truncating germline variants in the general population. However, **Table 2.4** shows that *PPP1R13B* hemizygous deletions segregate in the general population and do not seem to be enriched for NDDs, although they were significantly enriched in ALS patients (337). Therefore, more studies are needed to investigate the identity and frequency of variants resulting in loss of one *PPP1R13B* allele.

Interestingly, *PPP1R13B* shows an inverse expression with *TP53BP2* in the human brain and this dichotomy is most striking in the ventricular and subventricular zones (**Figures 2.30, 2.31, 2.32, 2.33**).

Figure 2.30 In the developing human brain, *PPP1R13B* and *TP53BP2* show significant spatiotemporal anti-co-expression. *PPP1R13B* is lowly expressed in the proliferating ventricular zone in which *TP53BP2* is most highly expressed. mRNA levels retrieved from Allen Institute's BrainSpan atlas, Developmental Transcriptome. Data pooled across top-level structures from 42 brain specimens; regions are sorted by mean *PPP1R13B* expression.

Figure 2.31 mRNA levels of *PPP1R13B* and *TP53BP2* across subregions of the human developing brain. Data taken from the BrainSpan LMD Microarray, a high-resolution of four specimens with ca. 300 distinct anatomical sites. Data from all specimens pooled by regions and subregions sorted by mean *PPP1R13B* levels.

Figure 2.32 *PPP1R13B* vs *TP53BP2* expression across selected neural cell types in the mouse. Data retrieved from Illumina’s Correlation Engine and replotted. Cell types sorted by mean *PPP1R13B* level.

Figure 2.33 *PPP1R13B* and *TP53BP2* are spatially anti-coexpressed in the adult human brain. Representative images of brain regions with highly (red) vs lowly (green) expressed mRNA of *PPP1R13B* and *TP53BP2*. Images were taken from a single specimen, dots represent sub-regions of global region shown on the left. Hemisphere (top) and right hemisphere (middle and bottom) pial surfaces shown for orientation. Image generated using Brain Explorer 2.

This striking dichotomy in spatiotemporal expression between *PPP1R13B* is driven at least partly by cell type specificity. *TP53BP2* is expressed dominantly in neural progenitors in the developing brain, and astrocytes and oligodendrocytes in the developed brain (**Figure 2.32**). In contrast, *PPP1R13B* is most highly expressed in neurons, especially sensory and cerebellar neurons.

A genome-wide spatio-temporal co-expression analysis revealed that *PPP1R13B* is co-expressed with genes significantly enriched in synaptic function (**Table 2.5, Table 2.6**). Regulators of multiple neurotransmitter receptors were represented (e.g. NMDA, GABA receptors) and the correlation was very robust ($R > 0.8$), increasing in statistical significance when more genes were added to the initial list. The enrichment for synaptic genes and genes regulating neurogenesis was observed using both data from the human Prenatal LMD Microarray and the human Developmental Transcriptome. In contrast, *TP53BP2* showed no co-expression with synaptic genes.

Table 2.5 *PPP1R13B* is spatiotemporally co-expressed with synaptic genes in the human brain. Microarrays from the Developmental transcriptome were used as input.

2.10 Missense mutations in *PPP1R13B* in human developmental diseases

De novo mutations have been implicated in NDDs including autism, schizophrenia and intellectual disability. To determine whether *PPP1R13B*

variants might play a role in these diseases, we mined published studies on *de novo* mutations in NDDs and the ClinVar database for any *PPP1R13B* mutations. Interestingly, multiple *de novo* missense mutations in *PPP1R13B* have been identified in NDDs (**Table 2.7**). Two *de novo* mutations were found in autism spectrum disorder patients: one novel intronic and one rare missense variant (G881R). One *de novo* missense mutation was found in childhood-onset schizophrenia (R72Q). No *de novo* variants in *TP53BP2* or *PPP1R13L* were found in these datasets.

Table 2.7 De novo *PPP1R13B* mutations discovered in NDD patients

Study	Disease	patient	SNV (nucleotide)	SNP ID	SNV (protein)	Inherited/de novo	ExAC AC
DeRubeis 2014 (48)	ASD	NDAR_INV PA860MY W_wes1	14:10420531 2C>T	rs373141 354	G881 R	De novo	4/120504 (all European)
Iossifov 2014 [Simons Simplex Collection] (143)	ASD	12603.p1	14:10421629 1AC>A	-	intronic	De novo	-
Ambalavanan 2016 (338)	Childhood-onset SCZ	COS2720	Chr14: 104251194G >A	-	R72Q	De novo	0/120740

A missense variant such as R72Q may have a dominant effect (poison allele) rather than just gene dosage change effects such as a deletion. *PPP1R13B* could be relatively tolerant to gene dosage but not to missense mutations in certain domains. This is consistent with the observations that *TP53BP2* controls proliferation of neural progenitors whereas *PPP1R13B* is spatio-temporally co-expressed with synaptic genes and preferentially expressed in neurons. Therefore, *TP53BP2* might be more important in controlling the early events in

CNS development and controlling the size of the NPC pool whereas *PPP1R13B* might play a role in synaptic function. Two of the *de novo* mutations are classified as Likely pathogenic based on ACMG's guidelines, with the third being of uncertain significance. Taken together, *PPP1R13B* is highly expressed in neurons, co-expressed with synaptic proteins, and disrupted by likely pathogenic *de novo* mutations in ASD and childhood-onset schizophrenia, which might disrupt ASPP1's function at the neuronal synapse.

2.11 Deleterious ASPP family variants and evolutionary constraint

Given the discrepancy between *PPP1R13B*'s pLI score and the observed frequency of *PPP1R13B* deletions in the general population, and on the other hand a low pLI score (<0.1) for *TP53BP2* whose deletions are associated with severe disease, we mined ExAC's data on the observed vs expected occurrence of LoF variants (**Table 2.8**). **Figure 2.34** depicts the pLI vs z(LoF) spectrum for all genes, z(LoF) being the z-score of observed vs expected number of LoF variants among all genes, and **Figure 2.35** shows all false negatives with curated confirmed haploinsufficiency status in ClinGen. These haploinsufficient genes include those whose deletion causes relatively mild phenotypes that impart less stringent selective pressure (e.g. *LDLR* associated with hypercholesterolemia). However, some genes in this set cause severe developmental phenotypes, such as *MEF2C*. Notably, z(LoF) of *TP53BP2* is the highest among genes with a pLI <0.2 , i.e. *TP53BP2* has a higher z(LoF) than all of the false-negatives in this analysis. This makes *TP53BP2* a likely false-negative haploinsufficient gene.

Table 2.8 Germline variants in ASPP genes detected by ExAC

Figure 2.34 Relationship between pLI and LoF z-score for genes in the non-psychiatric ExAC set. Position of ASPP genes highlighted as orange dots.

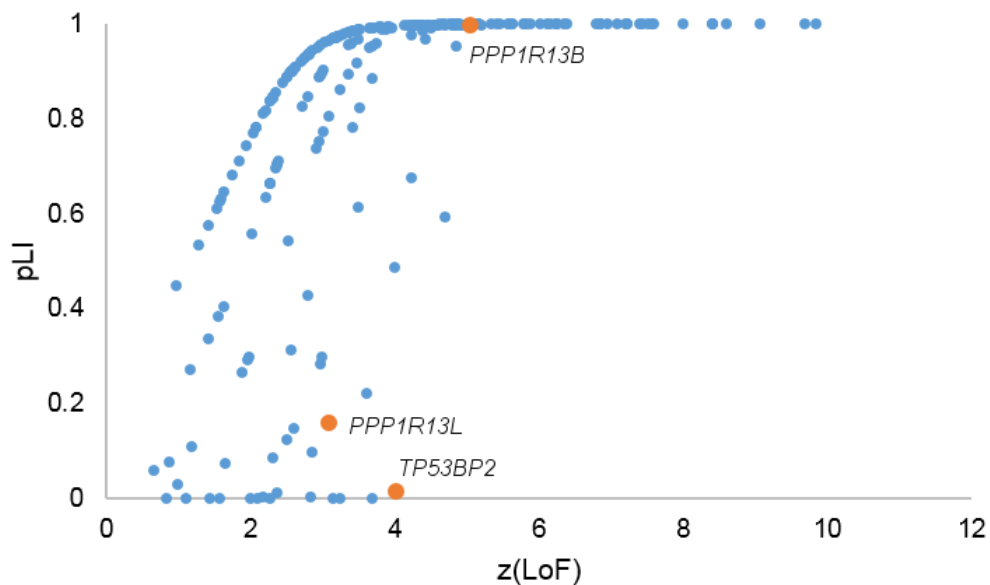

Figure 2.35 pLI vs z(LoF) for ClinGen haploinsufficient genes with sufficient evidence and the ASPP genes for comparison. Data taken from the ExAC non-psych set and ClinGen Dosage Sensitivity Map (retrieved 19/9/16). Some genes (n=7) were missing from the ExAC analysis; remaining n=242 genes plotted.

pLI is a Bayesian-derived score aimed at classifying all genes into 3 groups, and importantly, correcting for a bias in gene size whereby longer genes have higher z(LoF) scores (14). It is likely that this effort to exclude false positives

such as *TTN* produced a class of false negatives disqualified on the basis of their gene size. The ASPP family represents an interesting example of the limitations of the pLI score: whereas *TP53BP2* seems to be a haploinsufficient gene with incomplete penetrance with $pLI < 0.1$ and thus a false negative, *PPP1R13B* has deletions segregating in the general population and thus despite its very high pLI score, is unlikely to be a fully penetrant haploinsufficient genes. This observation also suggests the possibility that certain LoF SNVs might have additional toxicity beyond affecting gene dosage, for example by causing aberrant splicing. It would be interesting to see the mRNA isoform spectrum in patients carrying LoF variants versus those carrying deletions and also normal controls.

2.12 Inverse *PPP1R13B* vs *TP53BP2* expression may have evolved to avoid dosage imbalance in *TP53BP2*-dosage-sensitive tissues

Homozygous deletion of *Trp53bp2* in mice is lethal prior to E16, therefore ASPP2 performs non-redundant functions during embryonic development. In humans, truncating germline variants in *TP53BP2* are observed less frequently than expected for a recessive pattern of effect, and homozygous truncating variants have never been observed. Hemizygous deletions spanning the *TP53BP2* locus are observed at an extremely low frequency in the general population. Therefore, it is safe to assume *TP53BP2* is also non-redundant in human development. The data presented above suggests *TP53BP2* is dosage sensitive with developmental abnormalities associated with both hemizygous deletions and duplications of the gene. What properties of *TP53BP2* make this gene sensitive to dosage?

Birchler et al. demonstrated that single-gene dosage-sensitive modifiers of the white eye colour gene in *Drosophila* are enriched in transcription factors, chromatin components and signal transduction proteins (339). Tumour suppressor genes were also found to be dosage sensitive. ASPP2 is a transcription co-factor that modifies transcriptional activity of multiple TFs in a promoter-specific manner. ASPP2 also modulates signal transduction of the RAS and Hippo pathways, and the gene is a haploinsufficient tumour suppressor in mice. Therefore, *TP53BP2* belongs to a functional class of genes that is enriched in dosage sensitive genes.

Tolerance of genic CNVs in humans is also negatively correlated with the number of protein-protein interactions of the corresponding protein products, i.e. highly promiscuous proteins are unlikely to be deleted or duplicated in the general population (340). ASPP2 is a protein-protein interaction (PPI) hub that contains multiple PPI domains such as the RAS-association domain, SH3 domain or Ankyrin repeats. In fact, ASPP2 is not known to contain any catalytic, DNA-binding or lipid-binding domains, suggesting its sole role is a protein interactor. In the BioGRID database, the average number of non-redundant interactions per human gene is 13.3 whereas 110 interactions were detected for ASPP2. Therefore, ASPP2 interacts with a higher number of proteins than a protein selected at random. On this basis, CNVs containing *TP53BP2* are less likely to be tolerated than CNVs containing less promiscuous genes.

We showed above that *PPP1R13B* and *TP53BP2* are spatiotemporally anti-coexpressed in the human developing brain. The most striking difference is observed in the ventricular and subventricular zones where *TP53BP2* is expressed at very high levels and *PPP1R13B* at low levels. Given the high homology of these genes, the likely evolutionary origin of *PPP1R13B* is a gene

duplication of *TP53BP2*. If so, the most ancient protein-coding *PPP1R13B* orthologue (i.e. not pseudogene) must have had an overlapping spectrum of protein-protein interactions. This is also consistent with the notion that ASPP2 is the ancient ASPP protein from which ASPP1 and iASPP were derived later in evolution. The most ancient ASPP is most likely to be dosage sensitive, by virtue of having the most conserved functions.

In yeast and *Arabidopsis*, it has been demonstrated that following whole-genome duplication events causing tetraploidisation, genes return to diploidy in a non-random fashion, with macromolecular complexes remaining for longer periods than other genes. Given *TP53BP2*'s dosage sensitivity, the introduction of a close homologue with an overlapping interactome would create an imbalance in ASPP2's protein-protein interactions resembling a pure duplication. One solution to this problem is the positive selection of mutations in both genes that uncouple the competing dosage-sensitive nodes. However, such changes take place over many generations. A more immediate solution involves modulating the two genes' expression such that *PPP1R13B* does not compete with *TP53BP2* in tissues and developmental time points where *TP53BP2* is dosage sensitive. This is akin to an epigenetic compensation for a duplication.

We propose that the observed inverse expression of *PPP1R13B* and *TP53BP2* in the developing brain evolved as a means to compensate for the imbalance introduced by the original gene duplication of *TP53BP2*. Given that *TP53BP2* duplication seems to be associated with neurological phenotypes, it is likely that CNS development is among the processes most sensitive to *TP53BP2* dosage. However, it would be interesting to investigate which other tissues display this pattern of expression. In addition to inverse expression, protein truncation is

another mechanism to minimise competition between homologous proteins. iASPP shares the Ank-SH3 domains and the conserved Pro-rich region, but possesses a unique N-terminal Pro-rich domain. If *PPP1R13L* evolved from a duplication of *TP53BP2* in an ancestral organism, the endowment with a unique N-terminal domain would disqualify iASPP from participating in ASPP2's junctional complexes, which rely on the N-terminal coiled-coil domain. It is ASPP2's extranuclear function which is required for the regulation of cell polarity via Par3 which is non-redundant in brain development. Overall, ASPPs seem to have evolved distinct patterns of expression and domain structures to avoid dosage imbalance in tissues sensitive to *TP53BP2* (or the ancestral ASPP) dosage.

2.13 Generation of *Ppp1r13b* knockout and conditional-knockout mice

In order to evaluate the non-redundant role of ASPP1 in mammalian development, a model system is needed. The International Knockout Mouse Consortium has generated libraries of targeting vectors and embryonic stem cells with targeted loci for several thousand genes. A targeting vector for *Ppp1r13b* was generated by EUCOMM and used to generate ES cell clones positive for the tm1a cassette (**Figure 2.36**). The tm1a allele has conditional potential and a lacZ reporter, allowing the transcriptional activity at the gene promoter to be assayed *in vivo* (**Figure 2.36**).

Figure 2.36 tm1a(EUCOMM)Hmgu allele structure

ES cells on the C57BL/6N background and positive for the Ppp1r13b<tm1a(EUCOMM)Hmgu> allele were obtained from EUCOMM. Two independent tm1a(EUCOMM)Hmgu allele-positive clones were received: codes HEPD0653_6_F08 (abbreviated F08) and HEPD0653_6_07 (abbreviated C07). Long-range PCR was performed to test for the presence of the 5' and 3' targeting homology arms (**Figure 2.36**) using genomic DNA purified from the ES cells. The presence of the correctly sized amplicons confirmed the targeting of the homology arms to the correct genomic location. This experiment confirmed data later released through EUMMCR (<https://www.eummc.org/order/cart>) that shows both clones were positive for the correctly-integrated 5' and 3' arms.

The transgenic core led by Dr Ben Davies performed ES cells culturing, blastocyst injections and delivered 12 chimaeric offspring from F08-injected females and 9 chimaeric offspring from C07-injected females. The agouti coat colour was used to estimate degree of chimaerism. Eight of the twelve F08 chimaeras were >50% chimaeric whereas eight of the nine C07 chimaeras showed >50% chimaerism. The male chimaeras were mated with wild-type C57BL/6J females for approximately 6 months. No agouti offspring were obtained among 50 pups from the C07 chimaera matings but 21 agouti pups were obtained from the F08 matings.

Figure 2.37 Genotyping strategy for tm1a and tm1b mice

The F08 pups were screened for the presence of the tm1a cassette using primers developed on the chimaeric parent males which contain some tm1a-positive cells (**Figure 2.37**). The tm1a heterozygous mice confirmed by genotyping were first used to set up crosses with PGK-Cre and Flp recombinase lines to allow for tm1a cassette manipulation. Subsequently, tm1a heterozygous-heterozygous matings were established to assess the phenotype of the homozygous offspring. Neonatal deaths were observed in multiple heterozygous x heterozygous matings. However, genotyping some of these pups revealed that neonatal death was not specific to tm1a/tm1a homozygous pups. This suggests the original ES cells may have contained chromosomal abnormalities independent of the targeted allele which can cause neonatal lethality and/or developmental abnormalities.

Figure 2.38 Genotyping PCR to detect presence of the tm1b allele. Primers used were lacZ_F2 and Intron8_R1 as depicted in Figure 1.x. Last two lanes were positive for tm1b.

To avoid *Ppp1r13b*-independent abnormalities, *Ppp1r13b*^{tm1a/+} mice were back-crossed to a pure C57BL/6J line (S. Zhong, work in progress). In addition, *Ppp1r13b*-knockout mice (carrying the *Ppp1r13b*<tm1b(EUCOMM)Hmgu> allele) were obtained through the tm1a – PGK-Cre cross and the deletion confirmed by PCR (**Figure 2.38**). Similarly, mice carrying the *Ppp1r13b*<tm1c(EUCOMM)Hmgu> allele, which have a loxP-flanked copy of *Ppp1r13b*, were generated by from the tm1a – Flp cross.

Figure 2.39 Oedema in E17.5 *Ppp1r13b*^{-/-} embryos. The embryo's skin shows dissection damage, however the massive oedema is still visible. The numbers shown are arbitrary indices.

Heterozygous matings were established using the tm1b heterozygous mice. Two litters were examined at E17.5 embryonic age. One litter contained no tm1b/tm1b homozygous, i.e. *Ppp1r13b*^{-/-} mice. The second litter contained two

tm1b/tm1b mice including one showing severe oedema (**Figure 2.39**). This result agrees with an earlier report by Hirashima et al. of subcutaneous oedema in mid-gestation *Aspp1*^{-/-} embryos (261).

Discussion

We have described the discovery and assessment of candidate pathogenic variants in congenital diseases with varying genetic architectures (**Table 2.9**).

1q41q42 deletions have an established pathogenicity and the present work refined the likely contribution of *TP53BP2* haploinsufficiency towards the clinical phenotype. *TP53BP2* deletions are absent from published cohorts of disease-free individuals and occur in patients as *de novo* variants, suggesting these deletions have a high penetrance.

Table 2.9 Summary of variants studied in this chapter and evidence of pathogenicity

Variant	Phenotype	<i>De novo</i> / inherited	ACMG evidence codes (SNV)	ACMG classification	Notes
1q41q42 deletions	1q41q42 microdeletion syndrome; encephalocele	Most <i>de novo</i>	-	Pathogenic	Brain MRI consistent with <i>TP53BP2</i> dosage effect
1q41q42 duplication 1:223820857-224076362dup	Microcephaly; developmental delay, seizures, vision problems	Inherited (maternal)	-	Uncertain significance	Brain MRI consistent with <i>TP53BP2</i> dosage effect
1q41q42 duplication 1:222694279-224034322dup	Microcephaly, developmental delay, craniofacial, dental abnormalities, abnormal behaviour	Inherited (maternal)	-	Uncertain significance	Distal breakpoint within <i>TP53BP2</i>
<i>PPP1R13B</i> R72Q	Childhood-onset schizophrenia	<i>De novo</i>	PS2, PM2	Likely pathogenic	
<i>PPP1R13B</i> 14:104216291 AC>A	ASD	<i>De novo</i>	PS2, PM2	Likely pathogenic	
<i>PPP1R13B</i> G881R	ASD	<i>De novo</i>	PS2, PP3	Uncertain significance	

Chromosomal deletion-associated human disorders often have variable phenotypes and severity among individuals, and the vast majority of pathogenic deletions include multiple genes, hampering the identification of causal genes. Experimental model systems are, therefore, needed to aid the identification of causal genes in human developmental disorders. Here we have identified *TP53BP2* as a candidate gene responsible for brain abnormalities in 1q41q42 microdeletion syndrome and show that *ASPP2*-deficient mice also develop CNS abnormalities with 100% penetrance, and phenotypic differences depending on background. Notably, *TP53BP2* is the only gene in the critical region for brain abnormalities of the syndrome for which the gene-deficient mouse model has a CNS phenotype.

