ABSTRACT

By using a set of different star formation rate (SFR) indicators, including *Wide-field Infrared Survey Explorer* (WISE) mid-infrared and H α emission, we study the slope of the main sequence (MS) of local star-forming galaxies at stellar masses larger than $10^{10} M_{\odot}$. The slope of the relation strongly depends on the SFR indicator used. In all cases, the local MS shows a bending at high stellar masses with respect to the slope obtained in the low-mass regime. While the distribution of galaxies in the upper envelope of the MS is consistent with a lognormal distribution, the lower envelope shows an excess of galaxies, which increases as a function of the stellar mass but varies as a function of the SFR indicator used. The scatter of the best lognormal distribution increases with stellar mass from ~ 0.3 dex at $10^{10} M_{\odot}$ to ~ 0.45 at $10^{11} M_{\odot}$. The MS high-mass end is dominated by central galaxies of group-sized haloes with a red bulge and a disc redder than the lower mass counterparts. We argue that the MS bending in this region is due to two processes: (i) the formation of a bulge component as a consequence of the increased merger activity in groups, and (ii) the cold gas starvation induced by the hot halo environment, which cuts off the gas inflow on to the disc. Similarly, the increase of the MS scatter at high stellar masses would be explained by the larger spread of star formation histories of central group and cluster galaxies with respect to lower mass systems.

Key words: galaxies: evolution – galaxies: groups – galaxies: haloes – galaxies: starburst – galaxies: star formation.

1 INTRODUCTION

The formation and assembly of the stellar content of galaxies remain at the heart of galaxy evolution studies. Recent advances have led to an emerging picture where most galaxies form stars at a level dictated mainly by their stellar masses, and regulated by secular processes. This is seen as a rather tight relation between galaxy star formation rate (SFR) and stellar mass, so-called main sequence (MS) of star-forming galaxies, in place from redshift ~ 0

up to ~ 4 (e.g. Brinchmann et al. 2004; Noeske et al. 2007; Elbaz et al. 2007; Daddi et al. 2007; Pannella et al. 2009; Magdis et al. 2010; Schreiber et al. 2015). The SFR increases with the stellar mass (M_*) as a power law, $\text{SFR} \propto M_*^{\alpha}$, with an intrinsic scatter of about 0.2–0.3 dex for moderate to relatively low stellar mass galaxies (Speagle et al. 2014; Whitaker et al. 2015). Measurements of the slope α vary widely in the literature, ranging between 0.6 and 1.2 (see summary in Speagle et al. 2014). The observed relation suggests that prior to the shutdown of star formation, galaxy star formation histories are predominantly regular and smoothly declining on mass-dependent time-scales (see also Heavens et al. 2004), rather than driven by stochastic events like major mergers and

★ E-mail: paola.popesso@tum.de

starbursts. However, Ilbert et al. (2015) suggest that the scatter of the relation is not constant but it increases as a function of stellar mass, at least up to $z \sim 1.4$, reflecting a larger variety of star formation histories for the most massive galaxies.

Several studies also suggest that the relation is not a power law, but it exhibits a curvature with a flatter slope at the high-mass end with respect to the low-mass regime (Lee et al. 2015; Schreiber et al. 2015; Whitaker et al. 2015; Tomczak et al. 2016) though bending is not found in other studies (e.g. Rodighiero et al. 2014; Speagle et al. 2014).

Recently Renzini & Peng (2015, hereafter **RP15**) propose two different definitions of the MS: the ridge line connecting the peak of the 3D number density distribution of galaxies over the $\log(\text{SFR})$ – $\log(M^*)$ plane, or of the similar 3D distribution where the z -coordinate is given by the product of the number of galaxies times their SFR. Such definitions are defined as ‘objective’ because they do not require any selection of the SF galaxy population and do not make any assumption on the shape of SFR distribution around the MS. The two definitions give nearly parallel relations in the SDSS galaxy spectroscopic sample at $z < 0.085$ with slope 0.76 ± 0.06 over the stellar mass range of 10^8 – $10^{10.5} M_\odot$, without any particular bending as in Whitaker et al. (2014, see also Magnelli et al. 2014).

The MS relations retrieved in the literature differ for a variety of reasons, including how galaxies are selected in the first place. For example, pre-selecting MS galaxies, by separating *quenched* from star-forming systems, may include galaxies on their way to be quenched with low but still detectable SFR (for example using a colour selection, such as the *UVJ* selection). Such inclusion would have the effect of flattening the SFR– M^* relation.

An additional source of discrepancy might be due to the method used to locate the MS. The SFR distribution in the MS region is found in most of the cases to be lognormal (e.g. **RP15**). However, for such distribution, mean, median, and mode are different and would, then, provide different MS locations. Thus, comparing MS defined as the median of the lognormal distribution [the peak in the $\log(\text{SFR})$ – $\log(\text{mass})$ plane] might differ from the results retrieved in the stacking analysis and based on the mean galaxy SFR. In addition, if the SFR distribution around the MS deviates from a lognormal distribution, the discrepancy of the different indicators might further diverge. Brinchmann et al. (2004) show clearly that in the local Universe the lower envelope of the MS in the SDSS spectroscopic sample, in particular, at the high-mass end, exhibits a valley between the MS and the quiescence region, analogously to the so called ‘green valley’ in the mass–colour diagram. These excesses might affect, to different extend, the indicators used to identify the relation.

It is adamant, then, that knowing the SFR distribution in the MS region is the most robust way to properly study the MS relation and its scatter. To this aim, in this paper, we present the analysis of the SFR distribution in the MS region for galaxies with masses above $10^{10} M_\odot$ in the local Universe. Such distribution is used to define the MS location and its scatter and to investigate the biases due to the SFR indicators and the method used to locate the mean. To this aim, we use the most robust and reliable SFR indicators available in the local Universe, either the dust corrected $H\alpha$ -based SFR, or the combination of the UV light emitted by young stars and the infrared (IR) luminosity, accounting for the UV component absorbed and reprocessed by dust. In particular, in the local Universe we use two different samples: the SDSS spectroscopic sample with SFR based mainly on corrected $H\alpha$ SFR (Brinchmann et al. 2004) and the *Wide-field Infrared Survey Explorer* (*WISE*) sample matched to the SDSS sample of **S16**, with SFR based on *WISE* 22 μm data, when

available, and dust corrected UV-based SFR. To further check our results, we use also the far-IR *H-ATLAS Herschel/SPIRE*-based SFR of Valiante et al. (2016).

The paper is structured as follows. Section 1 describes our data set. Section 2 presents our method. Section 3 shows our results and Section 4 contains the summary of the findings and the discussion. We assume a Λ CDM cosmology with $\Omega_M = 0.3$, $\Omega_\Lambda = 0.7$, and $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$ throughout the paper.

2 DATA AND SAMPLE SELECTION

In the following section, we describe the local galaxy sample, which is defined on the basis of different catalogues and SFR indicators. The comparison of the different SFR indicators is shown in the Appendix. In this section, we describe the main results of such comparison.

2.1 The local galaxy sample

2.1.1 The SDSS data set

The first local galaxy sample is drawn from the Sloan Digital Sky Survey (SDSS; York et al. 2000). In particular, we use the spectroscopic catalogue containing $\sim 930\,000$ spectra belonging to the seventh data release (DR7; Abazajian et al. 2009). The spectra cover a wavelength range from 3800 to 9200 Å. They are obtained with 3 arcsec diameter aperture fibres. Further details concerning the DR7 spectra can be found at <http://www.sdss.org/dr7/>. The choice of the DR7 sample is dictated by the use of the SFR and M_* measurements taken from the MPA-JHU catalogue,¹ based on DR7. The stellar masses are obtained from a fit to the spectral energy distribution (SED) by using the SDSS broadband optical photometry (see Kauffmann et al. 2003; Salim et al. 2005 for details). The SFR measurements are based on the Brinchmann et al. (2004) approach. The $H\alpha$ emission line luminosity is used to determine the SFRs for the star-forming galaxies, as classified in the BPT diagram. For all other galaxies, either AGN or non-emission line galaxies, the SFRs are inferred from D4000–SFR relation (e.g. Kauffmann et al. 2003). The SFR estimates based on $H\alpha$ flux are corrected for dust extinction on the basis of the Balmer decrement. All SFR measures are corrected for the fibre aperture following the approach proposed by Salim et al. (2007). The stellar masses and SFRs are computed by assuming a Kroupa IMF and are adjusted to a Chabrier IMF for consistency with the other data sets. The accuracy of the $H\alpha$ and D4000 SFR indicators is performed and discussed in the Appendix.

