Abstract

Understanding how multiple signals are integrated in living cells to produce a balanced response is a major challenge in biology. Two-component signal transduction pathways, such as bacterial chemotaxis, comprise histidine protein kinases (HPKs) and response regulators (RRs). These are used to sense and respond to changes in the environment. *Rhodospirillum rubrum* has a complex chemosensory network with two signaling clusters, each containing a HPK, CheA. Here we demonstrate, using a mathematical model, how the outputs of the two signaling clusters may be integrated. We use our mathematical model supported by experimental data to predict that: (1) the main RR controlling flagellar rotation, CheY₆, aided by its specific phosphatase, the bifunctional kinase CheA₃, acts as a phosphate sink for the other RRs; and (2) a phosphorelay pathway involving CheB₂ connects the cytoplasmic cluster kinase CheA₃ with the polar localised kinase CheA₂, and allows CheA₃-P to phosphorylate non-cognate chemotaxis RRs. These two mechanisms enable the bifunctional kinase/phosphatase activity of CheA₃ to integrate and tune the sensory output of each signaling cluster to produce a balanced response. The signal integration mechanisms identified here may be widely used by other bacteria, since like *R. rubrum*, over 50% of chemotactic bacteria have multiple *cheA* homologues and need to integrate signals from different sources.

Introduction

Two-component signaling pathways are the major mechanism by which bacterial cells sense and respond to changes in their environment. They regulate processes as diverse as virulence, gene expression, development and motility [1]. Bacteria can have over 100 different two-component pathways per cell, one form of which controls swimming behavior. This chemosensory pathway has been extensively studied as an example of a two-component signaling pathway as it provides a model of signaling, signal termination and receptor adaptation. Mathematical modeling has proved particularly useful in helping to understand the complexity of *Escherichia coli* chemotaxis [2–10].

Most chemotactic bacteria sense changes in their extracellular environment using transmembrane chemoreceptors [11]. These chemoreceptors signal via an intracellular signaling cascade to the flagellar motor. In the case of *E. coli*, the signaling cascade is well understood [12,13]. The chemoreceptors form a quaternary complex at the cell poles with the scaffold protein CheW and the histidine protein kinase, CheA [14–16]. The chemoreceptors detect changes in the periplasmic chemoeffector concentration and control the rate at which CheA autophosphorylates on a conserved histidine residue. In response to decreased attractant concentra-

tion, the chemoreceptors signal to increase the rate of CheA autophosphorylation [17–19]. Following autophosphorylation, the phosphoryl group is transferred from the histidine residue of CheA to an aspartate residue in one of the two response regulators (RRs), CheY or CheB [20–22]. CheY-P is released from the chemotaxis cluster and diffuses through the cell to the flagellar motor. CheY-P binds the FliM component of the flagellar motors, causing the direction of flagellar rotation to switch from counter-clockwise to clockwise resulting in tumbling of the bacterium [23,24]. CheA-P also phosphorylates the methylesterase CheB, which facilitates adaptation of the chemoreceptor cluster [25,26]. CheY-P and CheB-P both naturally autodephosphorylate [27], although the rate of CheY-P dephosphorylation is enhanced by CheZ to allow signal termination within the time required for effective gradient sensing [28,29].

In contrast to *E. coli*, *Rhodospirillum rubrum* has a more complex signaling pathway with multiple copies of the signaling proteins encoded by three major chemosensory operons [30]. Many other bacterial species appear to have multiple chemosensory operons as analysis of sequenced genomes suggests that ~50% of species with any *che* genes have at least two *cheAs* [30–32]. This raises the question of how behavior is controlled by two or more homologous pathways and how sensory data from each of the

Author Summary

Chemotactic bacteria sense nutrient gradients and swim towards better environments for growth. A cluster of receptors in the cell membrane detects nutrient levels and signals via a cytoplasmic signaling pathway to the flagellum. The complexity of this signaling pathway varies across different bacterial species. The relatively simple pathway used by *Escherichia coli* is well understood; however, many bacteria, for example *Rhodobacter sphaeroides*, have more sophisticated pathways that, as well as being able to detect nutrients, are also able to assess the metabolic state of the cell. The receptors that detect metabolic state are located within an additional cluster that is physically distinct from the one that senses nutrients. In this work, we use a combination of experimentation and mathematical modeling to gain insight into the complex decision-making mechanisms that enable bacteria to weigh-up different stimuli and decide upon an appropriate response. We find novel communication mechanisms between the two signaling clusters that allow the outputs of the signaling pathways to be balanced and tuned according to the prevailing environmental conditions. The signaling principles identified here are likely to be used in other complex sensory networks.