Recently, a 1q41q42 microdeletion case with brain abnormalities was reported whose deletion included the last exon of *FBXO28*, suggesting *FBXO28* might also be responsible for these abnormalities (341). A mouse deficient in *FBXO28* is currently unavailable. Importantly, Case 6 in our report (**Figure 2.1, Table 2.1**) showed occipital encephalocele yet harbours a deletion that includes *TP53BP2* but excludes *FBXO28*. *FBXO28* lies outside the existing SRO for brain abnormalities, but it is possible that there are multiple dosage-sensitive genes for brain development in the 1q41q42 region and future studies are needed to investigate this. For example, patients with non-overlapping *DISP1* and *FBXO28* deletions both showed seizures (99, 100), despite the fact that *DISP1* is not contained in the critical region of the syndrome.

Few mouse models exist that are deficient in human 1q4-located genes and phenocopy the abnormalities associated with 1q4 deletions to a significant extent.

The ASPP2-deficient mice described here show craniofacial, eye, heart and urogenital abnormalities in addition to CNS defects, all of which are associated with 1q41q42 deletions. Interestingly, among the 31% of patients with *TP53BP2* deletions who presented with eye abnormalities, strabismus and optic nerve hypoplasia were common. Our HREM analysis of *Trp53bp2*^{Δ3/Δ3} embryos revealed hypoplastic or absent optic nerve and abducens nerve among 33% and 67% of B6 and BALB/c embryos, respectively. Given that the abducens nerve controls eye movement through the lateral rectus muscle, it would be interesting to test whether patients with strabismus and *TP53BP2* deletions have any abducens nerve abnormalities. We note that our ability to determine penetrance precisely is limited by the low number of *Trp53bp2*^{Δ3/Δ3} embryos (n = 3) on the BALB/c background analysed by HREM, due to the demanding nature of this technique. Overall, these observations might explain the significant phenotypic heterogeneity associated with 1q41q42 deletions: there are likely multiple dosage-sensitive genes in the region whose haploinsufficiency is both incompletely penetrant and variably expressed. The observation of NTDs in some of the ASPP2-deficient mice suggests it would be informative to investigate whether mutations involving *TP53BP2* might contribute to NTDs in humans.

To date, three different *Trp53bp2*-deficient mouse lines have been generated: exon 3 deletion mice reported by our group (*Trp53bp2*^{Δ3/Δ3}) (ref. 105), exon 4 deletion mice generated by the International Mouse Knockout Consortium (IKMC) (*Trp53bp2*^{Δ4/Δ4}) (ref. 342), and mice with deletion of exons 10-17 (*Trp53bp2*^{Δ10-17/Δ10-17}) (ref. 104). Homozygous deletion of exon 4 or exons 10-17 is lethal prior to embryonic day 9 with 100% penetrance, whereas deletion of exon 3 results in neonatal lethality with background-dependent penetrance. The exon 3

deletion is an in-frame deletion causing only the major isoform of *Trp53bp2* to be deleted completely; low levels of shorter forms of *Trp53bp2* can be expressed. Therefore *Trp53bp2*^{Δ3} acts as a hypomorphic allele, which has allowed us to discover developmental effects of ASPP2 deficiency that could not be observed with full-knockout alleles due to their early embryonic lethality.

Imaging of heterozygous *Trp53bp2*^{Δ3/+} embryos showed a lower frequency of structural abnormalities than observed in patients with heterozygous *TP53BP2* deletions. One possible explanation is that the exon 3 deletion is a hypomorphic allele, compared to the complete deletion allele in the patients. In addition, more than one gene is deleted in each 1q41q42 microdeletion. Therefore, the concomitant deletion of multiple haploinsufficient genes might exacerbate the phenotype, as is the case in other known contiguous gene deletion syndromes (44, 45).

At the protein level, the ability of ASPP2 to regulate apicobasal polarity and p53-dependent apoptosis is likely important for its role in neural tube closure. Recently, inappropriate activation of p53 during development was linked with the pathogenesis of CHARGE syndrome, a disorder characterized by abnormalities including developmental delay, heart defects, coloboma, cranial nerve abnormalities, choanal atresia and inner ear abnormalities (343, 344). The phenotypic spectrum in the CHARGE syndrome mouse model shows substantial overlap with the ASPP2-deficient mice (including neural tube defects, short lower jaw, coloboma and heart defects), suggesting dysregulated p53 activity might be responsible for these phenotypes in ASPP2-deficient mice. However, while p53-deficient and p53-overactivated embryos show primarily exencephaly (131, 343),

ASPP2-deficient embryos develop mainly spina bifida or craniorachischisis, pointing to the importance of p53-independent functions of ASPP2.

ASPP2 is also an important regulator of epithelial plasticity and apicobasal polarity (106, 130). Recent studies of Grainyhead-like 2 mutants have shown that dysregulated epithelial mesenchymal transition (EMT) can cause NTDs (345). It is possible that loss of epithelial character together with the loss of apicobasal polarity disrupt neural tube closure in ASPP2-deficient embryos. ASPP2-deficient embryos also showed overgrowth of neural tissue both in the brain and the spinal cord. The surplus of neuroepithelial cells might also contribute to NTDs and potentially other CNS phenotypes in these embryos through mechanical obstruction. Regardless of the exact cellular mechanism, the observed phenotypical similarities between ASPP2 deficiency in mice and humans highlight the importance of ASPP2 in controlling CNS development in both mice and humans.

These results may have implications to other diseases. Rare variants in *TP53BP2* have been linked with Tetralogy of Fallot (ToF), a congenital heart disease featuring VSD (346). Given the observation of VSD in ASPP2-deficient mouse embryos, patients with *TP53BP2* deletions and patients with rare missense *TP53BP2* variants, ASPP2 likely plays a causal role in preventing VSD in humans. It would be interesting to investigate the mechanism by which pathogenic *TP53BP2* variants disrupt heart development leading to the VSD phenotype.

Interestingly, *TP53BP2* duplications, associated with microcephaly and developmental delay, were found to be likely pathogenic. Consistently, *TP53BP2* duplications are absent from public databases of normal individuals and *TP53BP2*

is within the top 1% of genes predicted to exhibit triplo-sensitivity in the ExAC cohort. Ventricular dysmorphism is observed in both *TP53BP2* duplication and deletion patients. However, whereas *TP53BP2* deletions are associated with enlarged bodies and volumes of the lateral ventricles, *TP53BP2* duplication patient showed an effacement of the bodies of the lateral ventricles. These opposing effects of *TP53BP2* deletion and duplication on LV morphology may be related to ASPP2's role in controlling the differentiation of ganglionic eminence cells into the striatum, resulting in too few and too many striatal cells, respectively.

Spatiotemporal pattern of *TP53BP2* expression in the developing brain supports the notion of *TP53BP2*'s dosage sensitivity in the ganglionic eminence, in which *TP53BP2* levels are high and very consistent between individuals. In support of this hypothesis, ganglionic eminences in *Trp53bp2^{Δ3/Δ3}* mouse embryos show loss of cell polarity and general cell disorganisation. In addition, *Trp53bp2^{Δ4/+}* males showed hyperactivity in voluntary movement, and all *Trp53bp2^{Δ3/Δ3}* mice which survive birth exhibit hopping gait, presenting a possible link between ASPP2 and striatal control of motor function.

Of note is the increased severity of ASPP2 deficiency-related phenotypes in mice, as *TP53BP2* deletions have been observed at an approximate 2.3 male-to-female ratio among 1q41q42 microdeletion patients. Together with the striking sexual dimorphism in *TP53BP2* expression within human brains, these data suggest *TP53BP2* deletions may be more penetrant in males than females. Given that *TP53BP2* deletions are absent from existing cohorts of disease-free individuals, large scale studies of CNVs in the general population are necessary to ascertain whether *TP53BP2* deletions can occur in asymptomatic females.

Additionally, *de novo* single-nucleotide variants in *PPP1R13B*, which encodes ASPP2's sibling protein ASPP1, were identified in autism and schizophrenia patients. We showed that *PPP1R13B* is expressed in a spatiotemporally inverse manner with respect to *TP53BP2* in the developing brain, most strikingly in the ventricular zone where *TP53BP2* levels are high, which may reflect an evolutionary epigenetic compensation for *TP53BP2*'s dosage sensitivity in this tissue. *PPP1R13B* is expressed in neurons and spatiotemporally co-expressed with synaptic genes in the human brain. Accordingly, three *de novo* mutations in *PPP1R13B* have been identified in childhood-onset schizophrenia and autism spectrum disorder, diseases associated with synaptic dysfunction. ASPP1-deficient mice have been generated and will aid in the characterisation of ASPP1's function in the brain and other tissues.

Taken together, *TP53BP2* and *PPP1R13B* show distinct patterns of expression and distinct disease associations. In accordance with being an orthologue of the putative ancestral ASPP, *TP53BP2* shows dosage sensitivity in development and *TP53BP2* CNVs are associated with congenital disorders of the brain, and potentially heart and urogenital abnormalities. *PPP1R13B* is more redundant in development, however its neuronal expression implicate ASPP1 *de novo* mutations in neurodevelopmental diseases with a synaptic dysregulation.

Materials and Methods

Patient recruitment

Patients with 1q4 deletions and duplications were enrolled and de-identified data collected following the UK NHS Research Ethics Committee approval (09/H0606/78, Amendment 3), and in accordance with the Institutional Review Board protocols of the participating institutions.

Comparative genomic hybridisation

DNA isolated from patients' blood were analysed by chromosomal microarray following the participating institutions' standard protocols. With the exception of Case 7, all new 1q microdeletion and microduplication cases have been deposited on the DECIPHER database (<https://decipher.sanger.ac.uk/>).

Brain MRI and morphometry

De-identified brain MRI and/or CT scans were obtained in DICOM format from radiology departments where the scans were recorded. *Normal MRI controls used in the preparation of this article were obtained from the Pediatric MRI Data Repository created by the NIH MRI Study of Normal Brain Development.* To quantify lateral ventricles (LV) volume, MRI scans were first converted to Nifti format using MRIConvert (University of Oregon, USA; <http://lcn.uoregon.edu/downloads/mriconvert>) and subsequently analysed by ALVIN (347). Multiple scans in each series were used to compute LV volume to produce Figure 2b-left. Axial T1 scans only were used to compute LV volumes for

genotype comparison as shown in Figure 2b-right. Out of the fourteen 1q41q42 microdeletion MRI scans, two patient scans (Rosenfeld 9 and Case 7) were unsuitable for morphometry: Case 7 is a prenatal case and the scan for Rosenfeld 9 cannot be converted into Nifti. Therefore, the morphometric analysis of LV volume was performed with 12 patient scans.

Mice

Experiments with mice received UK Home Office approval, Project licence number 30/2862 and fully complied with the UK Home Office guidelines. For this study, *Trp53bp2*^{Δ3} mice in a pure C57BL/6J, mixed C57BL/6Jx129SvJ and pure BALB/c backgrounds were crossed to generate wild type, *Trp53bp2*^{Δ3/+} and *Trp53bp2*^{Δ3/Δ3} embryos (348). Pregnant females were sacrificed at the indicated time points during pregnancy and embryos were collected and genotyped using the following primers: 5'-CTCCACCCCAGGAAATTACA-3' (intron3), 5'-CGGTTTGGAAGTCAAAGGAA-3' (exon 3), and 50-GGACCGCTATCAGGACATA-30 (neomycin resistance gene).

Embryo sexing

The following primers for ZFY were used for sexing by PCR: 5'-GACTAGACATGTCTTAACATCTGTCC-3' and 5'-CCTATTGCATGGACAGCAGCTTATG-3'. The following GADPH primers were used as controls for the PCR reaction: 5'-TGGCTACAGTAACCGAGTGGT-3' and 5'-CTTTGAGTGGAAGCCGAAGT-3'.

Mouse micro-computed tomography (micro-CT)

Embryos generated from mice as described above were first sacrificed on ice-cold PBS, washed in phenol red-free Hank's salts with EDTA, removed from their yolk sac, their umbilical cord cut, and the freed embryo fixed in 4% formaldehyde for at least 24 h. Each embryo was then immersed in 2 ml Lugol solution (L6146, Sigma-Aldrich, St Louis, MO, USA) for 72 hours at 4°C. All incubations included the replacement of staining solution after the first 24 hours. Four embryos were embedded in 1% agarose (Web Scientific, Crewe, UK) in a dedicated sample holder and scanned using a micro-CT scanner (SkyScan 1172, Bruker, Kontich, Belgium) at a nominal isotropic pixel size of 4.9 µm (scan parameters: X-ray source voltage – 48 kV; current – 208 mA; filter – a 0.5 mm Al filter; number of projections – 900). The total scan time was 8 hours for four embryos.

The images projections were reconstructed with the scanner-built-in reconstruction software 'NRecon' and downsampled offline by a factor of two, resulting in a 9.8 µm isotropic voxel size. Image analysis (i.e. 3D segmentation and rendering) was performed in Amira (FEI Ltd, Hillsboro, OR, USA).

High resolution episcopic microscopy

HREM images of E14.5 embryos were obtained as previously described (324). We used the episcopic procedures for sectioning and image capture using a previously described arrangement of microtome and magnification optic (349).

Mouse echocardiography

Adult female BALB/c *Trp53bp2*^{Δ3/Δ3} mice (n=8) and age matched wild type controls (n=7) received echocardiographic examination at a mean age of 28 weeks. Mice were lightly anaesthetised using 1-1.5% isoflurane in 100% medical oxygen, kept

warm on a homeothermic blanket and imaged using a VisualSonics Vevo 2100 (Toronto, Canada) with 22-55 MHz transducer. B-mode trans-thoracic short-axis and long-axis images were obtained to assess left ventricular volumes and function and pulmonary artery Doppler flow as a measure of right-sided function. Images were obtained and analysed using Vevo 2100 v1.6.0 software by a single operator blinded to genotype.

Trp53bp2 exon 4 deletion mice ($Trp53bp2^{\Delta 4}$)

Publicly available phenotypic data for $Trp53bp2^{\Delta 4/\Delta 4}$ and $Trp53bp2^{\Delta 4/+}$ mice were mined from the International Mouse Phenotype Consortium (IMPC) URL <https://www.mousephenotype.org/data/genes/MGI:2138319> release 4.3, last updated 12 May 2016, and from Phenoview (<https://www.mousephenotype.org/phenoview>), updated 18 May 2016. Raw data were re-plotted using Graphpad Prism version 6.05 for Windows, (GraphPad Software, La Jolla, CA, USA). Experiment design by IMPC followed protocols of the International Mouse Phenotyping Resource of Standardized Screens (IMPreSS) (<https://www.mousephenotype.org/impress>). For statistical testing, results from IMPC's Mixed Model framework, linear mixed-effects model were adopted. P values below 0.05 were deemed significant.

Visualisation and statistical analysis

Data for panels in Figure 2.1a and 2.1c; were generated using the UCSC Genome Browser (<http://genome.ucsc.edu/>) (350), genome release hg19. Plots in panels Figure 2.1b, 2.3b, 2.2b and Figure 2.12a-d were generated using Graphpad Prism version 6.05 for Windows, (GraphPad Software, La Jolla, CA, USA). Chromosome

plots in Figure 2.8 were generated using Phenogram

(<http://visualization.ritchielab.psu.edu/phenograms/plot>) (351). Statistical tests were performed in GraphPad Prism (see above) and R (352).

Human brain expression data

Human brain mRNA expression data was mined from the Allen Brain Atlas (<http://www.brain-map.org/>). 3D visualisation of expression data was carried out using Brain Explorer available through the same portal.

Human germline variant data

Expected and observed frequencies of human truncating, missense SNVs were retrieved from the ExAC Browser (<http://exac.broadinstitute.org/>), v0.3.1 (14).

Primer design and DNA visualisation

DNA sequence manipulation including primer design and gene visualisation was performed using SeqBuilder (DNASTAR; Madison, WI, USA). Primer melting temperatures were computed using Oligocalc (<http://biotools.nubic.northwestern.edu/OligoCalc.html>) (353).

Ppp1r13b targeted allele mouse generation

Ppp1r13b knockout and conditional-knockout mice were generated as described in section 1.13. Targeting vector cloning and ES cell generation was performed by the EUCOMM consortium at the Helmholtz Zentrum Munchen (HMGU). ES cell culturing and blastocyst injections into pseudopregnant recipients were performed by the Trasgenic Core led by Dr Ben Davies. Chimaeric males were mated with

wild type females until F1 offspring obtained from multiple litters. For generation of tm1b and tm1c allele mouse lines, the PGK-Cre and Flp transgenes were removed by back-crossing to wild type mice and selecting Cre and Flp transgene-negative tm1b- and tm1c-positive offspring, respectively.

CHAPTER 3: RARE VARIANTS IN NEURAL TUBE DEFECTS

In this chapter, we explore the hypothesis that rare variants in *TP53BP2* and/or its direct binding partners *TP53*, *TP73* and *PARD3* contribute to NTD risk in humans. A case-control targeted sequencing study is performed in a cohort of 340 cases comprising mostly prenatal NTDs, and 240 controls of matched age and ethnicity.

RESULTS AND DISCUSSION

3.1 Rare nonsynonymous *TP53BP2* variants are present in both neural tube defect cases and matched controls

We showed in Chapter 2 that *TP53BP2* deletions are associated with NTDs and *Trp53bp2* deficiency causes NTDs in mice. Therefore, we decided to test whether mutations in the *TP53BP2* gene are also associated with NTDs in humans. 340 NTD cases of East Asian ethnicity and 240 matched controls were subjected to targeted next-generation sequencing of the *TP53BP2* gene locus. We focused our attention on rare variation of potentially large effect, rather than common variants of small effect. After filtering out common variants and variants of low-confidence we observed 4 distinct non-synonymous rare variants in the cases and 3 in the controls (**Figure 3.1a**). These SNVs were validated by Sanger re-sequencing (**Figure 3.2a**).

There was no significant burden of *TP53BP2* rare variants in cases compared with the controls. We also observed no difference in the distribution of missense mutations along the protein sequence of ASPP2 (**Figure 3.1b**). All four case-specific variants are novel, that is, not previously reported in ExAC or other

publicly available databases. In contrast, only 2 of the 3 missense variants in controls were novel. Therefore, we tested whether the case-specific variants had a deleterious effect on ASPP2 function. Given that ASPP2 was originally discovered as a binding partner of p53, the ability of mutant ASPP2 proteins enhance p53-dependent transactivation of the *BAX* promoter was assayed. All case-specific mutants were still able to stimulate p53-dependent transactivation of *BAX*, however ASPP2 K102E reached a limit of approximately 18-fold luciferase activity over the baseline and this activity did not increase with higher doses of ASPP2, whereas wild-type ASPP2 and the other 3 mutants were able to achieve higher degrees of transcriptional activity (**Figure 3.1c**). This resulted in a statistically significant reduction in trans-activation activity for ASPP2 K102E at 1000 ng plasmid used (**Figure 3.1c**).

A

Gene Name	Variant (genomic, hg19)	Variant (protein)	Frequency in cohort / controls (n = 337 / 240)	Novel?	NTD clinical details	Functional assay

3.2 A burden of missense *TP53* and *TP73* variants in neural tube defects

We next asked whether proteins directly modulated by ASPP2 are disrupted by rare variants in NTDs. ASPP2 enhances transcriptional activity of p53

family transcription factors on pro-apoptotic promoters. P53 and p73 have both been implicated in CNS development: p53-deficient and mutant mice show NTDs; p73-deficient mice show defects in CNS development. In contrast, p63 is dispensable in CNS development (354). Therefore, we sequenced *TP53* and *TP73* genes in human NTD cases by NGS. Focusing on rare nonsynonymous variants, 9 variants case-specific variants were validated by Sanger re-sequencing (**Table 3.1; Figure 3.3**) whereas only one variant in controls. In *TP53* we identified 2 nonsynonymous variants in a total of 3 NTD cases versus no nonsynonymous variants in controls (**Table 3.1**). Together, these 12 missense variants in cases versus 1 in controls represent a significant burden of rare variants in the two p53-family transcription factors in NTDs ($p = 0.0197$, Fisher's exact two-tailed test). However, this association would not survive multiple hypothesis testing correction. Therefore, a larger cohort is required to confirm the association of *TP53* and *TP73* rare variants with NTD risk.

Five of the case-specific variants are novel. One of these, p73 V190F, showed near-complete loss of transcriptional activity on the *BAX* promoter (**Figure 3.4**). This mutation lies within the DNA-binding domain and targets a highly conserved residue, suggesting V190F disrupts p73's ability to bind DNA. Although the other mutants were transcriptionally active at similar levels as wild-type p73 within the margin of error, this result demonstrates that some NTD patients harbour loss-of-function mutations in *TP73*.

Table 3.1 Details on rare *TP53* and *TP73* variants discovered in NTD cases. Figure 3.3 Sanger re-sequencing of case-specific nonsynonymous rare variants in *TP73*.

Figure 3.4 Transcriptional activity of NTD patient-derived p73 mutants. Left: relative luciferase activity on the BAX promoter; right: protein levels of the transfected mutants measured by Western blot.

3.3 A missense *TP53* variant is significantly enriched in neural tube defects and absent in unaffected siblings

When referenced to the major p53 isoform, the case-specific p53 variants identified encode p53 G279E and E358V. G279E is a DNA binding domain mutation observed in over 50 human tumours (source: IARC TP53 database; <http://p53.iarc.fr/>) as a somatic mutation, but absent from ExAC and other public databases, meaning its germline occurrence in the general population is less than 1 in 60,000. In our assay of *BAX* promoter transactivation the mutant protein showed no transcriptional activity (**Figure 3.5**). The recurrence of the mutation in the somatic cancer genome together with its absence or low abundance in the germline demonstrate this loss-of-function mutation has pro-tumour effects and is likely deleterious in normal tissues. Therefore, we sequenced the proband's parents and observed that the variant was paternally inherited from an unaffected father (**Figure 3.6**). This observation demonstrates that the mutation is not completely dominant, however it could be a variant that increases NTD risk.