2.1.2 The WISE data set

The *GALEX*–SDSS–*WISE* Legacy Catalog (GSWLC; Salim et al. 2016, hereafter **S16**) is obtained by cross-matching the SDSS spectroscopic catalogue with the *GALEX* UV and *WISE* data base in addition to SDSS and 2MASS photometric information. It contains physical properties of 700 000 galaxies with SDSS redshifts at $0.01 < z < 0.30$. GSWLC contains galaxies within *GALEX* footprint, regardless of a UV detection, altogether covering 90 per cent of SDSS. We use, in particular, the subsample with medium-deep *GALEX* observations of ~ 1500 s exposure (GSWLC-M), which covers 49 per cent of the SDSS area. This is done to combine relatively deep UV observations and high statistics. Indeed, the ‘deep’

¹<http://www.mpa-garching.mpg.de/SDSS/DR7/>

catalogue (GSWLC-D) samples only 7 per cent of the SDSS area, resulting in a rather poor statistics. GSWLC utilizes *WISE* observations at 22 μm (*WISE* channel W4) to determine SFRs independently of the UV/optical SED fitting. The depth of *WISE* observations over the sky is not uniform, but is still much more uniform than *GALEX* depth, and essentially covers the entire sky without gaps. The average 5σ depth in the W4 channel is 5.4 mJy.

The mid-IR SFRs in GSWLC are estimated from the total IR luminosity (8–1000 μm) by interpolating the luminosity-dependent IR templates of Chary & Elbaz (2001) so that they match the 22 μm flux. The IR luminosities (L_{IR}) are tested using Dale & Helou (2002) templates, where the IR SED shape-luminosity dependence is imposed from empirically calibrated relations of Marcella et al. (2006). The agreement is excellent with a scatter of 0.02 dex. To obtain mid-IR SFRs from IR luminosity, S16 use a simple conversion given by Kennicutt (1998), adjusted to Chabrier IMF using the 1.58 conversion factor (S07):

$$\log\text{SFR} = \log(L_{\text{IR}}) - 9.996, \quad (1)$$

where SFR is in $\text{M}_{\odot} \text{yr}^{-1}$ and the L_{IR} in L_{\odot} . The GSWLC provides also an estimate of stellar masses, SFRs and dust attenuations derived via SED fitting from the UV to the mid-IR data. The SED fitting is performed using the state-of-the-art UV/optical SED-fitting technique code CIGALE (Noll et al. 2009). A comparison between SFRs derived from SED fitting and mid- and far-IR-derived SFRs is provided in the Appendix. Despite a general agreement, the SFRs based on the SED-fitting tend to be underestimated with respect to the *WISE* SFR, in particular in the region well above the local MS locus. This results in a very large scatter of 0.4 dex with respect to the 1 to 1 relation.

Similarly to the GSWLC, also Chang et al. (2015) provide stellar masses and SFRs for a sample of 1 million galaxies drawn from the SDSS New York University Value-Added Galaxy Catalog (NYU-VAGC; Blanton et al. 2005; Adelman-McCarthy et al. 2008; Padmanabhan et al. 2008) and crossed-match with *WISE* data. However, as shown in the Appendix, the SFRs based on the SED fitting derived with MAGPHYS (da Cunha, Charlot & Elbaz 2008; da Cunha et al. 2012) from the UV to the W3 or W4 *WISE* channel at 12 and 22 μm , respectively, tend to be underestimated with respect to the H α -based and the SPIRE-based SFR. Thus, we use, in the further analysis, the *WISE* and SED-fitting SFR of GSWLC.

2.1.3 The H-ATLAS Herschel/SPIRE data set

Bourne et al. (2016) provide the DRI catalogue of multiwavelength associations to the H-ATLAS sources detected in the 5 *Herschel* bands at 100 and 160 μm with PACS and 250, 350, and 500 μm with SPIRE over an area of $\sim 150 \text{ deg}^2$. The IR sample is described in Valiante et al. (2016). Namely, the 250 μm detections are used as priors for the source extraction in the remaining *Herschel* bands. Thus, the H-ATLAS catalogue is a 250 μm -selected catalogue. The Valiante et al. (2016) catalogue includes 120 230 sources in total, with 113 995, 46 209, and 11 011 sources detected at $>4\sigma$ at 250, 350, and 500 μm , where the 1σ level is 7.4, 9.4, and 10.2 mJy, respectively. Bourne et al. (2016) provide a cross-match with SDSS, *GALEX*, 2MASS, and *WISE* photometry and with the SDSS and GAMA spectroscopic catalogues. We use the subsample of H-ATLAS DRI catalogue with spectroscopic counterpart at $z < 0.085$.

The total IR luminosity is estimated from the far-IR data as follows. We use all the available far-IR data points, with the addition

of the *WISE* 22 μm data point, when available, to compute the IR luminosities integrating the best SED template in the range 8–1000 μm . To this aim we use two different sets of templates to check the model dependence. We use the MS and starburst (SB) templates of Elbaz et al. (2011) and the set of Magdis et al. (2014). All templates provide IR luminosities extremely consistent to each other with an rms of 0.05 dex (see the Appendix). We refer to this *Herschel* far-IR luminosity-based SFRs as the most accurate measure of the galaxy SF activity. This is used in the Appendix to check the reliability of most of the other SFR indicators.

2.2 SFR indicators and samples

Each local galaxy sample described above presents different biases due to the combination of different selection effects and SFR indicators. To investigate such biases we check the reliability of the different SFR indicators and methods by comparing different SFR measures with the far-IR derived SFR, based on all the available mid and far-IR data points. All the plots of such comparison are shown in the Appendix. Here, we report the main results of such analysis. As shown in the Appendix, the *Herschel* based SFR are in very good agreement with the H α -based SFR of the MPA-JHU catalogue, with a 0.2 dex scatter (the left-hand panel of Fig. A2). The same agreement is observed between the mid-IR *WISE* SFR of S16 and the *Herschel* based SFR, with a scatter of 0.18 dex around the 1 to 1 relation (Fig. A7).

A much larger discrepancy is observed with the D4000-based SFR of the MPA-JHU sample. In the majority of the cases the D4000-based SFR estimate is heavily underestimated with respect to the far-IR-based SFR (the left-hand panel of Fig. A3). The unreliability of the D4000 SFR estimates is confirmed also when comparing the SFRs based on the mid-IR *WISE* SFR at 22 μm , which sample a larger range of SFR with respect to the far-IR H-ATLAS data set (the right-hand panel of Fig. A3). Also in this case the D4000-based SFRs appear to be on average 0.7 dex below the 1 to 1 relation with a quite large scatter of 0.4 dex. On the contrary, when compared with the SED-fitting SFR of S16 below the MS, the D4000-based SFR tends to provide a 1–2 dex overestimated SFR (Fig. A3), showing to be highly unreliable also in the quiescence region.

As shown in Fig. 1, the H α -based SFRs of the MPA-JHU catalogue sample very well the region down to 2σ below the MS of RP15 up to stellar masses of $10^{10.6} \text{ M}_{\odot}$. Above this threshold, the unreliable D4000 SFR estimates dominate the lower envelope of the MS and above $10^{10.8} \text{ M}_{\odot}$ they account for most of the SFR of the MS. It is, then, clear that the MPA-JHU SFR estimates cannot be used to study the location of the MS and its shape above $\sim 10^{10.6} \text{ M}_{\odot}$.

To overcome this problem, we use the calibration proposed by Oemler et al. (2017). As shown in the Appendix, such correction, based mainly on the galaxy inclination and the rest-frame NUV – g colour, where NUV is the *GALEX* near-uv filter and g is the SDSS g band, is able to correct most of the effects mentioned above, as clearly outlined also in the appendix of Oemler et al. (2017). In the further analysis, we will consider only the SFRs corrected according to the Oemler et al. (2017) calibration (see the Appendix for more details).

The SFRs based on the SED fitting of S16 correlate with the *Herschel* based SFRs with a larger scatter of 0.28 dex with respect to the *WISE* SFRs of the same catalogue (Fig. A7). We point out, however, that as shown in Fig. A8, the SFR based on SED fitting of the UV and optical range tend to be underestimated up to 0.5 dex at

Figure 1. Distribution of MPA-JHU galaxies in the $\log(\text{SFR})$ – $\log(M^*)$ plane colour-coded as a function of percentage of galaxies with SFR derived from dust corrected $H\alpha$ emission, in bin of SFR and stellar mass. The peak of the MS distribution at different stellar mass bins in the $\log(\text{SFR})$ – $\log(M^*)$ plane is overplotted (connected points) to show the peak of the SFR distribution in the Ms region. The error bars show the dispersion of the relation around the peak.

higher level of SFR. Indeed, we see a clear anticorrelation between the ratio of the SED-fitting SFR and the far-IR SFR as a function of the distance from the MS. For this exercise, we use the MS of **RP15** up to $10^{10.6} M_{\odot}$. This indicates, as expected, that the SFR based on UV+optical data is not capable of capturing the SF activity of the most star-forming and dusty objects well above the MS. The ratio of the two SFR estimates is, instead, around 1 for galaxies on and below the MS.