pathways are integrated to produce a balanced response. Under laboratory conditions, *R. sphaeroides* swims using a single sub-polar unidirectional flagellum (Fla1), which is controlled by the protein products of *cheOp₂* and *cheOp₃* [33–38]. The intracellular signaling cascade controlling the Fla1 flagellum comprises three CheA kinase proteins (denoted CheA₂, CheA₃, CheA₄), three CheY proteins (CheY₃, CheY₄ and CheY₆) and two CheBs (CheB₁, CheB₂) [34,35,39–42]. CheA₃ and CheA₄ are unusual CheAs in that they lack some of the domains found in *E. coli* CheA and neither protein is capable of autophosphorylation [43]. However, together CheA₃ and CheA₄ have all the activities of a functional CheA with CheA₄ forming a homodimer that binds ATP and phosphorylates the Hpt domain of CheA₃.

The signal transduction proteins are organized and localised into two distinct sensory clusters and the signaling output of both clusters is required for chemotaxis [43,44]. CheA₂ is located in a chemotaxis cluster at the cell poles, which comprises transmembrane chemoreceptors and the signal transduction proteins encoded by *cheOp₂* [44]. This cluster detects changes in the periplasmic concentration of chemoeffectors. Previous data show that CheA₂-P rapidly phosphorylates CheY₃, CheY₄, CheY₆, CheB₁ and CheB₂ (Figure 1), although the kinetics of phosphotransfer differ in each case [45]. CheA₃ and CheA₄ localize to a second chemotaxis cluster found in the cytoplasm [44]. This cluster contains the signal transduction proteins encoded by *cheOp₃* along with the soluble chemoreceptors and is believed to sense the metabolic state of the cell [44,46]. CheA₃-P rapidly phosphorylates only the RRs, CheY₆ and CheB₂ [43,47]. In addition, CheA₃ has an aspartyl-phosphate phosphatase activity that is specific for CheY₆-P; this activity is required for the rapid signal termination that is necessary for chemotactic responses [48]. CheA₃ in conjunction with CheA₄ can therefore be considered to be a bifunctional kinase/phosphatase.

In vitro studies have shown that all of the *R. sphaeroides* CheYs can bind the flagellar switch protein, FliM, and that this binding is strongest when the CheYs are phosphorylated [49], but less is known about the effect of CheY/CheY-P binding to FliM on flagellar rotation. CheY₆ is essential for chemotaxis and CheY₆-P

Figure 1. Diagram showing the RRs phosphorylated by the polar (blue) and cytoplasmic (red) chemotaxis clusters. The polar chemotaxis cluster contains CheA₂ and responds to the external environment. CheA₂ autophosphorylates and can then serve as a phosphodonor for all of the RRs. The cytoplasmic chemotaxis cluster contains CheA₃ and CheA₄, and is thought to respond to the metabolic state of the cell. CheA₃ is phosphorylated by CheA₄. Unlike CheA₂-P, CheA₃-P is not able to phosphorylate all of the RRs – it can only phosphorylate CheY₆ and CheB₂. All of the RR-Ps spontaneously autodephosphorylate; however, the dephosphorylation of CheY₆-P is accelerated by the phosphatase activity of CheA₃. doi:10.1371/journal.pcbi.1000896.g001

alone is capable of causing the chemotactic stop that is necessary for changing swimming direction [39]. However, CheY₆ alone cannot support chemotaxis; either CheY₃ or CheY₄ are also required. Furthermore, phosphorylation site mutants of CheY₃, CheY₄ and CheY₆ do not support chemotaxis [39], suggesting that phosphorylation of all of these CheYs is necessary for chemotaxis.

Thus there are two complete chemosensory pathways in *R. sphaeroides*, localized to different regions of the cell and with different patterns and kinetics of phosphotransfer to the RRs. However, the outputs of these two signaling pathways must be

integrated to control the behavior of a single flagellar motor. *In vitro* biochemistry identified which RRs are phosphorylated by each CheA and the kinetics of the interactions, however, assessing the relative contribution made to RR-P levels by each of these CheAs *in vivo* is more complex, since all of the RR-Ps will be competing with one another for phosphorylation by the CheAs. We used mathematical modeling to predict the possible signaling pathways within this complex system and tested these predictions experimentally.