Figure 3.5 Transcriptional activity of NTD patient-derived p53 mutants on the *BAX* promoter. Left: relative luciferase activity on the *BAX* promoter; right: protein levels of the transfected mutants measured by Western blot.

Figure 3.6 Sanger re-sequencing of case-specific nonsynonymous *TP53* variants

The second case-specific variant encoding p53 E358V was observed in two unrelated patients with spina bifida (**Table 3.1, Figure 3.6**). The variant is absent from all East Asian ExAC genomes as well as our internal matched controls, making it significantly enriched in this NTD cohort over the general population ($p = 4.1 \times 10^{-4}$, two-tailed Fisher's exact test). Moreover, the variant was absent in the proband's two unaffected siblings (**Figure 3.7**), although it was inherited from an unaffected father. The affected patients both had spina bifida, with the one also having encephalocele. Taken together, these data identify chr17: 7573954T>A as a candidate pathogenic variant in human spina bifida.

P53 E358 was able to transactivate the *BAX* promoter at wild-type p53 levels (**Figure 3.5**), suggesting its potential pathogenicity is independent of p53's transcriptional activity. Interestingly, the variant was also detected in the germline of an adult-onset sarcoma patient (patient identified in study first described in (355)). This raises the possibility that E358V is also a cancer-predisposing variant, causing the Li-Fraumeni syndrome. However, the mutant protein shows normal transcriptional activity on multiple target promoters (D. M. Thomas, *personal communication*). E358 is located within the tetramerisation domain of p53. Interestingly, loss of tetramerisation function through L344P mutation abolishes the oncogenic effects of p53 mutant D281G (356). It would be interesting to test whether E358V affects p53 tetramer formation. Regardless, more data are needed to assess its pathogenicity in cancer.

Figure 3.7 Pedigree of p53 E358V carrier. The variant segregates with the disease among the siblings, although the parent carrier is unaffected.

The observation of a recurrent rare missense variant specific to NTD cases prompted us to investigate which recurrent NTD-specific variants in other genes have been identified so far. **Table 3.2** shows NTD-specific nonsynonymous rare variants observed in at least 2 independent NTD cases, and their significance of enrichment compared with the ethnicity-matched ExAC cohort. When corrected for multiple hypothesis testing, only 4 variants fall within $p < 0.05$: VANGL1 S83L; TP53 E358V; CELSR1 N2309 and DVL1 T582P. Many of the remaining recurrent variants are in fact present at comparable frequencies in the general population. Thus, applying these criteria, chr17: 7573954T>A (p53 E358V) is a novel recurrent NTD-enriched variant which, unlike the other three significantly enriched variants, affects a gene not associated with planar cell polarity. It would be informative to sequence *TP53* in a larger cohort to validate the variant's genetic association with spina bifida.

Table 3.2 Recurrence statistics of NTD nonsynonymous variants in published literature and this study. 3.4 Genetic disruption of Par3-aPKC binding in human neural tube defects

ASPP2 regulates apicobasal polarity of neuroepithelial cells via Par3. Polymorphisms in the *PARD3* gene which encodes Par3 have been previously associated with NTDs in humans (128). However, it is unknown whether rare variants in *PARD3* contribute to NTD risk. Therefore, we performed targeted sequencing of *PARD3* in the NTD cohort and matched controls, and validated rare nonsynonymous variants by Sanger re-sequencing. Six nonsynonymous rare (MAF < 1%) variants were identified that were specific to NTD cases. Nine more variants were identified that were specific to controls (n = 5) or observed in both NTD cases and controls (n = 4) (**Figures 3.8, 3.9 and Table 3.3**).

Figure 3.8 NTD-specific missense variants are enriched in the aPKC-binding domain of Par3 and disrupt Par3's binding to aPKC. (a) Position of Par3 residues mutated in NTD cases (top, black arrows) vs matched controls (below, blue arrows), and variants detected in both cases and controls (bottom, grey arrows). **(b)** Binding of wild-type Par3 vs three aPKC-BD mutants to aPKC ζ (left) and aPKC ι (right). Hek293 cells were transfected with the aPKC and Par3 plasmids and Par3 was immunoprecipitated using anti-Myc tag antibody (left). Right: Par3 and aPKC ι proteins were expressed using in vitro translation and subjected to the immunoprecipitation assay as per aPKC ζ . Domain map of Par3 adapted from Macara et al. (360) with permission.

Interestingly, although the overall burden of nonsynonymous variants was comparable between cases and controls, the missense variants showed a striking

difference in distribution along the Par3 sequence (**Figure 3.8**). Three of the observed case-specific missense variants, one of which was observed in three unrelated cases, are located in the aPKC-binding domain (aPKCBD) of Par3. Two of these are novel: D783G and P913Q. No missense variants in aPKCBD of Par3 were observed in controls or shared between cases and controls. These data demonstrate there is an enrichment of Par3-aPKCBD missense variants in NTDs over controls.

Figure 3.9 Sanger re-sequencing traces validating rare *PARD3* variants discovered in NTD cases by Illumina sequencing. Variants which failed validation are not shown.

Given the enrichment of aPKCBD variants among cases, we asked whether these mutations affected Par3's ability to bind aPKC. Two isoforms of aPKC exist in humans: aPKC ι (iota) and aPKC ζ (zeta). Immunoprecipitation of exogenously transfected Par3 mutants in Hek293 cells produced lower levels of aPKC ξ bound to Par3 mutants than to the wild type. This effect was particularly severe for Par3 P913Q which bound less than 50% of the amount of aPKC ξ bound by wild type Par3 (**Figure 3.8b**). Similarly, *in vitro*-translated Par3 mutants bound less PKC ι than wild type, with the exception of T861S. Strikingly, Par3 P913Q pulled down virtually no PKC ι in this assay (**Figure 3.8b**). These results show that aPKCBD mutants disrupt Par3's ability to bind aPKC, with P913Q being particularly deleterious.

Discussion

We performed targeted sequencing of 4 genes in a cohort of 340 NTD cases and 220 matched controls. We observed similar frequency of missense *TP53BP2* mutations in cases and controls, suggesting *TP53BP2* deletions, such as the deletion observed in our encephalocele case presented in Chapter 2, contribute more significantly to NTD risk than *TP53BP2* SNVs. However, a total of 12 *TP53* and *TP73* missense variants in cases versus one *TP73* missense variant in controls were found and validated in our assay. These variants represent an overall burden of missense variants in these two p53-family transcription factors in NTDs ($p = 0.0197$, Fisher's exact test). An increased sample size will be crucial in confirming the role of rare *TP53* and *TP73* variants in human NTDs.

We also observed an enrichment of missense variants in the aPKCBD of Par3 among NTD cases, whereas such variants were absent from controls. Experimentally, these mutations disrupted Par3's binding to both isoforms of aPKC, implicating the genetic disruption of the Par3-aPKC interaction in the aetiology of NTDs. In epithelial cells, Par3 is known to regulate apical constriction through aPKC-mediated phosphorylation of ROCK (124). Apical constriction is an important process during neural tube closure, necessary for the folding of the neuroepithelial sheet that gives rise to the neural tube. It is possible that rare variants in aPKCBD weaken Par3's ability to mediate apical constriction. These heterozygous rare variants might be acting as hypomorphic alleles, reducing the amount of Par3 protein in the cell capable of binding aPKC. Given the association of polarity gene CNVs with NTDs (81), and the strong evidence of pathogenicity of *de novo* truncating variants in *SHROOM3* (119), it is likely that a polygenic burden

of variants disrupting apicobasal polarity and/or the process of apical constriction contributes to NTD risk. Thus, monoallelic disruption of Par3-aPKC binding may predispose foetuses to NTDs by reducing the effective dosage of Par3 during apical constriction.

Table 3.4 Summary of disease-associated variants identified. Question mark indicates the uncertainty surrounding the Par-aPKC binding assay as a well-established functional assay.

Variant	Phenotype	<i>De novo</i> / inherited	ACMG evidence codes	ACMG classification	Notes
<i>TP53</i> G279E	Spina bifida	Inherited	PS3, PM2, PP3	Likely pathogenic	
<i>TP53</i> E358V	Spina bifida	Inherited / n/a	PS4, PM2	Likely pathogenic	Co-segregation with disease; 2 unrelated cases
<i>TP73</i> V190F	Craniorachischis	N/A	PS3, PM2, PP3	Likely pathogenic	
<i>PARD3</i> D783G	Craniorachischis	N/A	PM2, PS3?	Likely pathogenic (?)	Enrichment of aPKCBD variants in cases
<i>PARD3</i> P913Q	Craniorachischis	N/A	PM2, PP3, PS3?	Likely pathogenic (?)	Enrichment of aPKCBD variants in cases

Our functional analysis of NTD-associated p53 and p73 mutations also identified loss-of-function alleles, p53 G279E and p73 V190F, that inactivate the proteins' transcriptional activity. Recently, a significant genetic overlap was found between genes targeted by *de novo* mutations in developmental disorders and driver genes in cancer (361, 362). Importantly, the functional impact of mutations identified in these genes was not always concordant, particularly for tumour suppressor genes. Therefore, it is possible that a subset of *TP53* mutations increase susceptibility to NTDs. The notion that these mutations might be acting differently to somatic cancer mutations and cancer susceptibility mutations seen in the Li-Fraumeni syndrome is supported by the fact that the recurrent variant we observed as significantly enriched in NTDs (p53 E358V) does not affect p53's

transcriptional function. It would be illuminating to investigate whether increased risk of NTDs exists among Li-Fraumeni patients. Interestingly, truncating germline variants have a high haploinsufficiency score in ExAC (pLI = 0.91), suggesting they are under negative selection which could have a developmental as well as cancer susceptibility component.

Among the individual variants identified, *TP53* variants G279E, E358, and *TP73* variant V190F can be classified as Likely pathogenic following the ACMG guidelines (**Table 3.4**) (ref. (65)). *PARD3* variants P913Q and D783G would qualify for this category if the functional test of Par3-aPKC binding is considered a well-established assay. Given the subjective nature of this statement, we mark the associated evidence types with a question mark (**Table 3.4**).

Altogether, our results support a role for a polygenic burden of rare missense variants in the aetiology of NTDs. Deleterious variants in multiple genes, such as *TP73* V190F or *PARD3* P913Q, are likely to have additive effects on NTD risk. WES or WGS studies of larger NTD cohorts will be instrumental in order to formally confirm the association of *TP53*, *TP73* and *PARD3* rare variants with NTD risk.

Materials and methods

Patient recruitment

Human NTD samples and associated controls were collected following an approval by the Committee of Medical Ethic in the Capital Institute of Pediatrics (Beijing, China) and the study was carried out in accordance with The Code of Ethics of the World Medical Association (Declaration of Helsinki) for experiments involving humans. Human samples were obtained from the Northern China, a region with a NTD prevalence of 199.38/10,000 based on the local epidemiologic surveillance data collected during January 2002 and December 2004 (109). The Committee of Medical Ethic in the Capital Institute of Paediatrics (Beijing, China) approved and the study was carried out in accordance with The Code of Ethics of the World Medical Association (Declaration of Helsinki) for experiments involving humans. The enrolled pregnant women were diagnosed by trained local clinicians using ultrasonography, and then registered in a database. As in our previous study (363), medical abortions were carried out by obstetricians to terminate NTD-affected pregnancies. Pathologic diagnosis of NTDs was performed by an experienced pathologist according to the International Classification of Disease, Tenth Revision. Written informed consent was obtained from the parents on behalf of foetus. The normal embryos aborted for non-medical reasons from the same region were used as geography-matched controls. Routine prenatal check-ups, questionnaire interviews and autopsies were completed for controls, and any embryos that harboured any pathological malformation or intrauterine growth retardation were excluded from the control group. Samples were first isolated, subdivided and immediately stored at -80°C. During transportation, the tissues were kept on dry ice.

DNA isolation, targeted gene sequencing and variant calling

Genomic DNA was extracted from muscle, skin, brain or lung. Twenty-five milligrams of tissue were used for DNA extraction with the DNeasy Blood and Tissue kit (69504, Qiagen, Germany) and stored at -80°C. The concentration and purity of DNA samples were determined by measuring their absorbance at 260 and 280 nm. Genomic DNA was sheared using Covaris™ Adaptive Focused Acoustics system (Covaris, MA). Samples were prepared for sequencing using the Truseq DNA Sample preparation Kit (Illumina, Inc, San Diego, CA) following the manufacturer's standard procedure. Custom capture oligos were designed using SureDesign website (<https://earray.chem.agilent.com/suredesign/>, Agilent technologies). The genes of interest were captured using the SureSelect Target Enrichment kit (Agilent Technologies, USA) with the following details. The hybridization reactions were carried out on an AB2720 Thermal Cycler (Life Technologies Corporation, USA) with following hybridization conditions: Incubated the hybridization mixture for 16 or 24 hours at 65°C with a heated lid at 105°C. After the hybridization reactions, the genes of interest were captured with magnetic beads (Invitrogen, USA). The capture production was enriched with following cycling conditions: 98°C for 30 s; 10 cycles of 98°C for 10 s, 60°C for 30 s, 72 °C for 30 s; 72°C for 5 min. Several libraries were pooled and subjected to bridge amplification on cBot (Illumina, Inc, San Diego, CA) following the manufacturer's standard cluster generation protocols. Following hybridization of sequencing primer, base incorporation was carried out on MiSeq Benchtop Sequencer (Illumina, Inc, San Diego, CA) following the manufacturer's standard sequencing protocols. The mean depth of coverage was 254.34x, and on average,

86.73% of targeted bases had sufficient coverage and quality for variant calling. The average read length was 251 bp. Sequence reads were aligned to the hg19 iteration of the reference human genome using BWA, version 0.5.9 (364). Base score recalibration and local realignment for indel (insertion or deletion) detection and duplicate removal were performed with GATK (365). SNVs were called using GATK (Samtools pileup (MapQ \geq 30,reads \geq 2) (version 1.1) (366) and Varscan (version 2.3) (367), short indels (insertions and deletion) were calling using Varscan with loose standard (min-coverage =1, min alternative allele reads=1, min-var-freq > 0.03). Genotypes were called using Bayes estimation and Binomial test. Variants were annotated with ANNOVAR (368) and searched in databases including dbSNP, 1000 genomes, Exome Variant Server, Exome Aggregation Consortium. Variants with a minor allele frequency of \geq 0.01 in dbSNP and/or ExAC were termed common variants, others rare variants. Rare variants absent in all databases were termed novel rare variants. All missense rare variants were validated by Sanger sequencing with custom primers (**Table 3.5**).

NB: Protein coding variants in *TP53BP2* were referenced to the Uniprot accession Q13625 which belongs to the full-length 1128-residue ASPP2 protein. However, the corresponding RefSeq transcript NM_001031685 encodes a 1134-residue protein and there is no reference RefSeq transcript with a correctly annotated start codon. Therefore the residue numbers given in this manuscript are referenced to the Uniprot sequence while the nucleotide numbers are referenced to the Refseq transcript.

Table 3.5: Primers for Sanger re-sequencing.

Gene symbol	Variant	Nucleotide position	Forward primer	Reverse primer

Plasmids and cloning

Single nucleotide variants were cloned by site-directed mutagenesis using whole-plasmid amplification with partially overlapping primers, amplification by Phusion Hot Start Polymerase II (Thermo Fisher Scientific, Waltham, MA), followed by digestion by DpnI (New England Biolabs, Ipswich, MA) for 3 h. The digested DNA was used to transform competent cells (Bioline, Taunton, MA) and the resulting colonies screened for the introduced mutation by Sanger sequencing. Plasmid DNA for mutant screening was prepared using the Plasmid miniprep kit (Qiagen, Hilden, Germany); plasmid DNA for transfections was prepared using the Plasmid Maxiprep kit (Sigma Aldrich, St Louis, MO). Luciferase plasmids, p53, ASPP2 expression plasmids were obtained as described previously (103, 107).

Luciferase assays

Twenty-four hours after plating, cells were transfected with the following plasmid combinations for specific experiments. H1299 cells were lysed in Passive Lysis Buffer (PLB) 20 h after transfection. Saos-2 cells were washed 1 time with PBS and supplemented with fresh growth medium 20 h post-transfection and subsequently lysed with PLB 40 h after transfection. Cells containing PLB were stored at -80°C and thawed in order to achieve homogenous cell lysates.

Luciferase assays were performed using the Dual-luciferase Reporter Assay System (Promega, Madison, WI) according to the manufacturer's instruction. The Luminescence module of the GloMax®-Multi+ Microplate with Instinct® plate

reader was used with 5-second integration. In this assay, the activities of firefly (*Photinus pyralis*) and Renilla (*Renilla reniformis* or sea pansy) luciferases are measured sequentially from a single sample. Renilla was used as an internal control for transfection efficiency. For each transfection, empty vector (pcDNA3) was used to control the total amount of DNA transfected. Firefly luminescence signal was normalized based on the *Renilla* luminescence signal. Mutant vs wild-type fold change values at each plasmid concentration were analysed using a two-tailed parametric t-test and corrected for multiple hypothesis testing by multiplying the p-value by the number of tests. Samples with a corrected $p < 0.05$ were deemed significant.

Western blotting

To quantify protein levels expressed in luciferase assays, twenty-four hours (H1299) or forty-eight hours (Saos-2) following transfection, cells were washed with PBS and lysed with Passive Lysis Buffer (PLB) (Luciferase buffer, Promega). Extracts were centrifuged at 16000 g for 20 minutes at 4°C. Protein concentrations were measured by Bradford assay (Bio-Rad). Protein sample was mixed with sample buffer before being loaded on an SDS-acrylamide-gel (8% manually carted Bis-Tris gel). Prestained protein marker (New England Biolabs) was used to determine the size of the protein. The SDS-polyacrylamide gel electrophoresis was initially run at 80V (250 mM Tris-base, 250 mM MOPS, 5mM EDTA, 0.5 % SDS and 5 mM Sodium Bisulfite) before being increased to 150 V after the visualisation of the marker bands. Subsequently, the proteins were transferred to nitrocellulose membranes and blocked with 5% milk in TBS containing 0.1% tween-20 (TBST) for 1 hour before being incubated with specific primary antibody overnight at 4°C. The following day, membrane was washed three times for 10

minutes with TBST before being incubated for 1 hr at room temperature with horseradish peroxidase-conjugated secondary antibody (Dako, Agilent, Santa Clara, CA, USA). For visualisation, membrane was washed with TBST and then developed using the ECL western blotting system (GE Healthcare, Chicago, IL, USA) on an autoradiography film.

Contributions

The following individuals directly contributed to the work presented in this chapter: Jaroslav Zak, Huili Li, Isaraphorn Pratumchai, Yihua Wang, Stefanie Werner, Ting Zhang and Xin Lu. J. Z. and X. L. designed study; H. L. and T. Z. designed the clinical study; J. Z. performed most experiments and analysed data; T. Z. and H. L. sequenced and re-sequenced patient samples and provided clinical data; I. P. produced Western blots in Figures 3.1c, 3.4 and 3.5, and contributed to luciferase assay readings in Figures 3.1c, 3.4 and 3.5 ; Y. W. produced Western blot in Figure 3.8b; S. W. contributed to luciferase assay readings in Figures 3.4 and 3.5.

**CHAPTER 4: IDENTIFYING DRIVER GENES IN HUMAN
CANCER**

RESULTS AND DISCUSSION

In this chapter, two fundamental questions are explored, using the ASPP genes as an example:

- 1) Using publicly available data, how can we assess the likelihood that a given gene plays a role in human cancer, and if it does, with pro- or anti-tumour effects?

Results section 4.1 uses an unbiased approach to assessing a gene's role in cancer and its classification as a pro- or anti-tumorigenic gene.

- 2) How can we utilise genomic data integration to identify rare candidate driver mutations in cancer and their molecular effects?

Results section 4.2 described analyses of genetic interactions between mutations, and associations between mutations and mRNA levels to identify candidate driver mutations and determine their mechanism of action.

Results section 4.1: An unbiased approach to assessing the role of individual genes in human cancer

Table 4.1 Genomic data sources and types of evidence available for an unbiased analysis of the role of individual genes in cancer. List up to date as of 10 September 2016. The column ‘causal on its own’ determines whether the type of evidence available from the specified data source can lead to an established causal role for a given gene without referring to other analyses or data sources. NT, normal tissue; TP, primary tumour.

4.1.1 Analysing the composition of classes of somatic mutations

Tumour suppressor genes are frequently inactivated by truncating mutations (e.g. *PTEN*; *NF1*) whereas oncogenes tend to show missense driver mutations (e.g. *KRAS*; *IDH1*). Vogelstein et al. proposed a ratiometric method to identify which cancer driver genes targeted by driver mutations in cancer (Mut-drivers) act as oncogenes and which as tumour suppressor genes (151). The 20/20 rule requires at least 20% of the recorded mutations to be at recurrent positions and missense for oncogene classification, or >20% of the recorded mutations to be inactivating for TSG classification (151). To evaluate whether the ASPP family genes – *PPP1R13B*, *TP53BP2* and *PPP1R13L* – are more likely to be oncogenes or TSGs, nonsynonymous mutations in these genes were collected and manually curated to avoid duplicates, mis-annotated mutations, erroneous reference transcript selection and other caveats present in public mutation databases.