While the SFR based on *WISE* data sample mainly the MS region but only partially the lower envelope, the combination of the SED-fitting-based SFR below the MS and the *WISE*-based SFR above and on the MS provides the most reliable set of SFR to study the location and the shape of the MS in the local Universe. Instead, due to the rather shallow flux limit at $250 \mu\text{m}$, the H-ATLAS galaxy sample is located mainly in the upper envelope of the MS and provide only a partial sampling of the relation.

In order to investigate the possible biases induced by the different sets of SFR estimates and selections, we perform the analysis of the SFR distribution in the MS locus in the same way, separately, with different galaxy samples. We discuss, then, consistency, discrepancies, and biases. In particular, we use (a) the MPA-JHU catalogue corrected with the calibration of Oemler et al. (2017, hereafter **O17**), defined by its SFR indicators as ‘ $H\alpha + D4000 \text{ O17}$ ’ sample, (b) the **S16** sample with $22 \mu\text{m}$ *WISE* SFR, when available, and SFR from SED fitting for all *WISE* undetected galaxies (hereafter ‘*WISE*+SED fit’ sample), (c) the subsample of **S16** limited to *WISE* detected sources at $22 \mu\text{m}$, complemented with galaxies classified as star forming in the BPT diagram and with SFR derived from dust corrected $H\alpha$ in the MPA-JHU catalogue (hereafter ‘*WISE*+ $H\alpha$ ’

sample), (d) the **S16** sample with SFR based purely on SED fitting (hereafter ‘SED fit’), and (e) and the H-ATLAS sample (hereafter ‘SPIRE’ sample). The sample (a) is used to study the distribution of the SFR around the MS below $10^{10.8} M_{\odot}$ in the upper envelope and at the peak of the MS, which is mostly sampled by the $H\alpha$ -based SFR estimates (Fig. 1). The samples (a) and (b) are able to cover also the lower envelope and the quiescence region of the $\log(\text{SFR})$ – $\log(M^*)$ plane and are used to investigate the SFR distribution also well below the MS. The sample (c) is based on the most reliable SFR indicators available in the local Universe, and it is used to study accurately the shape of the SFR distribution in the MS region. The sample (d) is used to check the biases due to the UV selection and the SED-fitting technique. The (e) sample is limited to the shallow H-ATLAS survey, and it is used only to check the shape of upper envelope of the SFR distribution retrieved with the other samples. In all cases, we apply a redshift cut at $z = 0.085$ in order to ensure mass and SFR completeness down to $10^{10} M_{\odot}$ (see also Peng et al. 2010).

All SFR and stellar masses are converted to a Chabrier IMF, when necessary, for consistency.

2.3 Sample completeness

In order to limit the analysis to a stellar mass complete sample, we cut each sample at $z < 0.085$ and stellar masses of $10^{10} M_{\odot}$.

For the ‘ $H\alpha + D4000 \text{ O17}$ ’ sample, the completeness in SFR is the same as for the mass, because a measure of the SFR is provided for each galaxy either from the $H\alpha$ emission or from the $D4000$ –SFR scaling relation of Salim et al. (2007), corrected for the **O17** calibration see previous subsections for details). For the **S16** ‘*WISE*+SED fit’ and ‘SED fit’ samples, the completeness in SFR for galaxies above our stellar mass threshold is the same, because a measure of the SFR is always provided at least via SED fitting. For the **S16** ‘*WISE*+ $H\alpha$ ’ sample, the completeness is dictated mainly by the completeness limit of the *WISE* catalogue in the W4 channel, whose sources dominate in number the sample. To be conservative, we indicate such threshold, corresponding to the SFR at the 5σ *WISE* flux limit, as our completeness limit. However, we point out that complementing the **S16** *WISE* subsample with the SF galaxies of the MPA-JHU sample populates the lower envelope of the MS, because the $H\alpha$ -based SFR mostly sample the MS well below the peak of the distribution at least up to $10^{10.6} M_{\odot}$, as shown in Fig. 1.

Above this mass threshold, however, the $H\alpha$ -based SFR is available only for a small percentage of galaxies, in particular in the lower envelope of the MS. Thus, the SFR distribution of the **S16** ‘*WISE*+ $H\alpha$ ’ sample in the high-mass range might be biased against faint sources in the far-IR (less dusty objects). The ‘SPIRE’ sample, which is purely far-IR selected, shares the same problem. Its completeness limit is set to the SFR corresponding to the 5σ limit at $250 \mu\text{m}$.

3 THE DEFINITION OF THE LOCAL MS

In this section, we measure the location of the MS in the local Universe at $z < 0.085$, where the SDSS spectroscopic sample offers an exquisite statistics for such purpose.

3.1 The SFR distribution in the $\log(\text{SFR})$ – $\log(M^*)$ plane

For each sample, we analyse the distribution of the galaxies SFR in a fine grid of stellar mass bins (0.2 dex wide in the 10^{10} – $10^{11} M_{\odot}$ stellar mass range). In order to properly find the location of the MS

and define the SFR distribution around it, we fit the SFR distribution with a lognormal component. We stress that we exclude from the fitting procedure the lower envelope of the MS, which could bias either the location or the dispersion of the best-fitting lognormal. The fit is limited to the region down to 0.3 dex below the MS, so to avoid any bias due to a possible excess of galaxies in the valley between the MS and quiescence region.

In the following analysis, we study the shape of the distribution of the residuals $\Delta MS = \log(\text{SFR}_{\text{gal}}) - \log(\text{SFR}_{\text{MS}})$, given by the distance from the SFR of the individual galaxy (SFR_{gal}) and the SFR on the MS at the mass of the galaxy (SFR_{MS}). In particular, we use as reference the relation of [RP15](#). This is obtained as the ridge line connecting the peak of the SFR distribution in the $\log(\text{SFR})$ – $\log(M^*)$ plane in the stellar mass range of 10^8 – $10^{10.5} M_{\odot}$, where the H α SFRs of the MPA-JHU sample dominate in number the MS region (see previous section). Thus, we consider it an accurate estimate of the MS location in the low stellar mass regime. The best fit is a power law with $\log(\text{SFR}) \propto \log(M^*)^{\alpha}$, with $\alpha = 0.76$ and scatter $\sigma \sim 0.3$. This approach allows us to verify if the MS is bending at higher stellar masses with respect to the best-fitting relation of the lower stellar mass regime.

Fig. 2 shows the distribution of the residuals ΔMS for the different galaxy samples considered here. In all cases, the upper envelope is well fitted by a lognormal distribution (the black Gaussian in logarithmic scale in each panel).

The lower envelope of the MS, instead, deviates, as expected, from a lognormal distribution with increasing significance towards higher masses, in particular in the ‘H α + D4000 O17’, the ‘WISE+SED fit’ and ‘SED fit’ samples. However, the shape of the distribution below the MS strongly depends on the SFR indicator used. In the ‘H α + D4000 O17’ sample the lower envelope and the high-mass end of the MS are sampled mainly by the D4000 indicator, corrected according to the [O17](#) calibration. In ‘WISE+SED fit’ and ‘SED fit’ samples, the valley and the peak in the quiescence region are sampled by SFRs derived through SED fitting, mainly driven by the *GALEX* rest-frame UV flux.

The red vertical line in each panel shows the $\Delta MS = 0$ location corresponding to the value of the MS of [RP15](#). It is apparent that the peak of the ΔMS distribution is not consistent with 0 in all samples towards high stellar masses. The significance of the deviation, however, depends on the SFR indicator used for the analysis. Obviously, the ‘H α + D4000 O17’ distribution is the most consistent with the [RP15](#) log–linear relation, because it is based on the a similar data set. Nevertheless, for all other samples, the peak of the distribution falls below 0 at least above $10^{10.5} M_{\odot}$, suggesting that the MS location is bending towards lower values of SFR with respect to the relation of the low stellar mass regime.

The last row of Fig. 2 shows the residual distribution based on the ‘SPIRE’ data, selected at 250 μm in the H-ATLAS sample. At lower masses, the H-ATLAS survey does not sample the whole MS due to the shallow flux limit. We compare the H-ATLAS distribution with the *WISE* best fit after volume correcting the best fit normalization. A Kolmogorov–Smirnov (KS) test reveals that the *WISE* best-fitting lognormal distribution is a good fit also for the far-IR selected sample, in particular at high masses, where the MS is fully sampled.