The aim of this study was therefore to combine our knowledge of the kinetic preferences of the signaling reactions gained from *in vitro* biochemistry with the *in vivo* data on protein copy number within a mathematical model that can predict the changes in RR-P levels resulting from changes in CheA activity at either cluster. This model was then used to analyze the contribution made by each cluster in controlling RR-P levels and the dynamics of the signaling reactions. Using the model, we identified unexpected key roles for reversed phosphotransfer between RR-P and CheA in the network, which would enable communication between the two sensory clusters and thus regulate the output signals. In addition, we demonstrated that the principal RR, CheY₆, with the aid of its specific phosphatase, the bifunctional CheA₃/CheA₄ kinase, could act as a phosphate sink for the other RR-Ps. Regulation of the output of sensory networks by the activity of key kinase/phosphatase proteins is likely to be a common mechanism, but this is one of the first to be identified that balances the outputs of two interconnected pathways.

Results

Construction of the mathematical model

Within an *R. sphaeroides* cell, CheA₂ has been shown to localize to the polar chemotaxis cluster, while CheA₃ and CheA₄ localize to the cytoplasmic cluster [44]. All the *R. sphaeroides* CheYs are free to diffuse throughout the cytoplasm of the cell enabling communication between the receptor clusters and flagellar motor. Unlike *E. coli*, the CheBs are also diffuse in the cytoplasm [39,44]. As illustrated in Figure 1, CheA₂-P can phosphorylate all of the RRs, whilst CheA₃-P is only able to phosphorylate CheY₆ and CheB₂. What is the reason for this discrimination and how does it contribute towards the chemotactic response of the cell? To understand the role of each signaling cluster we constructed an ordinary differential equation (ODE) model of an *R. sphaeroides* cell as detailed in Text S1. The model integrates *in vivo* protein expression levels with *in vitro* data on the kinetic preference of the CheAs for each of the RRs to predict RR-P levels throughout a simulated chemotactic response. The model includes the phosphorylation reactions shown in Table 1 and was parameterized with published reaction rate constants and protein expression levels (Table 2).

The parameters for the phosphotransfer reactions were obtained by parameter fitting the previously published *R. sphaeroides* chemotaxis phosphotransfer assay data [43,45,48], where CheA-³²P served as a phosphodonor to the RRs (Table 3). In the few cases where the assays were not very sensitive to the rate of reversed phosphotransfer from RR-P to CheA, reliable estimates of these rates were obtained using alternative phosphotransfer assays, in which RR-P was mixed with unphosphorylated CheA₂ or CheA₃ (examples shown in Figure 2). In these reactions, RR-P was generated using purified phosphorylated CheA P1 domains (either CheA₂P1-P or CheA₃P1-P) as the phosphodonor; control reactions lacking RR showed no phosphotransfer from CheA₂P1-P or CheA₃P1-P to either CheA₂ or CheA₃. These experiments showed that while CheA₂ is phosphorylated by

CheB₂-P (Figure 2C) it is not phosphorylated by CheY₆-P (Figure 2B). The parameter values obtained from these phosphotransfer reactions were then used in constructing the model.

Response regulator dephosphorylation rates show CheY₆ acts as a phosphate sink

R. sphaeroides responds to brief stimuli, returning to prestimulus behavior in less than 1 s [50]. This requires a rapid rate of signal termination. The measured autodephosphorylation half-times of the chemotaxis RRs, however, vary from ~4 s for CheY₆-P to ~4000 s for CheB₁-P (Table 4). As *R. sphaeroides* does not have a CheZ homologue, an alternative dephosphorylation mechanism is required. Recently, CheA₃ was shown to be a specific phosphatase for CheY₆-P [48], but no phosphatases have been identified for the remaining chemotaxis RRs.

Phosphate sinks have been shown to be involved in signal termination in several bacterial signaling pathways [51–54]. To test whether a similar mechanism operates in *R. sphaeroides*, we used the model to predict the decay timecourse of RR-P levels resulting from simultaneously switching off autophosphorylation of CheA₂ (reaction 1 in Table 1) and the phosphorylation of CheA₃ by CheA₄ (reaction 2 in Table 1). Although, the model incorporates the experimentally determined autodephosphorylation rates (reactions 10–15b of Table 1), interestingly, the model predicts that levels of all of the RR-Ps decay with half-lives shorter than ~7 s (Table 4), which is much faster than their experimen-

doi:10.1371/journal.pcbi.1000896.t002

tally measured autodephosphorylation rates. Within the model, only CheY₆-P has a phosphatase. The only route by which the model could predict dephosphorylation rates for the other RR-Ps that are faster than their autodephosphorylation rates is for one or more of the RRs to be acting as “phosphate sinks”, with the dephosphorylation of the target RR-P proceeding via reversed phosphotransfer to a CheA, which in turn transfers the phosphoryl group to the sink RR.