A snapshot of the manual database corresponding to v78 of COSMIC, v1.2.4 of cBioPortal, r23 of the ICGC Data Portal, data release 2.0 of the GDC plus legacy mutations from earlier releases, there were a total of 835 nonsynonymous somatic mutations in the ASPP genes. *PPP1R13B* and *TP53BP2* showed a comparable percentage of truncating mutations: 20% and 19% respectively (**Figure 4.1**) This proportion of truncating mutations was significantly larger than for *PPP1R13L* (**Figure 4.1**).

To rule out biases from including legacy mutations which might have been removed for quality control reasons, the analysis was repeated solely with mutations indexed by the four databases mentioned above at their synchronised

data freeze points. We achieved the same results, and also note that >90% of the manually curated mutations are contained in at least one of the current releases of the public databases. These results show that based on their mutation pattern, *PPP1R13B* and *TP53BP2* are more likely to be TSGs than oncogenes, and that they fall on the borderline of qualification as Mut-driver tumour suppressors using the ratiometric method by Vogelstein et al.

Figure 4.1 *PPP1R13B* (ASPP1) and *TP53BP2* (ASPP2) show significantly higher proportion of truncating somatic mutations among nonsilent mutations compared to *PPP1R13L*. Data based on snapshot of COSMIC v78, cBio v1.3.4 and ICGC r22 plus legacy mutations (top) and without legacy mutations (bottom). Fisher's two-tailed exact test, * $p < 0.05$; ** $p < 0.01$.

To test for the association of nonsilent ASPP mutations with *TP53* status, we compared the frequency of mutations in each ASPP gene in wild-type- versus mutant-*TP53* tumours (**Figure 4.2**). Mutations in *TP53BP2* were significantly more enriched in wild-type-*TP53* tumours compared to *PPP1R13L* mutations. This suggests *TP53BP2* mutations might be genetically interacting with *TP53* mutations.

Figure 4.2 Frequency of nonsilent (top) and missense (bottom) ASPP mutations in tumours harbouring wild-type vs mutant *TP53*. The source mutation set is identical to that used in Figure 3.5 top panel. * $p < 0.05$, Fisher's exact two-tailed test; wt, wild type.

4.1.2 Analysing the frequency of nonsilent/silent mutations

The vast majority of recognised driver mutations are nonsynonymous. Therefore, one can expect to be able to identify driver genes simply by ranking genes by the ratio of nonsilent/silent mutations. To test this hypothesis, nonsilent/silent ratios across 31 TCGA studies available through the Firebrowse API were collected for 18,310 genes and the distribution of ratios plotted (**Figure 4.3**). Ratios for *PPP1R13B*, *TP53BP2* and *PPP1R13L* were shown as blue, orange and grey lines, respectively. As a positive control, distribution of ratios for genes from the Sanger Cancer Gene Census was plotted (**Figure 4.3**, red line). Although some genes from the Cancer Gene Census showed high nonsilent/silent ratios (notably a local peak around 9), the overall distribution varies very little from the distribution of ratios for all 18,310 genes. The overlap of the distributions shows that the majority of Cancer Census genes have nonsilent/silent ratios that fall within the bulk of the genome-wide distribution. Notably, the nonsilent/silent ratios of *PPP1R13B* and *TP53BP2* are higher than the median of the Cancer Gene Census distribution so the ratios are consistent with a Mut-driver role for the genes. Altogether, these data demonstrate that while some recognised cancer genes do show high enrichment for nonsilent over silent somatic mutations, the ratio alone does not have sufficient sensitivity to detect cancer driver genes.

Figure 4.3 Density plot of nonsilent/silent somatic mutations per gene collected from 31 TCGA studies: distributions of curated cancer genes vs all genes do not significantly differ. The formula used to compute the ratio is $n_{non}/(n_{sil}+1)$ to avoid infinite values. Black distribution depicts 18,310 genes with at least 1 somatic mutation detected; red distribution depicts genes from the Sanger Cancer Gene Census. Vertical lines show ratios for *ASPP1*, *ASPP2* and *iASPP* genes marked in blue, orange and dark grey, respectively. Firehose version used: 2016_01_28. Data retrieved via Firebrowse API.

4.1.3 Analysing the occurrence of loss of heterozygosity for truncating mutations

The classical tumour suppressor gene model classifies TSGs as recessive genes by requiring a 'second hit', i.e. biallelic inactivation, to initiate tumorigenesis. Genes conforming to this recessive TSG model are therefore expected to show loss of heterozygosity accompanying truncating variants whereas this phenomenon does not occur in oncogenes. We examined the copy number of *PPP1R13B*, *TP53BP2* and *PPP1R13L* in tumours carrying truncating mutations in the respective genes, for which copy number status was available. Four tumours

with *PPP1R13B* truncating mutations accompanied by loss of *PPP1R13B* heterozygosity (LoH) were found (**Table 4.2**). Three tumours with truncating *TP53BP2* mutations with *TP53BP2* LoH, but no tumours with the same concomitant alterations in *PPP1R13L*, were found. The observation of recurrent truncating mutation + LoH events supports the role as TSG for *PPP1R13B* and *TP53BP2*.

Table 4.2 Truncating mutations in *PPP1R13B* and *TP53BP2* with loss of heterozygosity. Copy number status retrieved from cBio v1.2.4.

4.1.4 Mining mouse tumorigenesis transposon screens

An important problem in cancer genomics is distinguishing causal driver genes from genes whose dysregulation merely reflects the molecular landscape

shaped by the driver mutations. For example, many proteins are under-expressed in tumour tissue over normal tissue but only some of them actively inhibit tumorigenesis. Therefore, experimental models are needed to connect discrete genetic events with direct effect on tumour growth. Retrotransposon insertion screens in mice are one such model. In a mouse with a cancer-predisposing mutation transposon insertions at genic sites can initiate and/or promote tumour growth. Over-represented sites of insertion reliably identify known tumour suppressor genes in the relevant tissue type.

We mined the Candidate Cancer Gene Database (<http://ccgd-starrlab.oit.umn.edu/>) for screens in which insertions at any of the *ASPP* genes were over-presented. *Ppp1r13b* was identified as a hit in 7 independent mouse mutagenesis screens (**Table 4.3**). Interestingly, 3/7 screens were specific to colorectal cancer. This suggests *Ppp1r13b* is a tumour suppressor in colorectal cancer and potentially other tissues.

Table 4.3. Hits from mouse transposon screens. Retrieved from papers indexed through CCGD, last updated 5 Sept 2016.

<i>Ppp1r13b</i>	Pancreatic	<i>Kras</i> ^{G12D}	20	1475	(375)
-----------------	------------	-----------------------------	----	------	-------

The observations of LoH alleles in human tumours suggest there is added benefit to the loss of both alleles in some tissues. However, this does not imply *PPP1R13B* and *TP53BP2* must be purely recessive tumour suppressors. As demonstrated in two independent studies in mice, single copy loss of *Trp53bp2* is sufficient to significantly increase the incidence of tumorigenesis. Therefore, it is possible that the genes are haploinsufficient tumour suppressors which have to be fully inactivated only under specific conditions, for example in specific tissues. This is consistent with the observation that colon cancer, which shows the strongest evidence of tumour suppressor status of ASPP1, shows truncating mutations of *PPP1R13B* without loss of heterozygosity. This suggests single-copy loss is sufficient to reduce tumour suppressive effects of ASPP1 in colon cancer.

Solimini et al demonstrated that hemizygous deletions that occur frequently in cancer are enriched in genes with anti-proliferative effects (160). They suggest these deletions help optimise the proliferative potential of cancer cells. Therefore, monoallelic deletions of *PPP1R13B* could be acting as mini-drivers.

4.1.5 Analysing mRNA expression in tumour vs normal tissue

Tumour suppressor genes are genetically and/or epigenetically inactivated in cancer whereas oncogenes are typically upregulated at the mRNA level. To analyse whether a gene is more likely a TSG or an oncogene, or shows no evidence of significant mRNA dysregulation, we analysed mRNA levels in tumours and associated normal tissue samples from TCGA and microarrays curated by

Oncomine. Only tumour types with normal tissue samples available were included in this analysis.

PPP1R13B was significantly differentially expressed in 10 TCGA tumour studies and down-regulated in all 10 (**Table 4.4, Figure 4.4**). Across Oncomine datasets, applying a p-value threshold for *PPP1R13B* differential expression of $p < 1 \times 10^{-5}$ and an absolute fold-change > 1.5 yielded 19 tumour-versus-normal studies, all showing *PPP1R13B* downregulation in the tumours (**Table 4.5**). This striking concordance suggests *PPP1R13B* acts as a TSG across a broad number of tissues.

In contrast to *PPP1R13B*, *TP53BP2* shows evidence of both over- and under-expression in TCGA datasets: 7 studies with a significant difference (after applying a multiple testing correction), out of which *TP53BP2* was under-expressed in 5 (**Table 4.4, Appendix Figure S8**). Oncomine studies meeting the $p < 1 \times 10^{-5}$ and $|FC| > 1.5$ thresholds comprise 7 datasets with under-expression of *TP53BP2*, and 7 with over-expression of the gene (**Table 4.5**). Therefore, mRNA expression alone is not conclusive with respect to *TP53BP2*'s global classification as a TSG or oncogene. It is possible that *TP53BP2* has both tumour suppressive and oncogenic effects whose relative dominance is lineage-dependent.

PPP1R13L shows a high degree of concordance among TCGA studies: significantly up-regulated in 11 studies and downregulation in a single study (**Table 4.4, Appendix Figure S9**); Oncomine studies show 12 vs 6 tumour studies with over- vs under-expressed *PPP1R13L*, applying the same criteria as above (**Table 4.5**). Based on the overall concordance of these studies, *PPP1R13L* mRNA levels in tumours correspond to an oncogene rather than a TSG.

Overall, published microarray and RNAseq datasets demonstrate uniform down-regulation of *PPP1R13B* in tumour vs normal tissue, mainly upregulation of *PPP1R13L* in tumours, and an ambiguous pattern for *TP53BP2* with both over- and under-expression in individual tumour types (**Table 4.6, Figure 4.5**).

Figure 4.4 mRNA levels of *PPP1R13B* in TCGA primary tumours (TP) vs normal tissue (NT) across 23 tissue types and 3 aggregated tissue types. Student's two-tailed t-test; BLCA, bladder carcinoma; BRCA, breast invasive carcinoma; CESC, cervical squamous cell carcinoma; CHOL, cholangiocarcinoma; COAD, colon adenocarcinoma; COADREAD, colon and rectal adenocarcinoma; ESCA, oesophageal carcinoma; GBM, glioblastoma; GBMLGG, glioblastoma and lower-grade glioma; HNSC, head and neck squamous cell carcinoma; KICH, kidney chromophobe carcinoma; KIPAN, pan-kidney cancer; KIRC, kidney clear-cell carcinoma; KIRP, kidney papillary cell carcinoma; LIHC, liver carcinoma; LUSC, lung squamous cell carcinoma; PAAD, pancreatic adenocarcinoma; PCPG, pheochromocytoma and paraganglioma; PRAD, prostate adenocarcinoma; READ, rectal adenocarcinoma; SARC, sarcoma; STAD, stomach adenocarcinoma; THCA, thyroid carcinoma; THYM, thymoma; UCEC, endometrial carcinoma.

Table 4.4 mRNA levels in primary tumour vs matched normal tissue across 23 TCGA studies and 3 tissue aggregates. mRNA quantified by RSEM and scaled by log₂ transform; Student's two-tailed t-test corrected for multiple hypothesis testing by multiplying by the number of tests for each gene (n=26). Studies reaching significant differential expression highlighted in red. Log₂FC, log₂ of fold change; p(adj), adjusted p value. Blue shading = significantly underexpressed; orange shading = significantly overexpressed; red shading = statistically significant.

4.1.6 Mining genome-wide CRISPR sgRNA screen of cancer cell line viability

In addition to genetic studies in mice, human cell lines offer another opportunity for investigating causal effects of individual genes on cancer growth. Traditionally, knock-down techniques using short-interfering RNA (siRNA) or short-hairpin RNA (shRNA) reagents have been used to assess the effect of gene loss on cancer cell line growth. However, these techniques result in incomplete reduction in gene expression, and frequent off-target effects. With the advent of genome editing, genes can be removed at the DNA level, eliminating the uncertainty over mRNA dosage effects (376, 377).

A recent example of utilising the genome editing system CRISPR-Cas9 to probe the functional genome in cancer cell lines is a study by project ACHILLES which screened 33 cell lines with genome-wide sgRNA libraries (378). Mining this publicly available data revealed little cell line dependence on *PPP1R13B* for most cell lines in the panel (more positive values indicate less cell line gene-dependence) (**Figure 4.6**). Surprisingly, some cell lines showed a more negative response to the targeting of *TP53BP2* – the tails of the gene’s distribution reaches wider than the distribution of *PPP1R13L*’s sgRNA scores, suggesting a subset of cell lines is more sensitive to the deletion of *TP53BP2* than *PPP1R13L*, for example the pancreatic cancer cell line PANC0327 (*TP53BP2* score= -1.05). This observation might help explain why *TP53BP2* is upregulated in certain tumour types. However, a higher number cell lines needs to be screened in order to achieve a global survey of the ASPP genes’ effect on cancer cell line fitness.

Figure 4.6 Distribution of ASPP gene sgRNA scores in the ACHILLES CRISPR screen: x-axis indicates sensitivity to sgRNA integration: positive values indicate less sensitivity. Blue = *PPP1R13B*; red = *TP53BP2*; black = *PPP1R13L*.

4.1.7 Analysing the correlation between mRNA levels and cell line chemosensitivity

An important hallmark of oncogenes is mediating resistance to cell death, including cell death induced by anti-cancer drug treatment. Conversely, functional tumour suppressor pathways enhance the efficiency of drug action by triggering cell death or growth inhibition in response to drug treatment. Therefore, NCI's Cancer Target Discovery 2 Portal (<https://ctd2.nci.nih.gov/dataPortal/>) along with an accompanying paper by Rees et al. (379) were mined for information on gene correlation with drug sensitivity in cancer cell lines. First, the all-cancer-cell line correlations were mined and data points reaching experiment-wide significance were plotted (**Figure 4.7**). Strikingly, a large cluster of drugs correlates with poorer

cell line sensitivity (high z-scores) as a function of increasing *PPP1R13L* expression (**Figure 4.7**). In contrast, several drugs correlated with chemosensitivity in cell lines expressing high *PPP1R13B*. These associations reaffirm *PPP1R13B*'s profile as a candidate TSG whereas *PPP1R13L*'s as a candidate oncogene in human cancer.

Figure 4.7 Associations between ASPP mRNA levels and cell line chemosensitivity. Only associations clearing the experiment-wide Bonferroni-corrected significance threshold of $|z| > 5.83$. Positive association indicates correlation with resistance, computed as area under the dose response curve. CCLs, cancer cell lines; non_haem_lymph, non-haematopoietic and lymphoid cell lines. Data retrieved from Rees et al, 2016 (379). 481 compounds were tested in this experiment.

Plotting z-scores for all drug associations shows that the distribution of *PPP1R13L* z-scores is positively skewed (**Figure 4.8**), indicating an overall positive correlation with drug resistance and negative correlation with chemosensitivity in cancer cell lines. The z-scores of *PPP1R13B* are centred close to 0, however notable outliers exist in the negative-z-score region as shown above. Interestingly the z-scores for *TP53BP2*'s association form a narrow

distribution centred just below 0, implying that mRNA levels of *TP53BP2* in cancer cell lines correlate poorly with chemosensitivity.

Figure 4.8 All z-scores for Pearson correlation of ASPP gene mRNA levels with chemosensitivity; for all CCLs. Data mined from the CTRP v2 portal. Boxplots shows median, quartiles and whiskers show minimum and maximum values.

4.1.8 Lineage specificity of cancer genes

The TSG or oncogene function of some genes is restricted to one or more cell lineage (e.g. *MLL2*); other multi-modal genes act as TSGs in one lineage and oncogenes in another (e.g. *NOTCH1*). Therefore, to gain a full understanding of the functional role of a given gene in cancer, the data on its dysregulation must be de-convolved by tumour type. One challenge in performing such analysis is the lack of comprehensive data on all tumour types – with the exception of TCGA, most cancer studies were limited to a small number of analyses, such as whole-exome sequencing. In addition, studies vary significantly in their scale, introducing a bias in confidence as a function of sample size, e.g. the differential expression of

a sarcoma driver gene may be more significant in lung cancer because more lung tumours and matched tissue controls have been analysed to date.

Nevertheless, data may be parsed by tissue type and assessed for concordance of evidence on gene function. As an example, data for *PPP1R13B* and the mouse orthologue *Ppp1r13b* are presented in **Table 4.7**. The data reveal a convincing role for ASPP1 as a TSG in colon cancer: in mice, 3 independent transposon screen identified *Ppp1r13b* as a hit; the gene is significantly downregulated in human colon tumours vs normal tissue ($p < 10^{-14}$), and 14 truncating mutations in human colon tumours have been reported, making up 27% of nonsynonymous mutations in this tissue, significantly higher than expected by random chance. These highly concordant data demonstrate *PPP1R13B* is a TSG in colon cancer.

Table 4.7 Evidence of gene cancer role by tissue type for *PPP1R13B*. LoH, loss of heterozygosity.

Tumour type	Hit in mouse transposon screen?	Downregulated in human tumours vs normal tissue?	Truncating mutations in human tumours?	Truncating muts with LoH?	Missense muts with LoH?	% of truncating mutations of all nonsilent somatic
Colon	Yes (3x) Takeda 2015; March 2011; Starr 2009	Yes, $p=4.45E-15$	Yes n=14			14/51=27%
Liver	Bard-Chapeau 2014 (HBV+)	No, $p=n.s.$	Yes	Yes, n=2	Yes, n=2	
Peripheral nerve sheath (neurofibrosarcoma)	Rahrmann 2013	N/A	N/A			
Pancreas	Perez Mancera 2012	Yes, $p=0.092$	Missense only			
Stomach carcinoma	Takeda 2016		Yes, 7		Yes, n=2	
Bladder	-	Yes, 0.003	Missense only			
HNSC	-	Yes, $p=9.0E-4$	Missense only			
Lung adenocarcinoma	-	Yes, $p=6.0E-4$	Yes	Yes	Yes	
Lung squamous	-	Yes, $p=3.46E-9$	Yes	Yes	Yes, n=2	
Leukemia	Yamashita 2015 – p53/- potentiated	Yes				
Prostate		No, $p=0.076$			Yes	

Interestingly, loss of heterozygosity was not observed for nonsynonymous *PPP1R13B* mutations in colon cancer. This, along with the data presented above, suggests that *PPP1R13B* is not a recessive but dosage-dependent TSG in this tissue. Partial loss of ASPP1 function is sufficient to enhance tumorigenesis in the colon. In contrast, liver carcinomas are more likely to require full inactivation of *PPP1R13B*: 2 truncating and 2 missense mutations with LoH were observed but mRNA levels of *PPP1R13B* did not differ significantly between tumour and normal tissue. In accordance with the recessive model, it is possible the subset of liver tumours with biallelic inactivation of *PPP1R13B* benefit, while tumours carrying at least one wild type copy of the gene do not experience selection on ASPP1 levels. Taken together, these data suggest the classification of a TSG as strictly recessive versus dosage-dependent can vary by lineage.

4.1.9 Towards genome-wide classification of cancer genes

The data presented in this chapter provide unbiased, multi-platform, multi-source evidence that can be used to assess the likelihood of any gene being a cancer gene, as well as the likelihood of being a TSG versus an oncogene, or more broadly, being anti- or pro-tumorigenic. While each individual study has its caveats, concordance across multiple data types from multiple independent studies can provide conclusive evidence.

The ASPP genes represent a suitable example of the utility of this approach. Although an extensive body of evidence exists of the ASPP genes' involvement in cancer (see Chapter 1, section 1.4.6), none of the ASPP genes are included on the Sanger Cancer Gene Census (cancer.sanger.ac.uk/census/), Vogelstein et al.'s cancer gene list (151), the list of significantly mutated genes

called by MutSig2CV (162), or the Network of Cancer Genes 5.0 (200). Therefore, a significant gap exists between the experimental data supporting a causal role for ASPPs in cancer, and curated cancer genomic data-derived lists of cancer drivers. The analysis presented here aids in closing that gap. **Table 4.8** shows an example of how the different types of evidence can be interpreted. In this example, we establish thresholds for the classification of each gene as a TSG, oncogene (OG), or inconclusive (0). The number of TSG and OG points scored is tallied up and their concordance evaluated.