3.2 The MS location

In order to define the location of the MS, we use the derived best-fitting lognormal distributions in each sample. We use three different indicators: the mean, the median, and the mode of the lognormal distribution retrieved by fitting the upper envelope of the MS. If μ

and σ are the mean and dispersion of the normal distribution of the logarithmic variable $\log(\text{SFR})$, the mean, median, and mode of the lognormal distribution of the linear variable, SFR, are

$$\text{mean} = 10^{\mu + \sigma^2/2}, \quad (2)$$

$$\text{median} = 10^{\mu}, \quad (3)$$

$$\text{mode} = 10^{\mu - \sigma^2}. \quad (4)$$

In particular, the median SFR provides the *geometric* mean of the linear distribution. The median SFR coincides with the mode of the Gaussian distribution in $\log(\text{SFR})$, used for instance in [Ilbert et al. \(2015\)](#). The *arithmetic* mean SFR is instead used, by construction, in all the stacking analysis of the MS, in particular at high redshift (e.g. [Rodighiero et al. 2010, 2014](#); [Whitaker et al. 2014](#); [Schreiber et al. 2015](#)). The *geometric* and *arithmetic* mean of a lognormal distribution always differ, with the former being smaller than the latter. Thus, some caution must be used in comparing results obtained with different statistical indicators. The mode of the lognormal SFR distribution has never been used in the literature and we will not consider it in the further analysis.

Fig. 3 shows the MS location according to median indicator for each sample. All samples agree within 1.5σ . They all show a clear peak in the MS locus at any stellar mass and with a significant bending with respect to the [RP15](#) relation obtained at lower stellar masses. Table 1 reports the best-fitting parameters of the linear regression performed in the log–log space on the median and mean SFR points, estimated from the best lognormal fit, shown in Fig. 3 for each sample. In all cases, the slope of the relation is in the range of 0.30 – 0.38 ± 0.02 , which is much flatter than the 0.76 slope reported at lower stellar masses by [RP15](#).

The median SFR of the [S16](#) ‘SED fit’ sample distribution lies below the other relations almost at any mass bin, but it is still consistent within 1.5σ . We ascribe this discrepancy to the systematic underestimation of the SFR from SED fitting in the upper envelope of the MS, as shown in Fig. A6. Indeed, as visible in the histograms of Fig. 2, such region is much less populated in this sample than in the *WISE*+H α sample, with the results of an overall underestimation of the $\log(\text{SFR})$ distribution peak. We plot also the relation of [Peng et al. \(2010\)](#) based on liner regression between SFR and stellar mass for blue galaxies in the log–log space. We point out that such selection changes the SFR distribution around the MS, because, as shown in Fig. 4, galaxies are getting redder not only across but also along the MS. The selection of only blue galaxies excludes most of the systems populating the high-mass end of the MS and favours galaxies in the upper envelope of the relation, leading to a steeper relation.

The location of the mean, instead, depends on the value of the dispersion of the normal distribution of the logarithmic variable. As shown in Fig. 5, the dispersion of the normal distribution in the logarithmic space is increasing as a function of stellar mass in all samples but in the [S16](#) ‘SED fit’ sample. Also, this effect is related to the overall underestimation of the SFR from SED fitting in the upper envelope, which squeezes the distribution to a fix scatter of ~ 0.3 dex. Instead, all other samples indicate a scatter ranging from ~ 0.3 dex at $10^{10} M_{\odot}$ to ~ 0.4 dex at $10^{11} M_{\odot}$. This is found also by using the ‘WISE+H α ’ sample, and it is confirmed by the far-IR-based SFR of the H-ATLAS sample. We stress that the increase of scatter is purely driven by the galaxies in the upper envelope of the MS because the lognormal fit is performed only down to 0.3 dex below

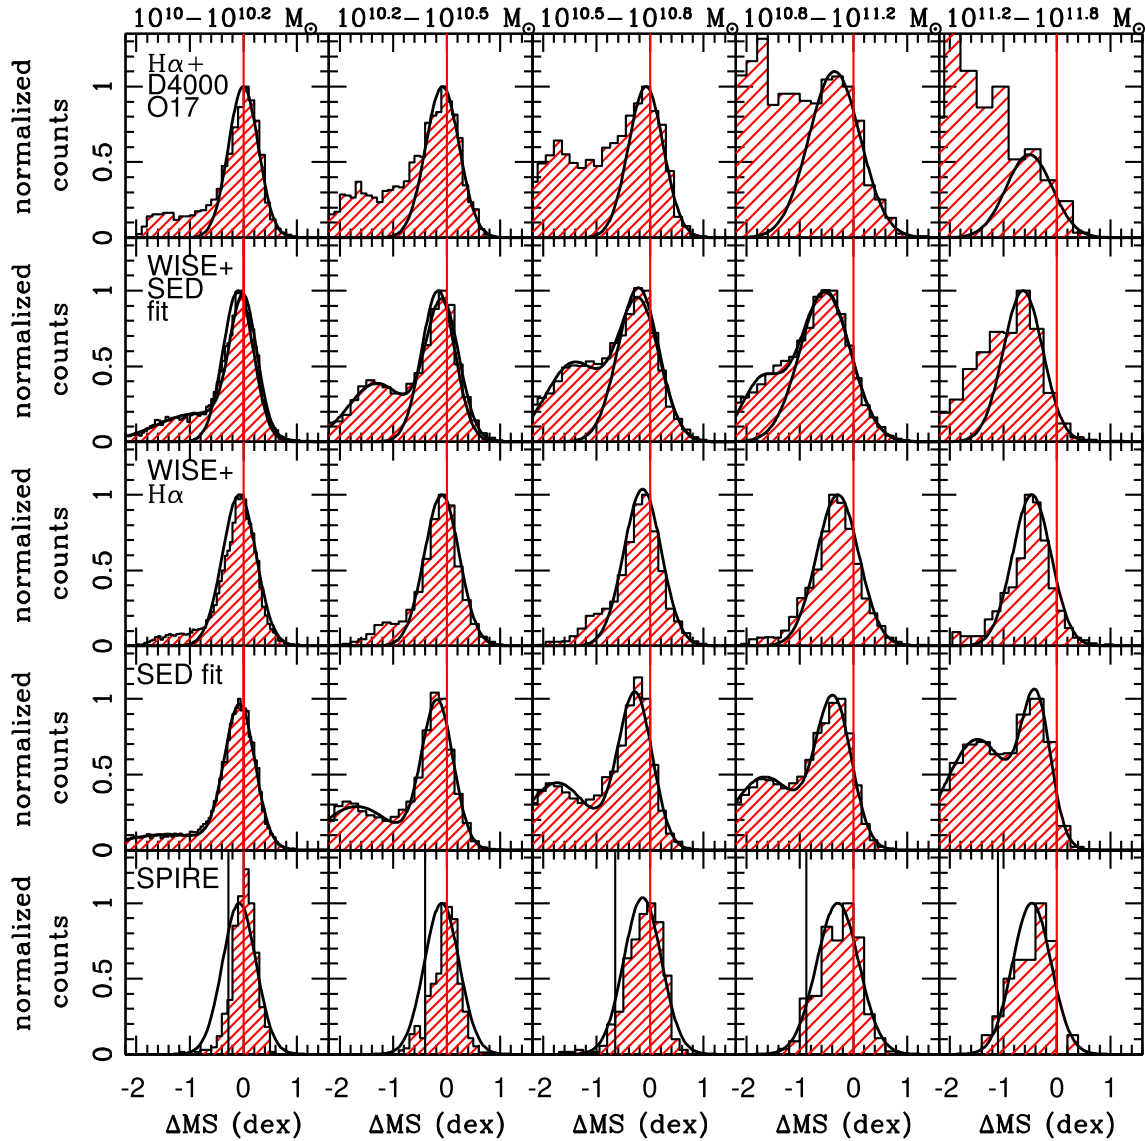

Figure 2. Distribution of the residual ΔMS around the MS in several stellar mass bins in the local Universe (red shaded histogram). The vertical red line, in all panels, shows the $\Delta\text{MS} = 0$ point corresponding to the MS location, given by the relation of [RP15](#). Each row shows the distribution based on different samples. From the top to the bottom, we show the distribution of the residuals based on (a) the MPA-JHU SFR (corrected for the [O17](#) calibration) and stellar mass estimates ($H\alpha + D4000$ O17); (b) the [S16](#) sample with SFR based on *WISE* 22 μm data point, when available, and SFR based on SED fitting elsewhere (*WISE*+SED fit); (c) the [S16](#) subsample with SFR based on *WISE* 22 μm data point, when available, and SFR based on dust corrected $H\alpha$ flux from MPA-JHU catalogue for BPT classified SF galaxies (*WISE*+ $H\alpha$); (d) the [S16](#) sample with SFR based on SED fitting only (SED fit); (e) the H-ATLAS 250 μm selected sample with SFR derived from far-IR data (SPIRE). In the bottom row, the black vertical line shows the luminosity limit corresponding to the 5σ limit of the 250 μm selected sample of Valiante et al. (2016). The solid curve in each panel shows the best-fitting normal distribution in the log–log space. For the ‘*WISE*+SED fit’ and ‘SED fit’ samples, we also show the best-fitting curve of the whole distribution including the quiescence region. In all panels, the distribution is normalized to the peak of the MS distribution.

the peak. Hence, there is no bias induced by the excess of galaxies in the valley between MS and quiescent region. The increase of the scatter implies that the MS relation provided by the mean SFR is steeper than the relation based on the median of the distribution, as indicated in Table 1. As for the MS based on the median SFR, the slope of the relation remains flatter than the 0.76 slope reported at lower stellar masses, lying in the range of $0.35\text{--}0.41 \pm 0.02$, and it.