For example, *PPP1R13B* scored 6 TSG points and 0 OG points, equivalent to a 100% concordance rate. Given that this evidence includes multiple hits from independent mouse mutagenesis screens, and in light of the experimental evidence discussed in Chapter 1.4.6, there is little doubt that *PPP1R13B* is a tumour suppressor gene in mice and humans. Its relatively low absolute somatic mutation frequency suggests that *PPP1R13B* mutations might act as rare driver mutations, mini-driver mutations, and/or that the major mode of action of *PPP1R13B* in cancer is that of an Epi-driver gene, i.e. epigenetic dysregulation of ASPP1 function is sufficient for inactivation in most tumours. This is consistent with the observation of an extremely high concordance rate of *PPP1R13B* mRNA under-expression across human cancers. Perhaps down-regulation of ASPP1 sufficiently reduces the threshold required for ASPP1-dependent activation of apoptosis, and somatic mutation of *PPP1R13B* is required only in tumours where ASPP1 experiences unusually high levels of activation and/or where pathways downstream of ASPP1, such as the cell-intrinsic apoptosis pathway, are not already inactivated by another mechanism.

PPP1R13L, implicated as a candidate proto-oncogene by existing experimental data, shows hallmarks of an oncogene such as consistent upregulation in tumours vs normal tissue, and significant association of mRNA levels with drug resistance in cancer cell lines (**Table 4.8**). However, a close inspection reveals that *PPP1R13L* does not frequently experience copy number gain or amplification in cancer, and few highly recurrent missense mutations have been found in *PPP1R13L*. Taken together, *PPP1R13L* dysregulation fits the profile of an Epi-driver oncogene, i.e. a pro-tumorigenic gene which can be sufficiently co-opted to drive tumour growth in its wild-type state by epigenetic and post-translational mechanisms.

Finally, *TP53BP2* shows an ambiguous pattern of dysregulation in cancer, with evidence of both TSG function (>20% truncating somatic mutations, downregulation in some tumour types) and OG function (>25% somatic amplification rate, upregulation in some tumour types). Given that *TP53BP2* is significantly mutated in human pancreatic cancer and shows truncating mutations in this dataset (266); *Trp53bp2* is a haploinsufficient tumour suppressor in mice (104, 105); and *ASPP2* is directly targeted by the oncoprotein CagA in the stomach (243, 244), it is likely that *TP53BP2* works as a TSG in some tissues and an OG in others.

Table 4.8 Multi-variable assessment and classification of potential cancer genes.

ASPP genes used as an example. Threshold of 20% truncating mutations were used (based on Vogelstein et al.); concordance threshold of 66% was required for expression data. N/C, not conclusive; homdel, homozygous deletion; NT, normal tissue; TP, primary tumour tissue; cBio, cBioPortal; hetloss, heterozygous deletion; CTRP, Cancer Therapeutics Response Portal.

In order to discover all cancer genes, the approach described in this section can be extended genome-wide. One possible strategy, demonstrated in **Table 4.8**, involves a points-based system with classification gates established with a training set of curated cancer genes. This approach is similar to clinical guidelines directing treatment based on empirically scored observations of the patient's phenotype. The data for each gene can be parsed dynamically from public APIs to ensure the classification can be updated as datasets grow.

The disadvantage of a points-based system is its limitation to the variables examined and the analysis applied to calculate scores. Scoring relies on intelligent decisions regarding the relative importance of different types of biological evidence. However, our understanding of the biology of cancer is incomplete. Therefore, a more powerful approach will utilise machine learning applied to a wide range of variables. The limitations of the machine learning approach are 1) the bias introduced by a specific class of curated cancer genes, and 2) the degree to which tumour data of different types and sources can be synchronised. However, we envisage that with the emergence of platforms such as the NCI Genomic Data Commons, the degree of harmonisation of cancer genomic and clinical data in the public domain will keep increasing. Future work will investigate the genome-wide application of this integrative approach to cancer gene classification.

Results section 4.2: Dissecting the mechanism of action of driver missense mutations

4.2.1 Genetic interaction between *TP53* and *PPP1R13B* mutations

In order to fully understand the biology of cancer, molecular mechanisms underlying tumorigenesis must be mapped. Two major challenges in the analysis of function of missense mutations in cancer are separating driver from passenger mutations, and deconvolving individual functions of a pleiotropic gene. *PPP1R13B* is an example of a pleiotropic gene: its protein product ASPP1 has multiple binding partners across distinct pathways, such as p53, p63, p73, YAP and PP1. It is unclear which, if any, of these interactions are targeted by missense mutations in cancer.

Figure 4.9 Frequency distribution of missense ASPP1 somatic mutations in wt TP53 (top) and mutant TP53 tumours (bottom) along ASPP1 protein sequence. Horizontal axis is the residue number at the centre of each bin. Mutations in the 640-720 region occur almost exclusively in wt-p53 tumours; Fisher's 2-tailed exact test comparing number of mutations in 640-720 bin vs total in other bins.

Because genetic interactions between somatic mutations can be lost in the background of passenger mutations, we analysed the domain distribution of missense mutations in ASPP1 in p53-wild type vs mutant tumours (**Figure 4.9**). Only mutations detected in tumours (not cell lines) were included in this analysis. Interestingly, we found one 80-residue region of ASPP1 that is mutated almost exclusively in wild-type p53 tumours ($p = 1.1 \times 10^{-4}$, Fisher's exact two-tailed test). This demonstrates there is a genetic interaction between somatic mutations in *PPP1R13B* and *TP53*. This sequence region, residues 640-720, is also the most frequently mutated region of ASPP1 in wild type-p53 tumours. It includes residues in the N-terminal part of the proline-rich (Pro-rich) region and the preceding residues (**Figure 4.9**). These data suggest the Pro-rich region of ASPP1 directly or indirectly modulates ASPP1's interaction with p53 and that this mechanism is targeted by missense mutations in human cancer.

Fig. 4.10 Missense mutations in Pro-rich region of ASPP1 are enriched in tumours with loss of *PPP1R13B* heterozygosity (hetloss). Tumours carrying missense *PPP1R13B* mutations with loss of heterozygosity and wt *TP53* (top, green) vs mutant *TP53* (bottom, red).

We also observed that mutations in and preceding the Pro-rich region are enriched in tumours with loss of *PPP1R13B* heterozygosity (**Figure 4.10**).

Missense mutations accompanied by LoH are a frequent mechanism of recessive TSG inactivation. This supports the hypothesis that the Pro-rich region and pre-Pro-rich-region sequence mutations have undergone positive selection in tumours and suggests they have an inactivating rather than activating role.

Figure 4.11 Somatic missense *TP53BP2* mutations in wt-p53 (top) and mutant-p53 tumours (bottom). The top mutated bin in wt-p53 tumours centred at residue 730 is not mutated in any mutant-p53 tumours. Data source: manually curated mutations from COSMIC v78, cBio v1.2.4 and ICGC r22. * $p < 0.05$, Fisher's exact two-tailed test comparing bin size with sum of other bins in wt-p53 vs mutant-p53 tumours.

Mutations in *TP53BP2* show a similar and statistically significant, but more narrowly defined relationship with *TP53* status in the Pro-rich region (**Figure 4.11**). The specificity of missense mutations to wild type-p53 tumours is limited to the ASPP2 residues 720-740, whereas in the more C-terminal part of the Pro-rich region (abbreviated C-Pro), mutations are more frequent in mutant-p53 tumours. This suggests the more N-terminal part of the Pro-rich region (abbreviated N-Pro below) in ASPP1 and ASPP2 plays a role in controlling the interaction of each protein with p53. However, as in ASPP1, the N-Pro region of ASPP2 is also the

most frequently mutated region of ASPP2 sequence in wt-p53 tumours (**Figure 4.11**), highlighting an important role for this autoregulatory region of ASPP1 and ASPP2 in cancer.

4.2.2 Proline-rich region mutations in *PPP1R13B* and *TP53BP2* correlate with tumour *BAX* mRNA levels

ASPP1 and ASPP2 enhance p53's transcriptional activity in a promoter-specific manner, thereby increasing the transcription of pro-apoptotic genes *BAX*, *TP53I3* and *BBC3* at the expense of other p53-target genes such as *CDKN1A*. Therefore, we asked whether missense mutations interacting with *TP53* mutation status correlated with altered *BAX* mRNA levels in each tumour. Because absolute levels of *BAX* are tissue-dependent, we used mRNA z-scores comparing the *BAX* mRNA level in each tumour to the expression level of *BAX* in other tumours of that tissue type. To visualise the distribution of *BAX* levels as a function of ASPP1 mutations, we plotted the density of tumours with negative vs positive *BAX* z-scores along the ASPP1 sequence (**Figures 4.12 and 4.13**).

Figure 4.12 *BAX* z-scores vs *PPP1R13B* missense mutations using different density bandwidths.

As expected, tumours with mutations in the N-Pro and preceding region had lower levels of *BAX* than other tumours of the same tissue type. Tumours with negative *BAX* z-scores also clustered within the ubiquitin-like fold, suggesting a role for this domain in regulating ASPP1's interaction with p53 (**Figures 4.12 and 4.13**). Similar results were observed for N-Pro mutations in ASPP2 (**Figure 4.13**) with all ASPP2 N-Pro-mutant tumours showing negative z-scores of *BAX*. This result was encouraging because there was no overlap between patients with N-Pro mutations in ASPP1 and ASPP2, suggesting this correlation is shared by the two proteins and can be replicated.

Figure 4.13 Density plot of tumours with above-average BAX mRNA levels (red) vs below-average (blue) within the tumour type, in mutant-ASPP1 (top) and mutant-ASPP2 (bottom) tumours, as a function of ASPP protein sequence. Pro, proline-rich region; SB, SH3-binding domain; SH3, SH3 domain; α , predicted α -helical sequence.

4.2.3 Dipolar correlation of Pro-rich region mutations with BAX levels

The distribution of *PPP1R13B*-mutant tumours with above-average BAX levels ($z > 0$) vs below-average levels ($z < 0$) shows a clear pattern within the

proline-rich region (**Figure 4.14**). Whereas in most domains tumours with positive and negative z-scores are mixed together, in the Pro-rich region a cluster of $z < 0$ tumours is adjacent to a cluster of $z > 0$ tumours with no visible overlap.

Strikingly, this region shows a more significant degree of differentiation by *BAX* levels than the C-terminus of ASPP1 which binds p53 family members directly. Unexpectedly however, not all Pro-rich region mutant tumours have negative z-scores, instead, mutations in the C-Pro region are associated with increased levels of *BAX* for both ASPP1 and ASPP2-mutant tumours (**Figure 4.14**).

This result is surprising for two reasons. Firstly, ASPP1 Pro-rich region mutations came exclusively from wild-type-*TP53* tumours, whereas ASPP2 Pro-rich mutations were observed in both wild type-*TP53* and mutant-*TP53* tumours. Secondly, it is unclear why somatic mutations linked with increased mRNA levels of a pro-apoptotic gene such as *BAX* would be positively selected. Indeed, the observation of negative selection of co-occurrence of mutations in the Pro-region of ASPP1, and in *TP53* within the same tumour suggests ASPP1 protein with Pro-rich-region mutations can exhibit enhanced pro-apoptotic activity in mutant-*TP53* tumours. Therefore, why are these ASPP1 and ASPP2 mutations not selected out?

One possibility is that mutant ASPP1 and ASPP2 with C-Pro mutations (somatic mutations in the proline-rich region closer to the C-terminus) exhibit both pro- and anti-tumour effects, of which the pro-tumour effect becomes dominant to allow positive selection (limited to wt-p53 tumours for ASPP1). In a mutant-p53 tumour, the anti-tumour effect becomes dominant and the mutation is selected out. To investigate this possibility, we surveyed the relationship between ASPP1, ASPP2 mutations and mRNA levels of other p53 target genes. Interestingly,

levels of *CDKN1A* which encodes the cell cycle inhibitor p21 were reduced in tumours carrying C-Pro mutations in *TP53BP2* and *PPP1R13B* (**Figure 4.14**). A cluster of below-average-p21-level tumours was observed in the C-Pro region of both genes. This is unexpected as *BAX* and *CDKN1A* levels are generally positively correlated in tumours and indeed in the N-Pro-mutant tumours, both *BAX* and *CDKN1A* levels are below average.

Figure 4.14 *CDKN1A* mRNA levels as a function of position of mutant *PPP1R13B* (top) and *TP53BP2* (bottom) residues with a focus on the Pro-rich region. Blue = $z < 0$; red = $z > 0$; left panels show the entire sequence of the proteins; right panels zoomed in on Pro-rich region. Only mutations indexed by cBio were included on this plot.

4.2.4 ASPP1 and ASPP2 mutations might redirect p53 family transcription factors to the *BAX* promoter to inhibit *CDKN1A* transcription

The observations that ASPP1 C-Pro missense mutations are negatively selected in mutant-*TP53* tumours but positively selected in wild-type-*TP53* tumours, and that these C-Pro tumours express above-average levels of *BAX* yet below-average levels of *CDKN1A*, present the interesting possibility that C-Pro ASPP1/2 mutations are positively selected based on their ability to divert the p53-family proteins from the *CDKN1A* promoter. If so, the levels of *BAX* in C-Pro ASPP mutation tumours would be increased at the expense of transcriptional activity at the *CDKN1A* promoter, thus decreasing *CDKN1A* mRNA levels. The relationship between *CDKN1A* and *BAX* z-scores in Pro-mutant tumours in both ASPP1 and ASPP2 support this hypothesis (**Figures 4.15 and 4.16**). There is an overall differentiation between N-Pro (blue) and C-Pro (green) mutant tumours with C-Pro mutations clustering in the *BAX*-positive *CDKN1A*-negative quadrant. The levels of *BAX* are significantly higher in C-Pro vs N-Pro mutant tumours (**Figure 4.16**) whereas *CDKN1A* levels are lower.

Figure 4.15 *CDKN1A* vs *BAX* z-scores in *PPP1R13B* (top) and *TP53BP2* (bottom) Pro-rich-region mutant tumours. Blue points = mutations in more N-terminal Pro-rich region (600-710 for ASPP1; 650-730 for ASPP2); green points = mutations in more C-terminal Pro-rich region (710-800 for ASPP1; 731-850 for ASPP2).

Figure 4.16 *BAX* and *CDKN1A* mRNA z-scores in *PPP1R13B*-mutant (left) and *TP53BP2*-mutant (right) tumours, focused on Pro-rich region mutants. Blue = proline rich segment closer to the N-terminus (N-Pro); green = Pro-rich segment closer to the C-terminus (C-Pro). Student's two-tailed t-test; ** $p < 0.01$.

An outstanding question is why do both N-Pro and C-Pro mutations in ASPP1 occur exclusively in wild type p53 tumours whereas C-Pro mutations in ASPP2 are associated with mutant p53? ASPP1 and ASPP2 both enhance p53-

p63- and p73-dependent transcription of *BAX*. However, ASPP2 is able to amplify p53-dependent *BAX* transcription to significantly higher fold increases than ASPP1 (Figure 4.17) (107). The effect of ASPP1 and ASPP2 on p63- and p73-dependent *BAX* transcription is equivalent within the margin of error. This suggests that there is stronger negative selection against ASPP2 C-Pro mutations in wild type-p53 tumours because the resulting *BAX* levels would be higher than in ASPP1 C-Pro tumours. This is consistent with the fact that ASPP1 C-Pro mutant tumours show a more dramatic increase in *BAX* with a mean z-score of approx. 1 compared with 0.3 for ASPP2 C-Pro mutant tumours (Figure 4.16), suggesting the presence of wild type p53 in ASPP1 C-Pro mutant tumours results in a higher magnitude of *BAX* transactivation. Therefore, the net balance between an unfavourable *BAX* increase versus favourable p21 decrease is overall tumorigenic in wild-type p53 tumours with ASPP1 C-Pro mutations, whereas likely to be overall anti-tumorigenic in wild-type p53 tumours with ASPP2 C-Pro mutations that are able to activate p53-*BAX* more robustly (Figure 4.17).

Figure 4.17 ASPP1 and ASPP2 enhance p53-family-dependent transcription of pro-apoptotic target genes. Reproduced from Bergamaschi et al (107) with permission.

Altogether, the results suggest that ASPP1 and ASPP2's ability to selectively recruit the p53-family proteins to pro-apoptotic promoters is hijacked by somatic mutations in order to maintain low levels of the cell cycle inhibitor p21 (C-Pro mutants), or inhibited in order to lower the levels of *BAX* (N-Pro mutants).

4.2.5 Pro-rich region is the top PTM regulatory domain in ASPP1

The observation of selection for missense mutations at the Pro-rich region in both ASPP1 and ASPP2 argues for an important role of this domain in regulating ASPP activity. An important way of regulating protein activity are post-translational modifications (PTMs). We asked whether the Pro-rich region played a role in regulating ASPP function by post-translational modifications. PTM data were retrieved from Phosphosite and the density of post-translationally modified sites plotted as a function of ASPP1 sequence (**Figure 4.18**).

Figure 4.18 Density of distinct post-translational modification sites in ASPP1, ASPP2 and iASPP (top, middle, and bottom, respectively).

The pattern of PTM site distribution among the 3 ASPPs offers an explanation as to the enrichment of candidate driver mutations around and within

the Pro-rich region of ASPP1: this region is the most widely used PTM regulatory domain in the ASPP1 sequence, in contrast to ASPP2 and iASPP that show a broader distribution of PTM sites and a heavily N-terminus-skewed distribution, respectively. These results suggest the Pro-rich region is the dominant regulatory domain of ASPP1 and therefore is preferentially targeted by oncogenic missense mutations to modulate, rather than completely inactivate, ASPP1's function.

The distribution of PTM sites across the Pro-rich region is uneven. In ASPP1 and ASPP2, the N-Pro segment and the preceding less conserved sequence have significantly more PTM sites than the more C-terminal side (C-Pro). Moreover, some of these C-Pro phosphorylation sites are conserved between human and mouse, and widely phosphorylated across multiple tissues, such as ASPP2 S737.

Figure 4.19 Alignment of Pro-rich region in ASPP family genes and the associated missense cancer mutations. Horizontal lines separate *TP53BP2* mutations (inside line) and *PPP1R13B* mutations (outside line). Green points indicate mutations in wild-type *TP53* tumours; red lines mark mutations in mutant-*TP53* tumours. Blue region marks the peptide interacting with Ank-SH3 domain in ASPP2: less transparent blue marks a stronger interaction, more transparent a weaker interaction. Yellow circles mark top 3 phosphorylation sites detected within the region in each protein, in human or mouse samples. The circles indicate the most frequently observed phosphosites in each protein, not an absolute frequency of phosphorylation.

Rotem et al. showed that the Pro-rich region of ASPP2 contains peptides which bind the C-terminus (Ank-SH3 domain) (253). 5 different peptides were able to bind the C-terminus, falling into 2 groups: 1) residues between 693-752 and 2) residues 893-912 (**Figure 4.19**). The strongest signal came from a peptide spanning residues 693-712. In turn, the Ank-SH3 peptides which interacted with the Pro region spanned residues 931-960 and 1083-1096. Interestingly, missense mutations in all of these regions, both in the Pro and Ank-SH3 regions, are uniformly associated with decreased tumour *BAX* levels (**Figure 4.20**). This suggests tumour missense mutations hijack ASPP2's autoregulatory interaction to decrease *BAX* transcription by inhibiting ASPP2's ability to enhance promoter activity of p53-family TFs.

Peptides shown to interact with the Ank-SH3 domain of ASPP2 end at L752. Interestingly, the most N-terminal Pro-rich region residue whose mutation is associated with increased *BAX* levels (C-Pro domain) is Y766. Therefore, the boundary between N-Pro and C-Pro based on the mutants' effects on *BAX* levels coincides with the boundary between the Ank-SH3-interacting domain (N-Pro) and the domain that does not interact (C-Pro) (**Figure 4.19**). This suggests ASPP2 N-Pro mutations modulate the directly interacting residues of N-Pro with Ank-SH3, whereas C-Pro mutations influence this binding indirectly.

Figure 4.20 Cancer mutations of residues involved in self-binding are associated with decreased *BAX* levels in human tumours. Sequence regions involved in self-interaction in ASPP2 are marked and shaded in blue.

4.2.6 C-terminal mutations in *PPP1R13L* disrupt iASPP's autoregulatory interactions

iASPP is an inhibitor of p53 and contains autoregulatory sequences which are dysregulated by CDK1 phosphorylation in melanoma (257). Therefore we asked whether this autoregulatory mechanism might also be disrupted by missense mutations in cancer. The domain distribution of missense mutations does not show a clear domain-specific interaction with p53 status, however multiple regions are mutated more frequently in wild-type p53 tumours than in p53-mutant tumours (**Figure 4.21**). These regions include residues 80-120, 440-480, 600-640 and 760-818. Interestingly, regions 80-120 and 600-640 contain an identical peptide sequence, SPRKA, that binds the Ank-SH3 domain in the C-terminus and residues 760-818 are involved in this interaction (**Figure 4.21**). Moreover, multiple residues in these regions have been mutated recurrently in

human cancer: R86 (2 counts); G92 (3 counts); H107 (2 counts); S120 (2 counts); A623 (4 counts); G761 (2 counts); R812 (4 counts).

Figure 4.21 iASPP residues preferentially mutated in wild type-p53 tumours are involved in autoregulatory interaction. (a) Distribution of missense mutations in human wild type-p53 (green) vs mutant-p53 (red) tumours; position of the Ank-SH3-interacting peptides shown; (c) iASPP peptide binding Ank-SH3 domain in the C-terminus; reproduced from Robinson et al (224) with permission. Residues marked with red circles are mutated in cancer; dots mark the number of times each residue has been mutated; yellow-filled mutations are mutations in the N-terminal SPRKA region; red-filled mutations mark direct mutations in the residues depicted in the crystal structure.

To investigate the effect of the C-terminal mutation on the interaction with iASPP's N-terminus, we recombinantly expressed C-terminal iASPP fragments and tested their binding to an N-terminal iASPP fragment. Strikingly, each C-terminal mutant showed decreased binding to the wild type-N-terminal fragment of iASPP (**Figure 4.22**). We also observed that most of the mutant residues cluster around the cleft between the ankyrin repeats and the SH3 domain, a site involved in the interaction with the Pro-rich region, with no mutations targeting residues on

the opposite face (**Figure 4.22**). Taken together, the data show missense iASPP mutations enriched in wild type-p53 tumours disrupt iASPP's autoregulatory interaction. The probable function of these mutations is to increase iASPP's inhibition of p53 by making the C-terminus available for binding, which is known to occur in wild type iASPP in melanoma by excessive CDK1 phosphorylation of the N-terminus.

Figure 4.22 iASPP mutations in the C-terminus disrupt interaction with the N-terminus. (a) Immunoprecipitation of recombinantly expressed C-terminal iASPP mutants with N-terminal wild type iASPP fragment (N-GST) and PP1 (middle lane); bottom lane = loading control for C-terminal iASPP. (b) location of C-terminal mutants within the tertiary structure.

The mutation of distinct Pro-rich regions in iASPP, including the SPRKA motifs, alongside the domain conserved between all ASPPs, points to a differential regulation of iASPP function. While most PTM sites in ASPP1 are concentrated in

and prior to the Pro-rich region, in iASPP the majority of sites are located in the N-terminal Pro-rich sequence unique to iASPP (**Figure 4.18**). Therefore, the distribution of driver missense mutations in iASPP reflects the usage of distinct regulatory sequences which are not shared by ASPP1 and ASPP2. However, despite differences in usage of specific domains, the basic paradigm of an autoregulatory intrinsically disordered domain modulating the protein-protein interactions of the ordered C-terminus by self-binding or dimerisation is shared between all 3 ASPPs, and based on the data presented in this chapter, is also targeted by missense mutations in cancer in all 3 ASPP genes.

Discussion

The data presented in section 4.2 demonstrate that ASPP's control of p53/p63/p73 activity is not only observed *in vitro*, but that this interaction shapes cancer genomes in sporadic human tumours. Specifically, we identified a genetic interaction between mutations in the Pro-rich regions of ASPP1, ASPP2 and iASPP with mutations in *TP53* and showed that these missense mutations act by perturbing the autoregulatory interaction between Pro-rich regions and the Ank-SH3 C-terminal domain, to modulate p53/p63/p73-dependent transcription at the pro-apoptotic versus cell cycle inhibitor gene promoters. These mutations seem to be mini-drivers, with evidence of positive selection in cancer but unlikely to have cell-transforming abilities in isolation. Although the absolute number of mutations detected that are likely to act by this mechanism is low, this is only a subset of the ASPP Pro-rich mutations observed in human tumours, limited by the number of tumour samples for which both exome sequencing and RNA sequencing data

were available. Thus, the total number of mutations of this class is higher than the number of dots plotted in **Figure 4.15** (see **Appendix Tables S4-S6** for all manually curated mutations).

Importantly, this methodology can be generalised to discover other mini-driver mutations. The code used to analyse genetic interactions between domain-specific missense mutations in different genes, as well as code used for mutations versus mRNA level analysis, take advantage of public APIs and can be applied to any pair of genes with non-zero mutation rate in cancer. As proof of principle, we queried the interaction between *TP53BP2* and *KRAS* mutations, which revealed a significant bias for *TP53BP2* mutations in the ubiquitin-like domain and N-Pro region of ASPP2 (**Figure 4.23**). This figure was obtained using cBioPortal public API data, demonstrating the sufficient power of the current database release (v1.2.4) to detect low-frequency mutation interactions. This figure provides further insight into the mechanism of action of N-Pro missense mutations in ASPP2. Oncogenic Ras has been shown to cooperate with ASPP2 to promote p53-dependent transcription of pro-apoptotic genes (247). S698A mutation targeting a key conserved residue in the N-Pro region of ASPP2 enhances the efficiency of this process (255). Therefore, N-Pro mutations in wild type-p53 and mutant-*KRAS* tumours are likely to limit p53's pro-apoptotic activity by dysregulating the N-Pro region of ASPP2, perhaps by strengthening the autoregulatory interaction of N-Pro with Ank-SH3, thereby increasing the relative abundance of the closed form of ASPP2 and preventing it from binding p53.

Application of similar methodology will aid in the discovery and functional annotation of rare driver and mini-driver mutations in human cancer.

Figure 4.23 Missense *TP53BP2* mutations in wild type- (green) versus mutant-*KRAS* (red) tumours.

Materials and Methods

The results presented in this chapter are in part based upon data generated by the TCGA Research Network: <http://cancergenome.nih.gov/>.

Mining somatic mutations in cancer

For manual curation of somatic mutations in ASPP genes, data were aggregated from COSMIC, cBioPortal, ICGC Data Portal and NCI Genomic Data Commons (GDC). The database versions used for final thesis figures were COSMIC v78; cBioPortal v1.2.4; ICGC r22 and GDC data release 2.0. Mutation data were parsed to synchronise classification with respect to mutation class, reference transcript, patient identifier, tissue source (primary tumour, metastasis, cell line etc), number of nonsynonymous mutations in sequenced sample, date mutation added and version of source database. Subsequently, duplicate mutations were deleted: double-indexed mutations, mutations from multiple biopsies of the same patient, mutations from different version of the same cell line etc. To control for contamination with legacy mutations that were have been removed from public databases, analyses were performed with all mutations and repeated with a set of mutations currently indexed by the source databases.

Copy number variants

Sample-level copy number data were retrieved from cBioPortal. The origin of TCGA data in cBioPortal is the Broad Firehose (<https://gdac.broadinstitute.org/>).

Mouse transposon screens

Data on mouse cancer transposon screens (insertional mutagenesis experiments) were mined from the Candidate Cancer Gene Database (<http://ccgd-starrlab.oit.umn.edu/about.php>) (380).

mRNA levels in tumour vs normal tissue

Sample-level TCGA data on mRNA levels derived from RNAseq were retrieved from the Firebrowse API (<http://firebrowse.org/api-docs/>) using scripts in the R programming language (352). Log2-transformed gene expression values were used to compare the normal vs tumour samples using a two-tailed Student's t-test. Multiple hypothesis correction was carried out by multiplying the raw p-value by the number of cancer studies tested. The R script is available in the Appendix and was tested in R version 3.3.1. Published microarray studies on tumour vs normal mRNA expression were retrieved from Oncomine (<https://www.oncomine.org/>) using the online graphical user interface (381). P values and fold changes reported by Oncomine were adopted.

sgRNA screen data

Gene-level data from the ACHILLES CRISPR screen were retrieved from the ACHILLES Data Portal (<https://portals.broadinstitute.org/achilles>). Following gene search in the Achilles v3.3.8 dataset, file entitled 'sgRNA level scores for [genename]' was downloaded. R programming language was used to plot density of the sgRNA level scores.

Chemosensitivity cell line data

Data on mRNA level correlations with drug sensitivity across cancer cell lines was retrieved from Rees et al (379). Data not included in the Supplementary information was mined through the Cancer Therapeutics Response Portal (<http://portals.broadinstitute.org/ctrp/>) or through the Cancer Target Discovery and Development (CTD2) Data Portal (<https://ctd2.nci.nih.gov/dataPortal/>). GraphPad Prism was used to produce some figures.

Genetic interaction between somatic mutations

Sample-level mutation data for a specific gene were retrieved from cBio using the R package CGDSR (<https://cran.r-project.org/web/packages/cgdsr/index.html>). The mutations were de-duplicated prior to plotting. The associated R script is available in the Appendix.

mRNA levels in mutation-carrying tumours

Sample-level mRNA z-scores were retrieved from cBio using the CGDSR package (see above). The density plots were produced using core function in R v3.3.1. The associated R script is given in the Appendix.

Post-translational modifications

PTM data were retrieved from PhosphoSite (<http://www.phosphosite.org/>) (382). The density plots were produced using core functions in R.

Cloning and protein expression

Site-directed mutagenesis was performed as described in Chapter 2. To recombinantly express C-terminal iASPP-His fragment protein (wild type and mutants), bacteria were transformed with the expression plasmid, incubated at 37°C for 16h, then protein expression induced with IPTG and the cultures incubated at ambient temperature at 250 rpm for 16 h. Resulting cultures were spun, supernatant discarded and the cell pellet sonicated on ice for 10-15 min until homogeneous. N-terminal iASPP-GST fusion protein was expressed following the same protocol.

Crystal structure visualisation

Mutated iASPP residues were visualised using Molsoft ICM Browser (Molsoft; San Diego, CA).

**CHAPTER 5: OVERCOMING T-CELL EXHAUSTION BY
SELECTIVE EXPANSION OF FOLLICULAR CYTOTOXIC T
CELLS**

RESULTS AND DISCUSSION

5.1 Exhausted effector phenotype of virus-specific CD8+ T cells in chronic LCMV infection

Figure 5.1 Sample similarity matrix for P14 cells based on gene expression
Hierarchical clustering follows similarity coefficients based on rld-transformed counts using DESeq2 package.

The signalling circuitry underlying dysfunctional T cell responses is still incompletely understood. Wherry et al. described the transcriptional profile of virus-specific CD8+ and CD4+ T cells in chronic LCMV infection (383, 384). However, these studies used microarrays as a means to determine gene expression levels, limiting the detection of certain genes. Moreover, tetramer reagent was used to isolate endogenous virus-specific T cells which might lead to minor contamination because tetramer staining often shows limited separation of

positive from negative cell populations. In order to gain a deeper understanding of the transcriptome of T cells specific for the immunodominant epitope, we used CD8⁺ T cells with a transgenic TCR specific for the gp33 epitope, which gives rise to the most abundant pool of LCMV-specific CD8⁺ T cells in B6 mice. A mouse line with a transgenic TCR specific gp33 was used as a source of antigen-specific CD8⁺ T cells (385). These mice, known as P14, were crossed with Thy1.1⁺ mice to allow for the specific identification and sorting of P14⁺ Thy1.1⁺ cells following adoptive transfer, as wild type C57BL/6 mice lack Thy1.1. Thy1.1⁺ P14 cells can be readily identified by flow cytometry and show a large separation from Thy1.1⁻ populations, minimising contamination with other cell types.

To obtain 4 sample groups of P14 cells in uninfected, acutely infected (Arm 8 d. p. i.) and chronically infected (cl13 15 and 30 d. p. i.), wild type C57BL/6 mice were injected with 2,000 P14 Thy1.1⁺ cells and infected with vehicle, LCMV Armstrong or clone 13 the following day. At day 8 post infection for Armstrong and days 15 and 30 for clone 13, splenocytes were harvested, stimulated with gp33 peptide for 2 h, and then subjected to total T cell isolation and cell sorting to isolate P14 Thy1.1⁺ cells. RNA was isolated from these cells and duplicated from each sample group were subjected to next-generation sequencing. The sample groups were abbreviated P14_naive (uninfected mice), P14_Arm_d8 (mice infected with Armstrong, 8 d. p. i.), P14_cl13_d15 and P14_cl13_d30 (mice infected with clone 13, 15 and 30 d. p. i., respectively).

Transcriptomes of all 8 samples were first compared for similarity using DESeq2. Replicates of three of the four sample groups clustered together but replicates for P14_Arm_d8 clustered independently of each other, suggesting a biological difference in the course of infection (**Figure 5.1**). One likely source of

this variability is incomplete T cell priming by LCMV Armstrong in some individuals. Therefore, additional replicates will be required to increase the robustness of this study and work is in progress to expand the sample number for both groups.

Differential expression analysis of P14 in chronic vs acute infection showed extensive overlap with the earlier study by Wherry et al. (**Figure 5.2**) (383). *Pdcd1*, which encodes the inhibitory receptor PD1, was the most prominently upregulated gene on P14 cells at d30 of chronic cl13 infection (**Figure 5.2**), along with inhibitory receptors *Lag3* and *Havcr2* (Tim3), but also chemokines *Ccl3*, *Ccl4*, *Ccl9*; and the cytokine *Ifng*. These data are consistent with the notion that exhausted CD8+ T cells first undergo priming and effector differentiation before losing cytokine production and upregulating very high levels of inhibitory receptors, hallmarks of the T cell exhaustion state.

Figure 5.2 Differential expression analysis of P14 cells in mice infected with cl13 for 30 days vs uninfected mice. Left: heatmap of top differentially expressed genes by variance; right: log₂fold change vs mean expression level for all non-zero expressed genes; significantly expressed genes marked in red.

5.2 Reduced absolute and relative numbers of terminally differentiated effector CD8⁺ T cells in chronically infected mice

To determine the phenotypic composition of the splenic CD8⁺ cell population in chronic vs acute infection, CD8⁺ cells from uninfected mice, mice infected with LCMV Arm for 8 days, and mice infected with LCMV cl13 for 30 days were sorted, stimulated with peptide of the 3 major immunodominant MHC class I epitopes (gp33, gp276 and np396), and their RNA isolated and sequenced. We

used deep sequencing (ca. 60 million reads per sample) to detect both major and minor populations of CD8+ cells.

As expected, the spleens of acutely infected mice contained significantly higher numbers of cells including CD8+ cells than uninfected or chronically infected spleens. RNA sequencing revealed that effector-associated genes dominated the transcriptional landscape of CD8+ cells in acute infection, with interferon gamma (*Ifng*) being the second most highly expressed gene by absolute level (the first one being *Eef1a1*). High levels of chemokines and effector molecules such as *Gzma* and *Gzmb* were also observed, consistent with an activated effector phenotype dominating the CD8+ population during acute infection.

Table 5.1 Sequencing reads obtained and mapping efficiency for total CD8+ cell samples (sequenced using paired-end 2x150 bp reads).

Sample	No. of reads	% mapped uniquely (mm10)
N1	57,282,531	86.68
N2	56,760,138	87.51
Arm1	64,322,597	89.79
Arm2	63,714,021	89.81
CI13-1	71,119,014	89.83
CI13-2	63,096,875	83.75
Mean	62,715,863	88.14

Similar to the antigen-specific P14 cells during chronic infection, differential expression analysis of CD8+ cells in chronically infected vs uninfected mice identified *Pdcd1*, as the most significantly upregulated gene in chronic infection (adjusted $p < 10^{-250}$). This is consistent with the fact that although PD1 levels increase upon T cell activation, very high sustained levels of PD1 are a hallmark of T cell exhaustion (**Figure 5.3**). Other upregulated genes include interferon-

induced GTPases *ligp1*, *Gbp2b*, *Gbp2*, *Gbp3*, *Igtp*, *ligp1* and others, which are known to dominate the transcriptome of cells stimulated with interferon gamma; chemokines *Cxcl10*, *Ccl4*; effector molecules *Gzma*, *Gzmb*, *Gzmk*; inhibitory receptor *Tigit*; inhibitory ligand *Cd274* (encodes PD-L1); enzyme *Odc1* (ornithine decarboxylase, a gene associated with cell transformation); pro-apoptotic genes *Bcl2l11*, *Fasl* and transcription factors *Ar*, *Plagl1*, *Irf4*, *Zhx2* and *Zeb1*. These results show that CD8⁺ cells in chronically infected mice contain effector-differentiated T cells but that those cells express inhibitory receptors and pro-apoptotic genes, indicative of T cell exhaustion.

Figure 5.3 *Pdcd1* mRNA levels across CD8⁺ total, virus-specific and CD8⁺ CD44^{low} cells in uninfected, acutely infected and chronically infected mice.

To compare the CD8⁺ cell compartments between chronically and acutely infected mice, we calculated differential gene expression between c13 d30 and Arm d8 samples. Surprisingly, *Pdcd1* was not differentially expressed between these two groups (**Figure 5.3**). Given that virus-specific exhausted CD8⁺ T cells

express very high levels of *Pdcd1*, this result suggests the relative concentration of effector CD8⁺ T cells in the chronically infected spleen is significantly reduced compared with the acutely infected mice. Indeed, the second most significantly upregulated gene in chronically vs acutely infected mouse-derived CD8⁺ cells was *Sell*, encoding L-selectin, a marker of naïve and memory CD8⁺ T cells. Therefore, chronically infected mice not only possess reduced numbers of splenocytes compared to acutely infected and uninfected mice, but they also show a lower percentage of effector-differentiated CD8⁺ T cells within the splenic CD8⁺ compartment.

Significantly downregulated genes in chronic vs acute infection include chemokines *Ccl1*, *Ccl4*; effector molecules *Gzma*, *Gzmb*, *Gzmc*; cytokines *Ifng*, *Il2*; regulators of T-cell activation *Cd44*, *Cd5*, *Cd80*, *Cd52*, *Ctla4*. This is consistent with a decrease in the percentage of effector CD8⁺ T cells in chronic infection and the onset of exhaustion.

5.3 Distinct transcriptional response to IFN- γ in effector vs naïve CD8⁺ T cells

The observed increase in interferon-induced GTPases in chronic infection despite the lower levels of *Ifng* presents a potential paradox. In mice, cell-autonomous defence GTPases of the GBP and IRG subfamilies dominate the transcriptional response to IFN- γ , accounting for over 30% of the genes induced by IFN- γ in mouse primary cells (386). IFN- γ response is mediated by the IFNGR receptors 1 and 2, encoded by *Ifngr1* and *Ifngr2* in mice. Whereas most mammalian cell lineages express these receptors, effector-differentiated CD8⁺ T cells lack *Ifngr2* transcripts (**Figure 5.4**). This suggests IFN- γ cannot signal

through the canonical heterodimer of IFNGR1 and IFNGR2 which is classically required for response to IFN- γ (387). IFNGR2, sometimes called IFNGR- β , is also absent in T_H1-polarised CD4⁺ T cells which are insensitive to the anti-proliferative effect of IFN- γ on T_H2-polarised CD4⁺ T cells (388). Therefore, the lack of robust transcription of IFN- γ -induced GTPases in effector and exhausted CD8⁺ T cells might reflect the low-to-no levels of IFNGR2 in these cells. In contrast, naïve CD8⁺ T cells express *Ifngr1* and *Ifngr2* and upregulated IFN- γ -induced GTPases upon viral infection. Given that spleens in chronically infected mice contain a higher percentage of naïve CD8⁺ T cells than spleens of acutely infected mice, the observed IFN- γ target gene transcripts might originate from the naïve CD8⁺ T cells exposed to IFN- γ which is being secreted by the remaining population of incompletely exhausted effector T cells. Alternatively, the observation of these interferon stimulated genes might reflect a shift in STAT signalling in the process of T cell exhaustion. In CD4⁺ T cells, absence of transcription factor T-bet causes an aberrant overlap between genes induced by type I IFN and IFN- γ (389). Indeed, GTPase genes including *Gbp2* and *ligp1* can also be induced by IFN- β and mRNA levels of T-bet were reduced in cl13-infected versus Arm-infected mice (**Figure 5.4**). It is possible that the lack of a repressor such as T-bet in exhausted CD8⁺ T cells leads to the expression of type I IFN targets through activation of IFNGR.

Figure 5.4 Lack of *Ifngr2* mRNA expression in antigen-experienced CD8+ T cells and reduced expression of *Tbx21* in CD8+ T cells from chronically infected mice.

5.4 Non-coding transcription at the immunoglobulin locus in a subtype of CD8+ cells enriched in chronic infection

Following the transcriptomic characterisation of LCMV gp33-specific (P14) and total CD8+ T cells in uninfected, acutely infected and chronically infected mice, we asked how the transcriptional landscape of naive CD44^{low} CD8+ T cells differed between chronic and acute infection. Sample clustering produced 4 distinct clusters with all CD8+ CD44^{low} cells forming one cluster, infected CD8+ total samples forming another cluster, all but one P14 sample from infected mice forming a third cluster, and naive P14 with P14_Arm_d8_2 forming a small cluster between the other P14 samples and CD8+ total samples. This is consistent with the fact that CD8+ total samples contain both CD8+ CD44^{low} cells and effector cells which are almost invariably CD44-high.

Figure 5.5 Transcriptomes of CD44^{low} cells, P14 cells and CD8^{total} samples cluster by group (CD8^{tot} naïve not shown). Sample distance matrix computed from gene counts in DESeq2.

Hierarchical clustering of samples based on the 50 top-variance genes surprisingly revealed a cluster of immunoglobulin genes as those that differentiate CD8⁺ total cells in chronically infected mice (c13 d30) from P14 cells and CD8⁺ CD44^{low} cells regardless of infection status (**Figure 5.6**). These immunoglobulin genes feature both constant and variable fragments of the heavy chain with some minor contribution from the kappa light chain.

Figure 5.6 A cluster of immunoglobulin genes distinguishes total CD8+ cells in chronically infected mice from other samples.