As previously mentioned, the number of galaxies in excess with respect to the lognormal component in the lower envelope of the MS depends strongly on the SFR indicator. Indeed, it appears to

be quite different also between the ‘*WISE*+SED fit’ and the ‘SED fit’ samples that differ for the inclusion of the *WISE*-based SFR. Such excess is likely responsible for the different level of flattening reported by different works in the literature in the local Universe MS. Indeed, if a running mean or median is used to define the location of the MS for such non-lognormal distribution, the excess of galaxies in the valley moves the value of arithmetic mean and median well below the mean and the median of the lognormal distribution. The exact location of such values is strongly dependent on how the SF galaxy sample is defined in first place and on the SFR indicator used.

Figure 3. Location of the MS based on the *median* of the best-fitting lognormal distribution for the different samples. The dashed lines of different colour show the best-fitting linear regression on each sample. The colour code of points and lines is indicated in the figure. The black line indicates the relation of **RP15** up to $10^{10.5} M_{\odot}$, and the grey line shows the relation of Peng et al. (2010).

4 DISCUSSION

We discuss here the two main findings of the paper which are (i) the bending of the MS at high masses and (ii) the increase of its scatter at high stellar masses.

4.1 The MS bending

One of the most used explanation for the bending of the MS is the change of the galaxy morphology along it. Several works in the literature propose that the slope of the MS and its scatter are due to an increasing prominence of an inactive bulge coexisting with an actively star-forming disc at increasing stellar masses (Wuyts et al. 2011; Whitaker et al. 2015; Abramson et al. 2014; Erfanianfar et al. 2016; Morselli et al. 2017). Abramson et al. (2014) show that, under the assumption that the bulge component is always inactive and that the SFR is purely due to the activity of the disc, one can remove part of the dependence of the sSFR on the stellar mass by normalizing SFR to the disc stellar mass. This flattens the slope of the sSFR–stellar mass relation to -0.2 with respect to what inferred from the **RP15** relation. However, as shown in Morselli et al. (2017), such assumption is too simplistic. By measuring the

Figure 4. Distribution of galaxies in the $\log(\text{SFR})$ – $\log(M_*)$ plane colour-coded as a function of the mean $g-r$ colour in bin of SFR and stellar mass. The mode of the MS at different stellar mass bins is overplotted (connected points). The error bars show the dispersion of the relation around the mode.

mean B/T ratio of galaxies in the MS region derived with the MPA-JHU catalogue, they show that the MS is sitting on the lowest value of the B/T, and that the mean B/T along the MS is increasing from 0.1 at $10^{10} M_{\odot}$ to 0.4 at $10^{11} M_{\odot}$. By matching the B/T estimates of Simard et al. (2011), as used in Morselli et al. (2017), with the **S16** ‘WISE+SED fit’ sample, we partially confirm the result. For this exercise, we use the MS relation of **RP15** below $10^{10} M_{\odot}$ and our definition of the MS above the same mass limit, in order to take into account the bending of the relation at high masses. The mean B/T of galaxies sitting on the MS (at $\Delta_{\text{MS}} = 0$ in Fig. 6) increases from 0.1 at $\sim 10^{9.5} M_{\odot}$ to 0.35 above $\sim 10^{11} M_{\odot}$. The only difference is that the minimum B/T is not obtained on the MS, but it is reached above the MS, with distance increasing as a function of the stellar mass (see Fig. 6). This indicates that pure disc galaxies follow a relation steeper than the MS provided by the bulk of the star-forming galaxy population, which at high masses is dominated by intermediate type morphology systems, as already seen in Salmi et al. (2012). This is also in agreement with the recent findings of Belfiore et al. (2018) based on MaNGA data. Indeed, despite the limited statistics of the current MaNGA sample with respect to the whole SDSS spectroscopic or the **S16** samples, Belfiore et al.

Table 1. Best-fitting linear regression in the $\log(\text{SFR})$ – $\log(M_*)$ of the MS relation. The parameter a and b indicate the slope and zero point of the best-fitting linear regression for each sample and for the median and mean MS, respectively.

	Median		Mean	
	a	b	a	b
$H\alpha + D4000_{017}$	0.36 ± 0.03	-3.57 ± 0.31	0.41 ± 0.03	-4.09 ± 0.34
WISE+SED fit	0.30 ± 0.03	-2.97 ± 0.32	0.35 ± 0.03	-3.43 ± 0.35
SED fit	0.38 ± 0.04	-3.83 ± 0.44	0.38 ± 0.04	-3.78 ± 0.42
WISE+H α	0.34 ± 0.03	-3.41 ± 0.38	0.36 ± 0.04	-3.57 ± 0.43

Figure 5. Dispersion σ of the best-fitting normal distribution of the $\log(\text{SFR})$ variable in the \log – \log plane for different samples. The colour code is indicated in the figure.

(2018) find that the MS is consistent with the PR15 steep relation only when it is limited to galaxies dominated by star formation at all radii, as pure disc galaxies tend to be according to their colours. However, the MaNGA high-mass end of the MS tends to be equally populated by completely star-forming galaxies and systems with a LIER-like central region (cLIER systems) but star forming at larger galactocentric distances. If also cLIER systems are considered, the MaNGA MS does bend at high masses as found here. In addition, according to Belfiore et al. (2018), the pure SF galaxies tend to populate the upper envelope of the MS, while cLIER systems are located in the lower envelope, as clear from their fig. n. 2. This would be consistent with the finding of Fig. 6, where the pure disc galaxies tend to have a much steeper MS than higher B/T systems. We will explore more in details this aspect in a dedicated paper.

However, the increase of the bulge component along the MS (from 10 per cent at 10^{10} to 35 per cent at $10^{11} M_{\odot}$) does not suffice to explain the observed bending, as confirmed also by Abramson et al. (2014). As shown in the upper panel of Fig. 7, if we reduce the extrapolation above $10^{10.5} M_{\odot}$ of the RP15 MS relation (holding at $<10^{10.5} M_{\odot}$) by a percentage equal to the mean B/T of galaxies on the MS (black curve in the figure), the reduced SFR is still much higher with respect to the observed SFR at the MS high-mass end retrieved with the ‘WISE+H α ’ (magenta line) and the ‘WISE+SED fit’ (red line) samples. Instead, one should take into account, as shown again in Morselli et al. (2017), that also the galaxy disc is getting redder along the MS, further lowering the SFR level at high masses. The results is confirmed also when using the S16 ‘WISE+SED fit’ sample rather than the MPA-JHU catalogue as in Morselli et al. (2017). In the middle panel of Fig. 7, we show the rest-frame ($g-r$) colour of galaxies within 1σ from the median SFR in the MS region. The colour of the galaxies as a whole is getting redder along the MS. The disc is slightly bluer than the whole galaxy and it follows the same curve getting redder at high masses. The bulge component is redder at any mass with respect to the whole galaxy and the disc component. In addition, it gets redder as

Figure 6. Mean B/T as retrieved from Simard et al. (2011) as a function of the distance from the MS in several stellar mass bins. The points and lines are colour coded as a function of the stellar mass bin as indicated in the figure. The dashed black line at $\Delta\text{MS} = 0$ indicates the location of the MS based on the median SFR. The other dashed lines indicate the 2σ interval around the MS at the stellar mass bin of the same colour.

a function of mass more rapidly, reaching a plateau above $10^{10.5} M_{\odot}$. Above this mass threshold, the mean colour of the bulge component in MS galaxies is consistent with the colour of spheroidal quiescent galaxies at the same mass and at 1.5 dex below the MS (star symbols in the middle panel of Fig. 7). The galaxy colour is much closer to the disc colour than to the bulge component, confirming that the disc is dominating over the bulge component at any mass along the MS. However, the colour excess between galaxy and disc increases from 0.05 dex at $10^{10} M_{\odot}$ to 0.13 dex at $10^{11} M_{\odot}$, showing the effect of a larger red and dead bulge component. In order to check if the redder colour of the galaxy and disc component at higher masses is due to a larger dust content rather than a mean older stellar age, we plot in the bottom panel of Fig. 7 also the mean value of the Balmer decrement, $H\alpha/H\beta$, for the same sample of galaxies. Indeed, the Balmer decrement is a direct estimate of the amount of dust in galaxies and it is used to correct the H α flux for dust extinction (Brinchmann et al. 2004). The values of the H α and H β fluxes are taken from the emission-line flux catalogue of Brinchmann et al. (2004) for all galaxies with H α and H β flux SNR higher than 3. This allows to sample 80–90 per cent of the whole galaxy population at 1σ from the MS at any mass. As shown in the panel, the Balmer decrement is rather constant along the MS for galaxies at stellar masses above $10^{10} M_{\odot}$. Thus, we conclude that the reddening of the galaxy and disc colour is not due to an increase of galaxy dust content but rather to an increase of the mean stellar population age. This suggests that the flattening of the MS at high masses is due to the two effects: the complete quenching of the bulge component above $10^{10.5} M_{\odot}$ and a reduced star formation activity of the disc component at increasing stellar mass. This is confirmed by the spatially resolved sSFR maps of the MaNGA sample of Belfiore et al. (2018). Indeed, they find that the average radial sSFR profile of MS galaxies exhibits a significant central depression towards higher masses, in particular above

Figure 7. Upper panel: distance in dex from the power-law relation of RP15 derived for galaxies at stellar masses below $10^{10.5} M_{\odot}$ of the best-fitting power law retrieved in this work for the ‘WISE+H α ’ (magenta line) and the ‘WISE+SED fit’ (red line) samples, respectively. The black curve shows the RP15 MS relation reduced by a percentage equal to the mean B/T of the galaxies within 1σ from the MS, under the assumption that the bending is due to the increase of the red and dead bulge component along the MS, as seen in Fig. 6. Middle panel: mean $(g-r)$ rest-frame colour of Simard et al. (2011) matched to the S16 ‘WISE+SED fit’ sample for galaxies within 1σ from the median SFR of the MS in bins of stellar mass. The colour is shown for the whole galaxy (empty points with central filled points), for the bulge component (black points) and for the disc component (empty points). The stars indicate the mean colour of spheroidal galaxies in the same mass bin and located in the quiescence region at more than 1.5 dex below the MS. Bottom panel: mean Balmer decrement ($H\alpha/H\beta$) of galaxies within 1σ from the MS of the WISE+SED fit sample. The $H\alpha$ and $H\beta$ fluxes are taken from the emission-line flux catalogue of Brinchmann et al. (2004). The error bars indicate the dispersion around the mean value.

$10^{10.5} M_{\odot}$. This is also accompanied by a general depression of the sSFR level at all radii towards higher masses. Indeed, Belfiore et al. (2018) provide also a measure of the sSFR within different galactocentric annuli (their table 2 and fig. 7). Despite the large scatter, in particular towards the high-mass end where the MaNGA statistics is limited, the sSFR–stellar mass relation appears in all cases as a clear anticorrelation with average slope of $\alpha = -0.24$. In addition, the relation based on the sSFR integrated in the central region appears to be steeper than the one based on the sSFR measured around and beyond the effective radius. This confirms that the SF activity is progressively suppressed at all radii towards the high-mass end, and, in particular, such suppression takes place more rapidly in the central than in the external region of the galaxy.

The quenching of the spheroidal component in nearly all semi-analytical models and hydrodynamical simulations is ascribed to the feedback of the central supermassive black hole (SMBH). There is a vast literature about the effects of the different implementations, either through powerful outflows (e.g. Debuhr, Quataert & Ma 2011, 2012; Choi et al. 2012, 2014, 2015; Wurster & Thacker 2013), or radio jets (Gaspari et al. 2011, 2014; Dubois et al. 2011, 2012, 2016; Schaye et al. 2015; Meece et al. 2017; Weinberger et al.

2017). As for the MS based on the median SFR, the slope of the relation remains flatter than the 0.76 slope reported at lower stellar masses, lying in the range of $0.35\text{--}0.41 \pm 0.02$, and it. However, while from the theoretical point of view there is consensus, a firm observational evidence is still lacking, in particular when it comes to the disc component. Indeed, if the effect of the SMBH feedback is recognized to have a local effect in the central galaxy region, it is still quite debated whether such effect can be extended on the kpc scale of the disc component (see for instance Rubin et al. 2010; Martin et al. 2012; Harrison et al. 2014; Brusa et al. 2015; Chisholm et al. 2015, 2016, 2017; Cresci et al. 2015; Ciccone, Maiolino & Marconi 2016; Concas et al. 2017, 2018; Fiore et al. 2017).

Thus, what else can cause the decrease of SF activity of the disc in massive galaxies? In this respect the effect of the environment might play a role too. To test this possibility, we match the S16 ‘WISE+SED fit’ sample to the host halo mass catalogue of Yang et al. (2007) based on SDSS data. As shown in the right-hand panel of Fig. 8, the mean host halo mass in the $\log(\text{SFR})\text{--}\log(M^*)$ plane is increasing along the MS with the stellar mass. This is due to the fact that the vast majority of galaxies are central galaxies (the left-hand panel of Fig. 8) and to the known correlation between the $M^*_{\text{central}}/M_{\text{halo}}$ versus M_{halo} , where M^*_{central} is the stellar mass of the central galaxy and M_{halo} is the total mass of the host halo (Yang, Mo & van den Bosch 2009; Behroozi, Wechsler & Conroy 2013). It is worth to notice that the region where the MS is mostly bending above $10^{10.5} M_{\odot}$ corresponds to host halo mass of $\sim 10^{12\text{--}12.5} M_{\odot}$. Such mass range is considered to be the mass threshold for the transition between a regime of cold to hot accretion (Dekel & Binboin 2006; Keres et al. 2009). In low-mass haloes, below $\sim 10^{12\text{--}12.5} M_{\odot}$, the central galaxy is fed with cold gas by the gas streams coming from the cosmic filaments. In high-mass haloes, instead, the gas filling up the halo volume is shock heated to the halo virial temperature during the gravitational collapse and the cold gas streams are no longer able to penetrate the halo and replenish the central galaxy (Keres et al. 2009). Feldmann (2017) in a fine-scale numerical simulation of a volume large enough to sample also galaxy groups, outline that the evolution of group galaxies is driven by (i) mergers, which lead to the bulge formation, (ii) the suppression of gas inflow in the hot atmosphere, and (iii) ram pressure stripping. Since the MS is dominated by central galaxies, mergers, and suppression of gas inflow must play the most important role. The first would explain the increase of the bulge mass towards high stellar masses in the galaxy group regime of the MS (above stellar masses of $10^{10.5} M_{\odot}$ and halo masses of $\sim 10^{12\text{--}12.5} M_{\odot}$). The second would lead to the a lack of cold gas supply and a progressive lowering of the SF activity in the external region, as observed in this work and in Belfiore et al. (2018). We argue that ram pressure stripping might play a fundamental role for the low-mass satellite. Indeed, Fig. 8 shows clearly that low-mass satellite galaxies of massive haloes tend to be segregated below the MS, towards the quiescence region. This is in agreement with the findings of Oemler et al. (2017), who explain with a toy model the distribution of passive and quiescent galaxies below the MS. Indeed, by using a simple model for disc evolution based on the observed dependence of star formation on gas content in local galaxies, and assuming simple histories of cold gas inflows, they show that the evolution of galaxies away from the MS can be attributed to the depletion of gas due to the star formation after a cut-off of gas inflow.