Figure 5.7 Presence of sterile heavy chain immunoglobulin transcripts in CD8+ splenocytes. Top: mapped reads in naïve (top track) and cl13_d30 CD8+ cells; view of the constant mu exons, constant delta exons, J segments and several D segments. Bottom: close-up view of the J segments and the surrounding non-coding regions. The region distal to the J1 segment is lost during somatic recombination in B cells.

Examining mapped reads surrounding the J segments of the heavy chain locus revealed extensive transcription in the distal region prior to the J1 segment. This non-coding region is lost during D to J recombination in B cell development which occurs on both alleles. Therefore, splenic B cells cannot express transcripts originating in this region and the observed reads serve as a marker of sterile transcription on un-recombined heavy chain immunoglobulin locus. Whether transcripts originating from recombined *Igh* loci exist in CD8+ T cells remains to be determined and will require more stringent negative controls as protein-coding *Igh* transcripts can originate from splenic B cells. These results demonstrate that CD8+ splenic cells exhibit sterile transcription at the heavy chain locus and the relative abundance of these reads within the CD8+ pool increases in chronic infection. Whether the observed sterile transcription of immunoglobulin intron sequence plays a functional role in T cells remains to be determined.

5.5 Follicular cytotoxic T cells (T_{FC}) selectively expand following IFNAR blockade

In conjunction with the presence of sterile immunoglobulin transcripts, we observed an upregulation of genes traditionally associated with follicular helper CD4+ T cells (T_{FH}) and germinal centre responses such as *Bcl6* and *Zeb1* (**Figure 5.8**). Interestingly, a novel subtype of CD8+ T cells characterised by the

expression of T_{FH}-associated markers *Tcf7*, *Cxcr5* and *Bcl6* has recently been discovered and named follicular cytotoxic T cells (T_{FC}) (214, 392, 393).

Examination of our data revealed that genes which distinguish the CXCR5⁺ T_{FC} population from CXCR5⁻ CD8⁺ T cells are all upregulated in CD8⁺ T cells in chronically infected mice when compared to acutely infected mice (**Figure 5.8**).

This suggests chronic LCMV infection is associated with an increase in the relative number of T_{FC} within the CD8⁺ compartment.

Figure 5.8 Upregulation of T_{FC}-associated genes in CD8⁺ T cells from chronically infected mice.

Given that antibody-mediated IFNAR blockade significantly accelerates clearance of LCMV clone 13 and is associated with increased germinal centre responses (394, 395), we wondered how T_{FC} are affected by IFNAR blockade. Wild type mice were treated with anti-IFNAR1 antibody or isotype control, followed by clone 13 infection and adoptive transfer of 2,000 virus-specific Thy1.1⁺ P14 cells. At day 10 post infection, Thy1.1⁺ P14 cells were sorted, and their RNA subjected to RNA-sequencing. In a principal component analysis the top two principal components separated naïve, isotype-treated and anti-IFNAR1 treated

cells into distinct clusters (**Figure 5.9A**). Interestingly, the variance separating naïve P14s from the two infected groups largely followed principal component 1 (PC1), a component orthogonal to the bulk of variance separating isotype and anti-IFNAR1-treated cells (parallel to PC2). Consistently, marker genes of T cell activation such as *Cd44* were comparably expressed in the infected P14 groups compared to naïve (**Figure 5.10**). This suggests P14 cells were activated in both anti-IFNAR1 and vehicle treated mice but developed distinct gene expression patterns.

Figure 5.9 Blockade of IFNAR significantly perturbs the transcriptome of virus-specific CD8⁺ T cells toward the T_{FC} phenotype. P14 cells were transferred into isotype or α IFNAR1 treated mice, followed by LCMV CL-13 infection the next day. P14 cells were then sorted at day 10 post infection and subjected to RNA-seq analysis. (A) Principal components analysis of naive, isotype-treated, or α IFNAR1-treated P14 cells separates P14 cells by treatment group. (B) Relative gene expression of top 25 genes with the highest variance between isotype- or α IFNAR1-treated P14 cells. (C) Volcano plot showing statistical significance (p value) versus fold increase of gene expression comparing α IFNAR1-treated P14 cells to isotype-treated control. Left half: downregulated

with aIFNAR1 treatment; Right half: upregulated with aIFNAR1 treatment. Genes with important function in T cells were highlighted. (D) Heat map of differentially expressed genes with key functions in CD8 T cells separated by functional class. (E) Normalized counts of *Cxcr5*, *Tcf7*, *Id3*, and *Havcr2* in P14 cells from uninfected, and LCMV CI-13 infected plus isotype control- or aIFNAR1-treated groups. (F) Gene set enrichment analysis demonstrating a significant enrichment of T_{FC} gene signature within P14 of the aIFNAR1-treated group but not the isotype-treated controls. T_{FC} gene set was constructed from publicly available dataset (GSE84105) by taking top 100 genes most significantly upregulated in CXCR5⁺ Tim3⁻ CD8⁺ cells versus CXCR5⁻ Tim3⁺ CD8⁺ T cells. Statistical significance was determined using DESeq2 and GSEA (see Materials and Methods).

Figure 5.10 Increased T_{FC} transcriptional signature in P14 cells from aIFNAR1-treated mice. (A) Normalized gene count of *Cd44* in P14 cells from uninfected, LCMV-infected isotype-treated and LCMV-infected aIFNAR1-treated mice. (B) Heatmap of genes with important functions in T cells in aIFNAR1 versus isotype control-treated mice infected with LCMV CI-13. Gene panel was adapted from Im et al. (214).

Differential expression analysis of P14s in anti-IFNAR1 versus isotype control-treated mice revealed 3565 differentially expressed genes (FDR<0.05).

P14 cells in anti-IFNAR1 treated mice expressed increased relative levels of surface markers *Sell*, *Fas* and *Ii7r*, molecules associated with naïve and memory

CD8⁺ T cells, while expressing lower levels of effector molecules such as *Ccl3*, *Ccl4*, *Ccl5* and *Gzmb* (**Figure 5.9C,D**). Strikingly, previously identified T_{FC} marker genes *Cxcr5*, *Tcf7* and *Id3* were among the 15 most significantly upregulated genes in P14 cells from anti-IFNAR treated versus isotype-treated mice (**Figure 5.9C-E**).

Quantifying the effect of anti-IFNAR1 versus isotype control treatment on the T_{FC} expression signature, the top 100 genes most significantly upregulated in virus-specific CXCR5⁺ Tim3⁻ cells compared to CXCR5⁻ Tim3⁺ cells were significantly enriched in the anti-IFNAR1 treated group (**Figure 5.9F**). Leong et al. recently reported the transcriptomes of CXCR5⁺ and CXCR5⁻ P14 cells from mice infected with the Docile clone of LCMV (396). Remapping the raw data together with our P14 RNA-seq data using a common pipeline and subsequent principal component analysis revealed that the majority of transcriptional variance separating CXCR5⁺ from CXCR5⁻ P14 cells is identical to the variance separating anti-IFNAR1 from isotype control-treated mice-derived P14 cells (**Figure 5.9G**). FACS experiments confirmed that T_{FC} are indeed significantly expanded during cl13 infection following IFNAR1 blockade (Huang, Zak and Pratumchai et al., manuscript in preparation). Taken together, these data show that T_{FC} cells share a characteristic transcriptome signature that can be readily identified across independent studies, and that IFNAR1 blockade during LCMV infection significantly increases the relative number of T_{FC} cells within the virus-specific CD8⁺ pool.

5.6 Unexpected upregulation of type I Interferon-stimulated genes in P14 cells following IFNAR1 blockade

Type I interferon is known to induce a gene expression programme relying on the STAT and IRF family transcription factors (397, 398). Intriguingly, we observed a significant upregulation of type I interferon stimulated genes (ISGs) in mice treated with anti-IFNAR1 compared with the isotype-treated controls (**Figure 5.11**). Gene set enrichment analysis demonstrated a strong upregulation of the Gene Ontology set Response to Type I Interferon after anti-IFNAR1 blockade versus isotype controls whereas no enrichment of this set was observed in genes upregulated in isotype controls versus anti-IFNAR1 treated mice (**Figure 5.11A**). This is unlikely to be caused by resurgence of IFNAR activity following antibody treatment because virus-specific CD4⁺ T cells expressed significantly lower levels of ISGs in anti-IFNAR1 treated mice compared to controls as expected (**Figure 5.12**).

IFNAR is not the only receptor able to activate the JAK-STAT pathway; cytokine receptors can also signal through JAK-STAT (399). Therefore, it is possible that alternative signals converging on the JAK-STAT axis give rise to the observed transcription of genes that are also induced by IFNAR activation. For example, IFN- γ receptor (IFNGR) activation induces IFN- β -stimulated genes in CD4⁺ T cells in the absence of T-bet (389). We asked whether T-bet deficiency in the presence of IFN- γ might be responsible for the observed ISG expression. Although levels *Tbx21*, the gene encoding T-bet, were significantly reduced in P14 cells from anti-IFNAR versus isotype-treated mice, the gene is still expressed at moderate levels (**Figure 5.12**). Moreover, expression of *Ifngr1* in P14 cells was reduced even more significantly than expression of *Tbx21* (**Figure 5.12**).

Therefore, IFNGR activity is unlikely to be solely responsible for the upregulation of ISGs following INFAR blockade.

It is possible that the upregulation of type I IFN target genes is partly caused by the increased ratio of TFC to effector CD8⁺ T cells. Indeed, we observed that CXCR5⁺ TIM3⁻ CD8⁺ T cells express higher levels of type I IFN stimulated genes than CXCR5⁻ TIM3⁺ CD8⁺ T cells (**Figure 5.11C**). This effect was replicated in CXCR5⁺ vs CXCR5⁻ P14 cells (**Figure 5.11D-E**). However, the entire P14 cell compartment is not composed merely of CXCR5⁺ cells. Moreover, the mice were treated with anti-IFNAR antibody, suggesting type I IFN signalling should be attenuated. Therefore, other factors are likely to contribute to the observed upregulation of type I IFN stimulated genes.

Figure 5.11. T_{FC} phenotype is associated with increased expression of type 1 IFN stimulated genes. (A) Significant enrichment of type 1 IFN response genes in P14 cells from aIFNAR1-treated mice versus isotype-treated controls. Analysis was performed using GSEA. (B) Gene expression heatmap of Gene Ontology ‘Response to type 1 interferon’ gene set in P14 cells from aIFNAR1 versus isotype control treated mice. (C) Fold change of genes in the Gene Ontology ‘Response to type 1 interferon’ gene set in CXCR5⁺ Tim3⁻ CD8⁺ versus CXCR5⁻ Tim3⁺ CD8⁺ T cells (GSE84105) calculated using GEO2R. (D) Gene expression heatmap of Gene Ontology ‘Response to type 1 interferon’ gene set in CXCR5⁺ versus CXCR5⁻ P14 cells from mice infected with LCMV Docile (GSE76279). (E) Normalized gene counts of type 1 IFN receptor chains (*Ifnar1*, *Ifnar2*) and example type 1 IFN stimulated genes (*Ifit1*, *Irf7*) in CXCR5⁺ P14, CXCR5⁻ P14 (GSE76279) and P14 cells from aIFNAR1-treated and isotype control treated mice. Read counts were normalized using a single pipeline containing both datasets.

Figure 5.12. Reduced expression of type I IFN stimulated genes in virus-specific CD4⁺ T cells during cI13 infection following IFNAR blockade (left). *Tbx21* and *Ifngr1* levels in P14 cells following IFNAR blockade (right).

5.7 IL-27 induces transcription of canonical type I interferon target genes via STAT1

Two other cytokines are also known to activate the JAK-STAT pathway: IL-6 and IL-27. These cytokines bind distinct receptors which however share a common subunit, gp130 (400). IL-6 levels in serum of cI13-infected mice are significantly increased by IFNAR1 blockade (394). It is unknown how levels of IL-

27 are affected by IFNAR1 blockade. We set out to investigate whether IL-6 and/or IL-27 signalling on virus-specific CD8⁺ T cells after IFNAR blockade might contribute to the observed upregulation of ISGs.

The distinct transcriptional responses elicited by IL-6 versus IL-27, and their utilisation of STAT1 versus STAT3, were extensively characterised by Hirahara et al. (401). Making use of their publicly available RNA-seq data, we compared genes upregulated by IL-6 and/or IL-27 treatment with genes upregulated in mice treated with anti-IFNAR versus isotype-treated controls. To ensure uniformity, raw sequencing reads were remapped and differential expression analysis performed using a common pipeline for all datasets. 39% of genes induced by both IL-27 and IL-6 at 6 h post-treatment were also significantly upregulated by anti-IFNAR versus isotype. These genes included the cytokine *Il21* and transcription factor *Maf*, which are both important for T_{FH} function (402), but overall no Gene Ontology terms were enriched at a statistically significant level. Strikingly, a strong bias was observed in the overlap between IL-6-only-induced versus IL-27-only-induced genes with anti-IFNAR-upregulated genes: 20% of IL-6-only-induced genes at 6 h post-treatment were also significantly upregulated after anti-IFNAR versus isotype whereas the overlap was 50% for IL-27-only-induced genes and anti-IFNAR upregulated genes ($p = 4.0 \times 10^{-7}$, Fisher's exact two-tailed test) (**Figure 5.13**). This bias towards IL-27- versus IL6-induced genes was also observed for genes upregulated at 24 h after treatment ($p = 4.0 \times 10^{-5}$, Fisher's exact two-tailed test) (**Figure 5.13**). Therefore, although genes induced by both IL-6 and IL-27 were upregulated in anti-IFNAR- versus isotype-treated mice, IL-27-specific target genes were significantly enriched in the anti-IFNAR-induced transcriptome compared to IL6-specific targets.

Figure 5.13. Comparison or the overlap between IL-6 and IL-27-induced genes with genes upregulated by anti-IFNAR vs isotype treatment. Publicly available data (GSE65621) were used to obtain genes induced by IL-6 and/or IL-27 compared to vehicle-treated cells, and compared to differentially expressed genes from anti-IFNAR vs isotype-treated mice.

Enrichment analysis of genes induced by both IL-27 and anti-IFNAR treatment showed a highly significant overlap with type I IFN target genes: the top enriched GO term was 'cellular response to interferon-beta (Bonferroni-corrected $p = 8.4 \times 10^{-20}$). The enrichment of these type I IFN target genes remained highly significant for genes induced at 24 h post-IL-27-treatment (**Figure 5.13**). In addition, mRNA levels of the IL-27 receptor subunit *WSX1* that is not shared with the IL-6 receptor and is encoded by the *Il27ra* gene, were significantly increased following IFNAR blockade (**Figure 5.14**). Expression of *Il6ra* was also increased but remained at much lower absolute levels than *Il27ra*. The striking overlap

between IL-27 and type I IFN induced genes stems from their activation of STAT1. Whereas IL-6 preferentially induces STAT3 phosphorylation, the response to IL-27 is skewed towards STAT1, a transcription factor also activated by IFNAR (401). These results lend credence to the hypothesis that IL-27R activation in the presence of anti-IFNAR antibody results in the transcription of canonical type I IFN stimulated genes, offering to resolve the apparent paradox.

Figure 5.14. mRNA levels of IL-27 and IL-6 receptors are increased following IFNAR blockade. Normalised counts shown, mean \pm s.d. p-values were calculated using DESeq2 package, differential expression analysis function and adjusted for multiple hypothesis testing.

5.8 IL-27R is essential for the selective expansion of T_{FC} following IFNAR blockade

Having determined IL-27R as a candidate receptor that is over-activated on P14 cells following IFNAR blockade, we wondered whether this activation had functional significance during LCMV cl13 infection. Wild-type and IL-27R-deficient mice (*Il27ra*^{-/-}) were treated with anti-IFNAR1 antibody or IgG1 isotype control and

infected with LCMV cl13. At day 9 post infection, virus-specific splenic T cells were examined using a tetramer stain and FACS. The percentage of CD4⁺ T_{FH} cells of total CD4⁺ T cells increased in a similar manner in both wild type and *Il27ra*^{-/-} mice after anti-IFNAR treatment (**Figure 5.15A-C**). Consistently with previous studies, germinal centre B cells also exhibited a relative increase following IFNAR blockade and this effect was replicated in *Il27ra*^{-/-} mice (**Figure 5.15D-F**). Remarkably, although the percentage of virus-specific T_{FC} increased in wild type mice following IFNAR blockade, this increase was completely abolished in *Il27ra*^{-/-} mice (**Figure 5.15G-I**). Taken together, these data demonstrate that IL-27R is required for the selective expansion of virus-specific T_{FC} and this requirement holds even in the presence of expanded germinal centres and T_{FH} cells. (Experiments in Section 5.8 were performed in collaboration with Isaraphorn Pratumchai and Zhe Huang; Huang, Zak and Pratumchai et al., manuscript in preparation).

Figure 5.15 *I127ra*^{-/-} mice do not exhibit expansion of T_{FC} following IFNAR blockade. Panels A, D, G show the number of T_{FH}, GCB and T_{FC} cells in the spleen; panels B, E, H show the percentage of T_{FH}, GCB and T_{FC} cells of their parent population as specified. Experiments performed in collaboration with Isaraphorn Pratumchai.

Discussion

The introduction of checkpoint inhibitors in cancer therapy brought unprecedented clinical responses. These therapies, including antibodies targeting PD-1, PD-L1 and CTLA-4, rely in part on the ability to reactivate tumour-specific CD8⁺ T cells that had lapsed into the hypofunctional state of T cell exhaustion. Two factors that still limit checkpoint inhibitor responses are epigenetically-imprinted durability of T cell exhaustion, and scarcity of tumour-specific T cell clones which may not have the ability to self-renew (403, 404). The recent identification of T_{FC} as the cell type responsible for the proliferative burst of CD8⁺ effector cells following anti-PD-1 treatment (214) opened doors to strategies towards improving the efficacy of checkpoint inhibitors.

Here we examined the transcriptional landscape of total and virus-specific CD8⁺ T cells during the exhaustion-associated phase of persistent viral infection. Previously identified markers of exhaustion were upregulated on virus-specific P14 cells during chronic versus acute infection. However, we also observed upregulation of T_{FC} markers such as *Bcl6* in total CD8⁺ T cells, suggesting the percentage of T_{FC} of total CD8⁺ T cells increases during persistent versus acute infection. Treatment with anti-IFNAR1 antibody prior to LCMV cl13 infection significantly increased the expression of T_{FC} markers in virus-specific P14 cells and FACS experiments confirmed the selective expansion of both the total number and percentage of T_{FC} among virus-specific CD8⁺ T cells. Intriguingly, type I IFN stimulated genes were also upregulated following IFNAR blockade. We found a combination of factors as the likely cause: increased *Ifnar1*, *Ifnar2* and type I IFN target genes on CXCR5⁺ versus CXCR5⁻ P14 T cells; reduced levels of T-bet following IFNAR blockade enabling activation of type I IFN targets by IFN- γ , and

induction of STAT1 by IL-27. Given that type I IFN and IL-27 both activate STAT1 and share a significant number of downstream target genes, blockade of IFNAR likely acts to amplify the magnitude of IL-27 downstream signalling even in the presence of a stable amount of IL-27 ligand.

Experiments with IL-27R-deficient mice demonstrated the essential role of IL-27R in the selective expansion of T_{FC} following IFNAR blockade. Wu et al. previously showed that IFNAR^{-/-} P14 cells form a higher percentage of T_{FC} during LCMV infection (405). Therefore, it is possible that IFNAR blockade leads to prioritisation of IL-27-dependent STAT1 target genes which positively regulated T_{FC} proliferation and/or survival. If so, activation of IL-27 signalling in the presence of attenuated IFN signalling might potentiate the efficacy of anti-PD-1 by expanding the T_{FC} population, thereby increasing the tumour-specific CD8⁺ T cell pool. Future experiments are warranted to address whether modulation of the IL-27/IFN balance can enhance anti-PD-1 responses.

Materials and Methods

LCMV virus stocks

LCMV Armstrong and LCMV clone 13 (406) were propagated in BHK cells. BHK cells were infected with virus and incubated for 60 h, then virus harvested from the medium. Viral stocks were aliquoted and kept at -80 °C.

Antibody treatments

Mice were treated with 1 mg of anti-IFNAR1 antibody intraperitoneally (clone MAR1-5A3) or a mouse IgG1 isotype control (clone MOPC21) one day prior to virus infection. For PD-L1 blockade, isotype or aIFNAR1 treated LCMV CI-13 infected mice received 200 mg isotype or anti-PD-L1 antibody every 3 days starting on day 15 post infection with a total of 5 treatments, then T cells and viral titers were analyzed at day 35.

Mouse LCMV infections

Wild-type C57BL/6 mice were injected intraperitoneally with LCMV Armstrong 200 µl at 10⁶ pfu/ml, or intravenously using the tail vein with LCMV clone 13 at 2x10⁶ pfu/ml in a total volume of 200 µl.

Splenocyte isolation and counting

Mice were sacrificed using a lethal dose of isoflurane and mouse spleens dissected. The spleens were injected with collagenase and incubated at 37°C for

30 min, then mechanically disrupted using a cell strainer, RPMI and a syringe. The resulting cell suspension was subjected to red blood cell (RBC) lysis, spun at 1500 rpm for 10 min and the supernatant removed. The RBC-free splenocytes were resuspended in RPMI and counted using the BioRad automated TC20 cell counter and slides.