However, we point out that the gas starvation induced by the gravitational heating in massive haloes is not sufficient to guarantee the shut-down of the SF activity in the central galaxy. Indeed, the cooling time of the hot gas in massive groups and clusters of galaxies, although long, is shorter than the Hubble time. Thus, the

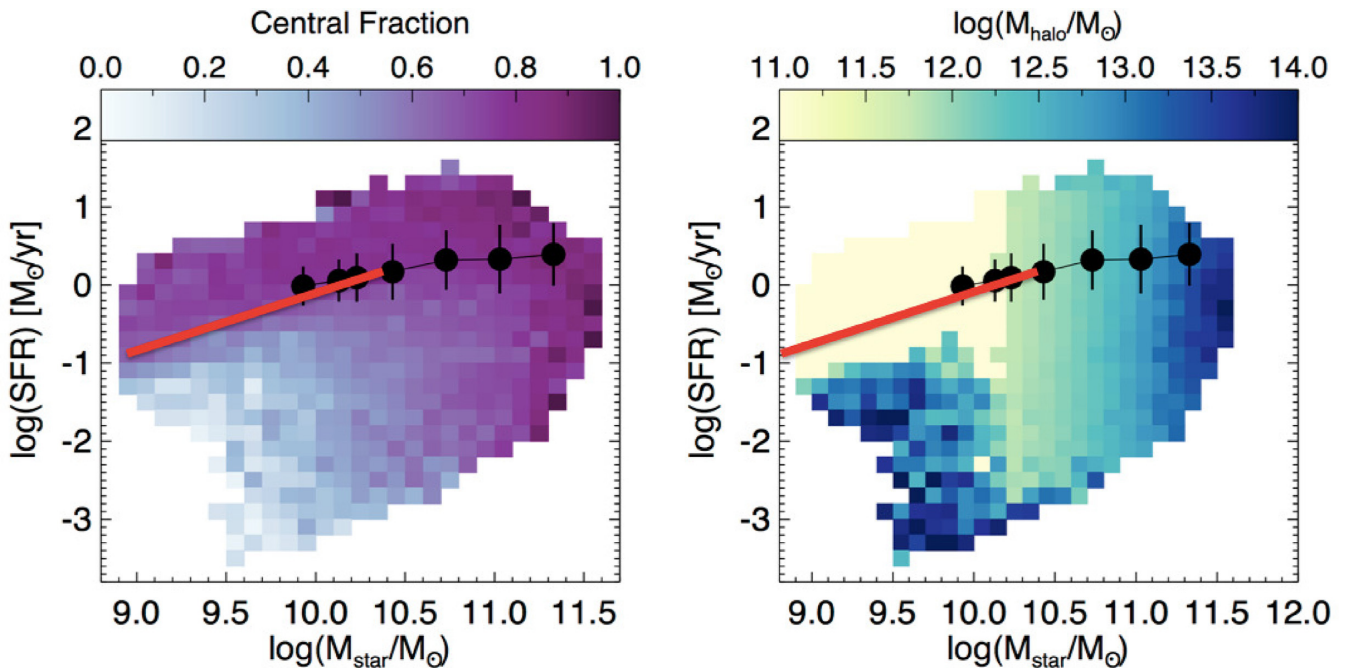

Figure 8. Left-hand panel: $\log(\text{SFR})$ – $\log(M^*)$ plane based on the [S16 WIDE+SED](#) fit sample, colour coded as a function of the fraction of central galaxies identified in the host halo catalogue of Yang et al. (2007). Right-hand panel: same as the left-hand panel but colour coded as a function of the mean host halo mass in bin of SFR and stellar mass $0.1 \text{ dex} \times 0.1 \text{ dex}$ wide. Also the host halo mass is retrieved by matching the [S16](#) catalogue with the halo mass catalogue of Yang et al. (2007). The low-mass regime (below $10^{10} M_\odot$) is dominated by isolated galaxies, for which only an upper halo mass limit is provided in the Yang et al. (2007) catalogue. This is why in this region it is not possible to observe any halo mass gradient as at higher masses. In both panels, the black points indicate the location of the local MS based on the median indicator while the red solid line shows the relation of [RP15](#) at lower masses.

hot gas might cool down and lead to the formation of cooling flows able to replenish the galaxy of cold gas and trigger the SF process. In this respect, all simulations advocate once again the effect of the central SMBH to prevent the cooling of the gas by dumping large quantity of energy into the circum-galactic medium through radio jets and lobes (see Croton et al. 2006; Genel et al. 2015; Schaye et al. 2015).

4.2 The increase of the MS scatter as a function of mass

In this section, we analyse the possible causes of the increase of the scatter as a function of stellar mass. Such increase is observed also by Ilbert et al. (2015) on a completely different data set. Indeed, they use *Spitzer* MIPS mid-IR and *Herschel* PACS far-IR data in the COSMOS field up to redshift ~ 1.4 to perform a very similar analysis.

As for the bending of the MS, much of the scatter of the relation is usually ascribed to the large range of morphological types of galaxies across the MS. Whitaker et al. (2015) show that the mean Sérsic index of MS galaxies at intermediate and high redshift in the *Candels* fields is increasing not only along the MS, as shown in the previous section, but also across it from the starburst region towards the lower MS envelope. Morselli et al. (2017) confirms that in the local Universe, there is a large spread of B/T across the MS. However, the mean B/T increases above and below the MS. By matching the [S16 WISE+ SED](#) fit sample with the Simard et al. (2011) catalogue in Fig. 6, we show that this is confirmed also with more accurate SFR estimates than the D4000-based SFR used in Morselli et al. (2017). We will not discuss here the increase of the B/T towards the starburst region, as it is largely discussed in Morselli et al. (2017). We only point out here that such behaviour

is confirmed by spatially resolved $H\alpha$ maps of galaxies in MaNGA (Belfiore et al. 2018; Ellison et al. 2018; Guo et al. 2018) and SAMI data (Medling et al. 2018).

However, we point out here that such spread in morphological types across the MS is not increasing as a function of the stellar mass above $10^{10} M_\odot$. The mean B/T is increasing as a function of stellar mass but the dispersion around it for galaxies within 2σ from the median SFR in the MS region is 0.12–0.15 without any dependence on the stellar mass (see Fig. 6). Thus, even in this case the change in morphological type mix across the MS is not sufficient to explain the increase in scatter as a function of mass.

Ilbert et al. (2015) ascribe, instead, such aspect to the larger spread in star formation histories of massive galaxies with respect to the low-mass counterparts. In this respect, Oemler et al. (2017) point out that the peak of the MS should be determined by the age of the galaxies and by mean value $\text{SFR}(t)/\langle \text{SFR} \rangle$. If the bulk of the galaxies are roughly coeval, then only the range of shape of the star formation histories $\text{SFR}(t)$ will set the scatter of the relation at fixed stellar mass. The particular shape of $\text{SFR}(t)$ is not relevant. Oemler et al. (2017) clearly show that any star formation histories that are not completely random will produce a correlation of SFR with mass with the observed scatter. Since the majority of the MS galaxies are statistically central galaxies, their SF and accretion history is bound to the merger history of their host halo. Hirschmann et al. (2013) nicely show that the merger three of a group-sized halo of mass $\sim 10^{13} M_\odot$ is much more complex with respect to a $\sim 10^{11} M_\odot$ halo. Indeed, in massive haloes the frequency of merger and accretion episodes is much higher than in low-mass haloes. Such increased complexity might lead to a much larger range of possible evolutionary patterns for massive central galaxies, thus to a larger spread in $\text{SFR}(t)/\langle \text{SFR} \rangle$ and so to a larger scatter of the MS towards the high-mass end.

5 SUMMARY AND CONCLUSIONS

We summarize here briefly the main findings of the paper. We study the MS of star-forming galaxies in the local Universe by analysing the SFR distribution in the $\log(\text{SFR})$ – $\log(M^*)$ plane. To this aim, we use different SFR indicators, including SED fitting, $H\alpha$ -derived SFR and mid- and far-IR derived SFR, in order to take into account selection effects and biases.

In the local Universe, the SFR distribution in the MS region is well fitted by a lognormal distribution only in the upper envelope of the MS, consistently for all SFR indicators. At lower SFR, the distribution shows a clear excess of galaxies with respect to the lognormal distribution. Such excess increases as a function of stellar mass, but its significance depends strongly on the SFR indicator. Similarly, the dispersion of the lognormal distribution is not constant but it increases as a function of mass. The most robust SFR indicators, such as the dust corrected $H\alpha$ and the IR-derived SFR, agree in finding a dispersion ranging from ~ 0.3 dex at $10^{10} M_{\odot}$ to ~ 0.4 dex at $10^{11} M_{\odot}$, as found with a very similar analysis by Ilbert et al. (2015) up to $z \sim 1.4$. Above $10^{11} M_{\odot}$, the location of the MS is very uncertain and it strongly depends on the SFR indicator used.

We use different indicators to identify also the location of the MS, such as the median and the mean of the best lognormal SFR distribution in several stellar mass bins. For all SFR indicators, the MS relation flattens progressively at high stellar masses with respect to the relation found by RP15 at lower masses. The significance of such bending depends, though, on the SFR indicator and on the MS indicator used in the analysis.

Because of this systematics, one must be cautious in comparing different results in the literature. Indeed, several slopes of the MS has been estimated ranging from 0.6 to 1.2, with or without bending at the high-mass end. This suggest that such discrepancies might be due to the different indicators used either to define the MS location or to estimate the SFR, or galaxy sample selection effects.