T cell stimulation and isolation

Splenocytes were seeded in a 96-well plate at a concentration of 1 million per well in 200 μ l of T cell stimulation medium. Gp33 peptide was added at a final concentration of 20 μ M in medium to each well and the cells incubated at 37°C for 2 h. Subsequently the cells were pooled, spun at 1,500 rpm for 10 min and the supernatant discarded. The cell pellet was subjected to total T cell isolation using the Mouse Total T cell Isolation kit (Stem Cell Technologies) following the manufacturer's instructions.

Cell staining and sorting

Total mouse T cells were resuspended in stain buffer (PBS with 1% FBS) and appropriate antibodies added. The suspension was incubated at 4°C for 30 min, spun at 1,500 rpm for 10 min, supernatant discarded and cells resuspended in sorting buffer (PBS, 1% FBS, 1 mM EDTA). The cells were subjected to sorting at the Flow Cytometry Core Facility and collected in sort buffer.

RNA isolation

RNA from total CD8⁺ cells was isolated using the RNeasy Mini Kit (Qiagen; Hilden, Germany) with a DNase digest step using the RNase-Free DNase Set (Qiagen; Hilden, Germany) according to the manufacturer's instructions. RNA from P14 cells was isolated using the PicoPure RNA Isolation Kit (Thermo Fisher; Waltham, MA) with a DNase digest step using the RNase-Free DNase Set (Qiagen; Hilden, Germany) according to the manufacturer's instructions. The RNA integrity was assessed by the Bioanalyzer (Agilent; Santa Clara, CA, USA).

RNA sequencing

For RNA from total CD8⁺ cells with satisfactory RIN scores (>8.5), libraries were constructed using the polyA-capture kit (NEB) and subjected to 2x150 bp sequencing on the NextSeq 500 sequencer (Illumina; San Diego, CA) at a mean depth of ca. 62.7 million reads per sample. For RNA from P14 cells with satisfactory RIN scores, libraries were constructed using the SMARTer v2 Universal Low Input RNA kit (Clontech; Mountain View, CA) and subjected to 2x150 bp sequencing on the NextSeq 500 sequencer (Illumina; San Diego, CA) at a mean depth of 25 M. For RNA from P14 cells with anti-IFNAR1 or isotype treatment amplified cDNA was prepared using SMART-Seq v4 Ultra Low Input RNA Kit (Clontech, Mountain View, CA), sheared using Covaris tubes (Covaris, Woburn, MA) and Illumina libraries constructed using the NEBNext Ultra DNA Library Prep Kit (NEB, Ipswich, MA) and sequenced using the NextSeq 500 system (Illumina, San Diego, CA) at a depth of 20-25 million single-end 75 bp reads per sample. Illumina's bcl2fastq Conversion Software (version 2.17.1.14) was used to de-multiplex reads and convert BCL files generated by the Illumina NextSeq 500 to FASTQ.

Read mapping and differential expression analysis

Quality of raw RNA-sequencing reads was checked using FastQC version 0.11.3 (Barbaham Institute, Cambridge, UK; <http://www.bioinformatics.babraham.ac.uk/projects/fastqc/>). Reads were mapped to the mouse genome (GRCm38 assembly with Ensembl v87 transcriptome annotations) and gene counts calculated using STAR version 2.5.2a (407) using the following parameters: `--quantMode GeneCounts --outSAMtype None --sjdbGTFfile /Ensembl/Mus_musculus.GRCm38.87.gtf --sjdbOverhand 74`. Statistical normalization and differential expression analysis were performed using the R package DESeq2 version 1.14.1 (408).

Principal component analysis and expression data visualisation

Principal component analysis was performed using R function `prcomp`, and the top 500 genes with the highest variance between samples were used. R version 3.3.2 was used for statistical analyses (352). Heatmaps were generated using R package `pheatmap` version 1.0.8 (409). Volcano plots were generated using custom code in the R language. GSEA version 2.2.3 was used for gene set enrichment analysis (410). Gene expression signature for CXCR5⁺ Tim3⁻ CD8⁺ versus CXCR5⁻ Tim3⁺ CD8⁺ T cells was retrieved from the publicly available dataset (GSE84105) by comparing CXCR5⁺ Tim3⁻ to CXCR5⁻ Tim3⁺ samples with GEO2R and calculating top 100 CXCR5⁺ specific genes by statistical significance (411). Raw RNA-sequencing data for CXCR5⁺ and CXCR5⁻ P14 cells (GSE76279) were re-analyzed using the pipeline described above.

THESIS CONCLUSIONS

The goal of this thesis was to identify and functionally assess candidate pathogenic variants in cancer and congenital disorders. We have identified novel pathogenic deletions causing the 1q41q42 microdeletion syndrome; a candidate pathogenic 1q41q42 deletion in encephalocele; candidate pathogenic 1q41q42 microduplications, *de novo* single-nucleotide variants in childhood-onset schizophrenia and autism spectrum disorder; missense variants in neural tube defects, and candidate driver somatic mutations in cancer. The candidate pathogenic variants identified in this thesis are summarised in **Table 6.1**.

Table 6.1 Summary of disease-associated variants identified. Where appropriate, ACMG evidence codes and classification are given.

Variant	Phenotype	<i>De novo</i> / inherited	ACMG evidence codes (SNV)	ACMG classification (congenital disorders)	Notes
1q41q42 deletions	1q41q42 microdeletion syndrome; encephalocele	Most <i>de novo</i>	-	Pathogenic	Brain MRI consistent with <i>TP53BP2</i> dosage effect
1q41q42 duplication 1:223820857-224076362dup	Microcephaly; developmental delay, seizures, vision problems	Inherited (maternal)	-	Uncertain significance	Brain MRI consistent with <i>TP53BP2</i> dosage effect
1q41q42 duplication 1:222694279-224034322dup	Microcephaly, developmental delay, craniofacial, dental abnormalities, abnormal behaviour	Inherited (maternal)	-	Uncertain significance	Distal breakpoint within <i>TP53BP2</i>
<i>PPP1R13B</i> R72Q	Childhood-onset schizophrenia	<i>De novo</i>	PS2, PM2	Likely pathogenic

<i>TP53BP2</i> K513fs + LoH	Prostate carcinoma	Somatic	-	Likely pathogenic	
<i>TP53BP2</i> P898fs + LoH	Lung squamous cell carcinoma	Somatic	-	Likely pathogenic	ASPP2-deficient mice get spontaneous lung carcinomas
<i>PPP1R13B</i> Pro-rich region missense mutations	Solid tumours	Somatic	-	Likely pathogenic	Enriched in wild-type-p53 tumours, associated with <i>BAX</i> and p21 levels
<i>TP53BP2</i> Pro-rich region missense mutations	Solid tumours	Somatic	-	Likely pathogenic	Associated with <i>BAX</i> and p21 levels
<i>PPP1R13L</i> autoregulatory domains missense mutations	Solid tumours	Somatic	-	Likely pathogenic	Mutations disrupt self-binding; associated with <i>BAX</i> levels

Using a mouse model of ASPP2 deficiency, we showed that *TP53BP2* haploinsufficiency is likely to be responsible for structural brain abnormalities, and potentially encephalocele risk in 1q41q42 microdeletion patients, and that other phenotypes such as ventricular septal defect, cleft palate, and urogenital abnormalities also overlap between ASPP2-deficient mice and humans. Our

observation of microcephaly, developmental delay and seizures associated with 1q41q42 microduplications suggests *TP53BP2* is also triplosensitive in humans, albeit with incomplete penetrance. Analyses of spatiotemporal gene expression in human brain development, brain MRIs of *TP53BP2* CNV patients, and phenotypes of *ASPP2*-deficient mice suggest a function for *ASPP2* in promoting the differentiation of striatum from the ganglionic eminences. *TP53BP2* deletion, diploid and duplication patients show an association between *TP53BP2* copy number, and caudate nucleus and lateral ventricle volumes. Dosage sensitivity of *TP53BP2* may also lead to abnormalities in ganglionic eminence-derived GABAergic interneuron populations in the cortex, which might underlie the observed epilepsy in 2/3 *TP53BP2* duplication patients.

Future studies will pinpoint the most critical developmental processes which are sensitive to *TP53BP2* dosage. Given that *ASPP2* plays a role in multiple steps of CNS development and *ASPP2* deficiency is associated with multiple distinct CNS phenotypes in mice, it is possible *TP53BP2* deletions confer both NTD risk and brain abnormality risk. Larger sample sizes are needed to deconvolve the contributions of haploinsufficiencies of individual genes towards the 1q41q42 microdeletion syndrome; current evidence supports a role for *DISP1*, *TP53BP2*, *FBXO28*, but other genes such as *CAPN2* might also play a role. Importantly, our approach can be generalised to discover other dosage-sensitive genes in brain development. By integrating patient CNV and MRI data with population genomic statistics (such as ExAC), and patterns of spatiotemporal gene expression in brain development, it is possible to identify dosage-sensitive gene candidates and link them to the most critical stages in brain development.

Three *de novo PPP1R13B* mutations have been identified in childhood-onset schizophrenia and autism spectrum disorder. Based on the absence of 2/3 mutations from public databases, *PPP1R13B*'s pattern of expression in neurons, its spatiotemporal co-expression with synaptic genes, and the observation of ASPP1 protein in synaptic fractions, these mutations are biologically plausible candidate pathogenic variants. The newly generated ASPP1-deficient mice will provide a useful experimental system in which to assess the role of ASPP1 in brain development.

In a cohort of 340 neural tube defect cases, we identified a burden of rare missense variants in the apoptotic regulators *TP53* and *TP73*, including two loss-of-function variants (p53 G279E; p73 V190F) and one recurrent variant in *TP53* significantly enriched over the general population at a single-variant level (p53 E358V). This study also found a case-specific enrichment of missense variants in the aPKC-binding domain of *PARD3*, which were experimentally shown to disrupt Par3's binding to aPKC. The collective burden of these rare variants might point to a single step in neural tube closure: apical constriction. Par3 is known to control this process via aPKC-dependent control of ROCK. Recently, apoptotic cells have been shown to drive apical constriction by pulling myosin II cables (412). If this process also controls apical constriction in neural tube closure, the enrichment of both *PARD3* and *TP53* pathway missense variants in NTD cases might point to genetic disruption of apical constriction as a risk factor for human NTDs. This hypothesis is consistent with the implication of *PARD3* CNVs in NTD risk, and the discovery of 2 independent *de novo* truncating mutations in *SHROOM3*, another regulator of ROCK-dependent apical constriction.

An unbiased integrative analysis of cancer clarified the role of ASPP genes in human tumorigenesis. *PPP1R13B* shows highly concordant hallmarks of a tumour suppressor gene, with a causal role supported by multiple mouse mutagenesis screens and the recurrence of truncating variants in multiple cancer types, most prominently colorectal cancer. Based on the unequivocal multi-source evidence for ASPP1's tumour suppressive role in colorectal cancer, truncating *PPP1R13B* mutations can be considered pathogenic. *PPP1R13L* shows hallmarks of an Epi-driver oncogene, being broadly upregulated across cancer types, and high iASPP levels correlating with cancer drug resistance. *TP53BP2* has context-dependent behaviour suggesting pleiotropic function which may be pro- or anti-tumorigenic depending on the tissue type and molecular makeup of each tumour. This bipolar nature of *TP53BP2*'s role is in contrast to the molecular functions uncovered for ASPP2 so far, which are virtually all tumour suppressive. The genomic data suggest ASPP2 can play tumour promoting roles, or at least be compatible with tumour growth in certain tissues. Investigating these oncogenic modes of ASPP2's action at the molecular level will help bridge the gap between the current mechanistic understanding of ASPP2 and the genomic view of *TP53BP2* in human tumours.

Our mechanistic analysis of missense mutations in cancer uncovered a common theme of dysregulation: mutation of the autoregulatory Pro-rich regions in order to modulate p53 family-dependent transcriptional activity. This example serves as proof of principle that rare somatic mutations can be positively selected, and the methodology employed in discovering them can be scaled up to a genome-wide search. With the rise of harmonised cancer genomic data

repositories, cloud computing and public APIs, such analyses can be applied to discover a class of rare driver and mini-driver mutations which are otherwise overlooked by gene-level burden-type tests such as MutSig2CV.

Overall, the data presented in this thesis expand the genomic catalogue of human disease, and inform our understanding of the genetic architectures of congenital diseases and cancer. High-penetrance CNVs identified in syndromic developmental delay cases are consistent with a known role for *de novo* and rare CNVs in these disorders. In contrast, the diverse polygenic burden of rare missense variants found in our NTD cohort highlights the complex genetic makeup of this disease and suggests many incompletely penetrant rare variants, both SNVs and CNVs, may comprise the genetic risk of NTDs. In cancer, our results support a role for rare somatic mutations that are likely to be highly context-dependent, for example ASPP2 N-Pro mutations observed in *KRAS*-mutant wild type-*TP53* tumours. Such context-dependent mutations shift the view of somatic cancer genomes from Mendelian-like, with dominant oncogenic alleles and recessive tumour suppressor mutations in a sea of passengers, to a more complex architecture which includes a significant contribution from rare alleles of moderate to small effect.

ACMG Guidelines on variant classification

Appendix Table S1. ACMG Guideline criteria for classifying pathogenic variants.

Reproduced from Richards et al. (65) with permission.

Evidence of pathogenicity	Category
Very strong	<p>PVS1 null variant (nonsense, frameshift, canonical ± 1 or 2 splice sites, initiation codon, single or multiexon deletion) in a gene where LOF is a known mechanism of disease</p> <p>Caveats:</p> <ul style="list-style-type: none"> • Beware of genes where LOF is not a known disease mechanism (e.g., <i>GFAP</i>, <i>MYH7</i>) • Use caution interpreting LOF variants at the extreme 3' end of a gene • Use caution with splice variants that are predicted to lead to exon skipping but leave the remainder of the protein intact • Use caution in the presence of multiple transcripts
Strong	<p>PS1 Same amino acid change as a previously established pathogenic variant regardless of nucleotide change</p> <p>Example: Val→Leu caused by either G>C or G>T in the same codon</p> <p>Caveat: Beware of changes that impact splicing rather than at the amino acid/protein level</p> <p>PS2 De novo (both maternity and paternity confirmed) in a patient with the disease and no family history</p> <p>Note: Confirmation of paternity only is insufficient. Egg donation, surrogate motherhood, errors in embryo transfer, and so on, can contribute to nonmaternity.</p> <p>PS3 Well-established in vitro or in vivo functional studies supportive of a damaging effect on the gene or gene product</p> <p>Note: Functional studies that have been validated and shown to be reproducible and robust in a clinical diagnostic laboratory setting are considered the most well established.</p> <p>PS4 The prevalence of the variant in affected individuals is significantly increased compared with the prevalence in controls</p> <p>Note 1: Relative risk or OR, as obtained from case-control studies, is >5.0, and the confidence interval around the estimate of relative risk or OR does not include 1.0. See the article for detailed guidance.</p> <p>Note 2: In instances of very rare variants where case-control studies may not reach statistical significance, the prior observation of the variant in multiple unrelated patients with the same phenotype, and its absence in controls, may be used as moderate level of evidence.</p>
Moderate	<p>PM1 Located in a mutational hot spot and/or critical and well-established functional domain (e.g., active site of an enzyme) without benign variation</p> <p>PM2 Absent from controls (or at extremely low frequency if recessive) (Table 6) in Exome Sequencing Project, 1000 Genomes Project, or Exome Aggregation Consortium</p> <p>Caveat: Population data for insertions/deletions may be poorly called by next-generation sequencing.</p> <p>PM3 For recessive disorders, detected in <i>trans</i> with a pathogenic variant</p> <p>Note: This requires testing of parents (or offspring) to determine phase.</p> <p>PM4 Protein length changes as a result of in-frame deletions/insertions in a nonrepeat region or stop-loss variants</p> <p>PM5 Novel missense change at an amino acid residue where a different missense change determined to be pathogenic has been seen before</p> <p>Example: Arg156His is pathogenic; now you observe Arg156Cys</p> <p>Caveat: Beware of changes that impact splicing rather than at the amino acid/protein level.</p> <p>PM6 Assumed de novo, but without confirmation of paternity and maternity</p>
Supporting	<p>PP1 cosegregation with disease in multiple affected family members in a gene definitively known to cause the disease</p> <p>Note: May be used as stronger evidence with increasing segregation data</p> <p>PP2 Missense variant in a gene that has a low rate of benign missense variation and in which missense variants are a common mechanism of disease</p> <p>PP3 Multiple lines of computational evidence support a deleterious effect on the gene or gene product (conservation, evolutionary, splicing impact, etc.)</p> <p>Caveat: Because many in silico algorithms use the same or very similar input for their predictions, each algorithm should not be counted as an independent criterion. PP3 can be used only once in any evaluation of a variant.</p> <p>PP4 Patient's phenotype or family history is highly specific for a disease with a single genetic etiology</p> <p>PP5 Reputable source recently reports variant as pathogenic, but the evidence is not available to the laboratory to perform an independent evaluation</p>

LOF, loss of function; OR, odds ratio.

Appendix Table S2. ACMG Guideline criteria for classifying benign variants.
 Reproduced from Richards et al. (65) with permission.

Evidence of benign impact	Category
Stand-alone	BA1 Allele frequency is >5% in Exome Sequencing Project, 1000 Genomes Project, or Exome Aggregation Consortium
Strong	BS1 Allele frequency is greater than expected for disorder (see Table 6)
	BS2 Observed in a healthy adult individual for a recessive (homozygous), dominant (heterozygous), or X-linked (hemizygous) disorder, with full penetrance expected at an early age BS3 Well-established in vitro or in vivo functional studies show no damaging effect on protein function or splicing BS4 Lack of segregation in affected members of a family Caveat: The presence of phenocopies for common phenotypes (i.e., cancer, epilepsy) can mimic lack of segregation among affected individuals. Also, families may have more than one pathogenic variant contributing to an autosomal dominant disorder, further confounding an apparent lack of segregation.
Supporting	BP1 Missense variant in a gene for which primarily truncating variants are known to cause disease
	BP2 Observed in <i>trans</i> with a pathogenic variant for a fully penetrant dominant gene/disorder or observed in <i>cis</i> with a pathogenic variant in any inheritance pattern
	BP3 In-frame deletions/insertions in a repetitive region without a known function
	BP4 Multiple lines of computational evidence suggest no impact on gene or gene product (conservation, evolutionary, splicing impact, etc.) Caveat: Because many in silico algorithms use the same or very similar input for their predictions, each algorithm cannot be counted as an independent criterion. BP4 can be used only once in any evaluation of a variant.
	BP5 Variant found in a case with an alternate molecular basis for disease
	BP6 Reputable source recently reports variant as benign, but the evidence is not available to the laboratory to perform an independent evaluation
	BP7 A synonymous (silent) variant for which splicing prediction algorithms predict no impact to the splice consensus sequence nor the creation of a new splice site AND the nucleotide is not highly conserved

Appendix Table S7. Top brain regions by *PPP1R13B* expression (human brain)

Age	Region with the highest <i>PPP1R13B</i> expression	Top level structure	ASPP1 level
8 pcw	upper (rostral) rhombic lip	neural plate	2.5409
9 pcw	dorsal thalamus	thalamus	2.6319
12 pcw (3 samples)	dorsal thalamus	thalamus	2.62-2.86
13 pcw	mediodorsal nucleus of thalamus	thalamus	3.328
13 pcw	cerebellum	neural plate	2.91
16 pcw	mediodorsal nucleus of thalamus	thalamus	3.22

Appendix

17 pcw	striatum	basal nuclei (basal ganglia)	3.25
19 pcw	mediodorsal nucleus of thalamus	thalamus	3.10
21 pcw	striatum	basal nuclei (basal ganglia)	3.15
24 pcw	primary somatosensory cortex (area S1, areas 3,1,2)	neural plate	2.67
37 pcw	primary auditory cortex (core)	neural plate	2.94
4m (2 samples)	primary visual cortex (striate cortex, area V1/17)	neural plate	3.07; 2.99
10m	cerebellar cortex	Neural plate	3.77
1 yr	primary visual cortex (striate cortex, area V1/17)	Neural plate	3.18
2 yr	primary somatosensory cortex (area S1, areas 3,1,2)	Neural plate	2.20
3 yr (2 samples)	cerebellar cortex	Neural plate	3.39; 3.11
4 yr	cerebellar cortex	Neural plate	2.70
8 yr (2 samples)	cerebellar cortex	Neural plate	3.30
11 yr	cerebellar cortex	Neural plate	2.99
13 yr	cerebellar cortex	Neural plate	3.19
15 yr	cerebellar cortex	Neural plate	3.13
18 yr	cerebellar cortex	Neural plate	2.79
19 yr	cerebellar cortex	Neural plate	3.28
21 yr	cerebellar cortex	Neural plate	3.20
23 yr	cerebellar cortex	Neural plate	3.27
30 yr	cerebellar cortex	Neural plate	3.18
36 yr	cerebellar cortex	Neural plate	3.31
37 yr	cerebellar cortex	Neural plate	3.20
40 yr	primary visual cortex (striate cortex, area V1/17)	Neural plate	2.84

Appendix Figure S8. *TP53BP2* expression TP vs NT from Firehose data run 2016_01_28.

Appendix Figure S9. *PPP1R13L* expression TP vs NT from Firehose data run 2016_01_28.