The analysis of the mean B/T in the MS region along and across the relation shows that the B/T increases from 0.1 to 0.35 from 10^{10} to $10^{11} M_{\odot}$ is not sufficient to explain the bending of the MS at very high masses. In addition to the increase of the bulge component, we observed also indication for a decrease of the SF activity of the disc along the MS. While the quiescence of the bulge component could be due to the effect of central SMBH feedback, we speculate that the lower SFR of the disc at high masses could be due, instead, to the gas starvation induced by the gravitational heating in massive haloes. Indeed, we observe that above $10^{10.5} M_{\odot}$, where the bending is most significant, the totality of the galaxies in the MS region are central galaxies of group and cluster-sized haloes. As suggested by Ilbert et al. (2015), the larger spread of merger threes and evolutionary paths of the group and cluster central galaxies could explain also the increase of the MS lognormal component as a function of the stellar mass.

We conclude that the slope and the shape of the MS in the local Universe are dictated by the interplay between morphological transformation and environment and not simply by the stellar mass.

ACKNOWLEDGEMENTS

This research was supported by the DFG cluster of excellence ‘Origin and Structure of the Universe’ (www.universe-cluster.de). We thank L. Abramson for the extremely useful comments that helped improving the manuscript. P.P. thanks also M. Sargent, E. Daddi and A. Renzini for the very useful discussion.

APPENDIX: COMPARISON OF DIFFERENT SFR INDICATORS

In this section, we compare different SFR indicators available for the local galaxy sample. In particular, we consider as the most robust SFR estimate the one based on the L_{IR} measured by integrating from 8 to 1000 μm the best-fitting template of the H-ATLAS *Herschel* SPIRE 250 μm data point and all available IR data points from 22 to 500 μm . Fig. A1 shows the comparison of such L_{IR} obtained by using the Elbaz et al. (2011) and Magdis et al. (2010) templates, respectively. The agreement is very good with an rms of 0.08 dex.

We keep as a reference the SFR based on the L_{IR} derived with the Elbaz et al. (2011) templates in the further comparison. Fig. A2 show the comparison of the *Herschel*-based SFR with the $\text{H}\alpha$ -based SFR of the MPA-JHU catalogue (Brinchmann et al. 2004). The $\text{H}\alpha$ -

Figure A1. Comparison of the far-IR L_{IR} derived in the low redshift sample with the Elbaz et al. (2011) MS and SB templates versus the L_{IR} derived with the Magdis et al. (2014) templates. The L_{IR} is obtained by integrating the template best fitting the *WISE*, *PACS*, and *SPIRE* data from 8–1000 μm .

Figure A2. Comparison of the SFR based on the far-IR L_{IR} derived in the low-redshift sample with the Elbaz et al. (2011) MS and SB templates versus the dust corrected $\text{H}\alpha$ -based SFR of the MPA-JHU catalogue.

based SFRs are in very good agreement with the IR SFR with a scatter of 0.23 dex. The D4000-based SFR are, instead, largely underestimated with respect to the IR-based SFR (Fig. A3). Such underestimation is confirmed also when comparing the D4000-derived SFRs with the *WISE*-based SFRs of S16, which are sampling a larger SFR range with respect to the H-ATLAS sample. On the contrary, when compared with the SFRs based on SED fitting of S16, which sample mainly the quiescent region, the D4000-derived SFRs appear to be heavily overestimated at low SFRs (below $0.01 M_{\odot} \text{ yr}^{-1}$) up to two orders of magnitude (Fig. A4). This is due to the fact that, for quiescent galaxies, the D4000 provides by construction only an upper limit to the actual level of star formation activity, imposed by the minimum value of the Balmer break. Oemler et al. (2017) propose a calibration of the $\text{H}\alpha$ and D4000-derived SFRs able to largely correct for such effects. The $\text{H}\alpha$ and D4000-derived SFRs are calibrated versus IR + UV based SFR with a correction based

Figure A3. Left-hand panel: Comparison of the SFR based on the far-IR L_{IR} derived in the low-redshift sample with the Elbaz et al. (2011) MS and SB templates versus the D4000-based SFR of the MPA-JHU catalogue. Right-hand panel: Comparison of the SFR based on the mid-IR *WISE* SFR of S16 versus the D4000-based SFR of the MPA-JHU catalogue.

Figure A4. Comparison of the SFR based on the SED-based SFRs of Salim et al. (2016) and the D4000-based SFRs of the MPA-JHU catalogue.

Figure A5. Comparison of the SFR based on the SED-based SFRs of Salim et al. (2016) and the D4000-based SFRs of the MPA-JHU catalogue corrected according to the calibration of Oemler et al. (2017).

on the galaxy inclination and the $\text{NUV} - g$ rest-frame colour, where NUV is the *GALEX* NUV filter and g is the SDSS g filter. We follow the calibration provided in Oemler et al. (2017). To this aim, use the Simard et al. (2011) catalogue of bulge–disc decomposition to retrieve the galaxy inclination and the Bianchi et al. (2017) revised *GALEX* catalogue to retrieve the NUV magnitude for the local SDSS sample. Fig. A5 shows the corrected $\text{H}\alpha$ and D4000-derived SFRs versus the *WISE*-based SFRs of S16. Although the scatter is still large, 0.37 dex, and mainly due to the D4000-derived SFRs, the calibration is able to largely correct for the effects discussed above and shown in Figs A2 and A3.

Fig. A6 shows the comparison of the Chang et al. (2015) SFR based on SED-fitting results of MAGPHYS code, from *GALEX* to *WISE* data. As already reported by S16, for a large percentage of galaxies, the Chang et al. (2015) catalogue provides largely underestimated values of the SFR. Although such galaxies are in 60 per cent

of the cases classified as star-forming systems in the BPT diagram, according to the classification reported in the MPA-JHU catalogue, their SFR is in disagreement with the $\text{H}\alpha$ -based and IR-based SFR estimates by several order of magnitudes. S16 discuss that this is likely due to the fact that the Magphys SED-fitting results are mostly driven by the higher SNR $12\ \mu\text{m}$ data point than the low SNR $22\ \mu\text{m}$, leading to artificially extremely low SFR.

Fig. A7 shows the comparison of reference SFR with the S16 catalogue SFR estimates. S16 provide SFRs based on SED fitting with *Cigale* from *GALEX* UV to near-IR data and an alternative estimate of the SFR based on the *WISE* $22\ \mu\text{m}$ data only, when available. The right-hand panel shows the comparison between the *WISE*-based SFRs and the far-IR derived SFRs. The agreement is as good as for the $\text{H}\alpha$ SFRs with a rms of 0.18 dex. We find a larger scatter between the SED fitting derived SFRs and the far-IR-based

Figure A6. Comparison of the SFR based on the far-IR L_{IR} derived in the low-redshift sample with the Elbaz et al. (2011) MS and SB templates versus the SED fitting derived SFR of Chang et al. (2015) estimated with Magphys.

SFRs with a scatter of 0.46 dex. In addition, we find that the SFRs based on SED fitting, mainly driven by the *GALEX* UV data, tend to be underestimated towards high value of SFR. This is more clearly visible in Fig. A8, which shows the ratio between the SED-fitting-based SFRs and the far-IR-based SFRs versus the distance from the MS of RP15 up to stellar masses of $10^{10.5} M_{\odot}$. The SFRs based on the SED fitting tend to be underestimated at larger distances from the MS location towards the upper envelope. This shows that SFRs based on UV and optical data only, despite the dust correction, are not able to capture the star formation activity of the dusty objects that tend to populate the upper envelope of the MS (Saintonge et al. 2011).

Similarly to Oemler et al. (2017), we also explore the dependence of the SFR indicators on the galaxy inclination. The SFRs of S16

Figure A8. Relation between the ratio $\text{SFR}_{\text{SEDfit}}/\text{SFR}_{\text{IR}}$ of S16 SFR based on the SED-fitting results and the far-IR-based SFR based on *WISE*, PACS, and SPIRE data versus the distance from the MS of RP15 (black points). The red stars indicate the median $\text{SFR}_{\text{SEDfit}}/\text{SFR}_{\text{IR}}$.

based on *WISE* data do not show any dependence on the galaxy inclination. The $H\alpha$ and the D4000-based SFRs calibrated according to Oemler et al. (2017) include by construction the correction for the inclination dependence. We point out that this correction applies, in particular, to galaxies that in the original MPA-JHU catalogue would lie in the lower envelope of the MS, as shown in Morselli et al. (2017). The UV-based SFR derived through SED fitting do not show a clear trend with the inclination. Indeed, the obscuration due to the auto-extinction of the inclined disc is mixed with the effect shown in Fig. A8 for very dusty objects above the MS. Thus, a clean calibration is not easily applicable.

Figure A7. Left-hand panel: comparison of the SFR based on the far-IR L_{IR} derived in the low-redshift sample with the Elbaz et al. (2011) MS and SB templates versus the SFR based on mid-IR L_{IR} derived from the *WISE* 22 μm data point of S16. Right-hand panel: comparison of the SFR based on the far-IR L_{IR} derived in the low-redshift sample with SED fitting derived SFR of S16 estimated with Cigale.