To determine which RRs could act as sinks, we simulated RR-P decay rates in cells deleted for a single RR e.g. for the cell lacking CheY₃ we changed Y_{3T} to zero and measured the simulation half-lives of the remaining RR-Ps. We found that only the removal of CheY₆ greatly increased the simulation half-lives of the remaining RR-Ps (Table 4), suggesting that CheY₆ acts as a phosphate sink

for all of the other RR-Ps. Without CheY₆, the simulation half-lives of the remaining RRs were in some cases (CheY₃-P, CheY₄-P and CheB₂-P) increased beyond their autodephosphorylation half-times (Table 4). This is the result of significant quantities of CheA₃-P and CheA₂-P being present at steady state, and persisting for some time after the autophosphorylation reactions (reactions 1 and 2) were turned off. This allows levels of RR-P to be replenished resulting in a RR-P simulation half-time that is slower than their autodephosphorylation half-times. Interestingly, even in the absence of CheY₆, the simulated dephosphorylation rate of CheB₁-P was faster than its autodephosphorylation rate. In the absence of CheY₆, the other RRs (CheY₃, CheY₄ and CheB₂) may act as phosphate sinks for CheB₁-P i.e. CheB₁-P acts as a phosphodonor for CheA₂ which in turn donates the phosphoryl

groups to CheY₃, CheY₄ and CheB₂. To test this we set the rate of phosphotransfer from CheB₁-P to CheA₂ (k_{-6}) to zero and found that the simulated dephosphorylation half-time for CheB₁-P was increased to 4295 s, which is comparable with its autodephosphorylation half-time indicating that in the absence of CheY₆, one or more of other RRs therefore act as phosphate sinks for CheB₁.

To confirm that the ability of CheY₆ to act as a phosphate sink was robust to changes in parameters we performed a sensitivity analysis, where we varied each parameter by factors of 0.1, 0.5, 1.5 and 10, and measured the effect on the simulation half-life of CheB₁-P (Table S1). For the parameters that were determined

experimentally, the standard error lies well within the range covered by factors of 0.5 and 1.5. The simulation half-life of CheB₁-P was robust to large changes in the majority of parameters, and in all cases remained much faster than the CheB₁-P autodephosphorylation rate, but as would be expected showed some sensitivity towards those parameters directly involved in the operation of the CheY₆ phosphate sink i.e. the rates of phosphotransfer between CheB₁ and CheA₂ and between CheA₂ and CheY₆. In addition, the system was also sensitive to large changes, well outside the range covered by experimental error in parameter determination, in the total concentrations of CheA₂ and CheY₆. This sensitivity analysis indicates that the parameter space in which the phosphate sink mechanism will work efficiently is broad and extends well beyond the range of experimental errors in the parameters themselves, suggesting that this pathway is likely to operate *in vivo*.

In summary, these simulated data suggest that not only is CheY₆ a key regulator of flagellar motor rotation in *R. sphaeroides*, but it also acts as a “phosphate sink” ensuring rapid dephosphorylation of the other chemotaxis RRs (Figure 3A). This is very different from the *S. meliloti* sink where the sink CheY does not bind to the flagellar motor.

The phosphatase activity of CheA₃ is required for CheY₆ to work as an efficient phosphate sink

In addition to containing the Hpt domain needed for phosphorylation of CheY₆, CheA₃ is also a phosphatase specific for CheY₆-P. This phosphatase activity has previously been shown to be essential for chemotaxis [48]. We used the model to determine the effect of phosphatase removal on RR-P levels and signal termination times, by setting the rate constants for the CheA₃ phosphatase reactions (15a) and (15b) in Table 2 to zero. The model predicted very high steady state concentrations of all of the RR-Ps (Table 5), with phosphorylation levels of the total chemotaxis RR pool rising from ~55% to ~97%. This was the result of increased levels of CheY₆-P (due to decreased dephosphorylation) leading to higher CheA₂-P and CheA₃-P concentrations and therefore higher levels of the other RR-Ps. The model also predicted that the signal termination times for all of the RR-Ps would be longer without the phosphatase (Table 4), as CheY₆ would be less effective as a phosphate sink for the other RR-Ps. The model therefore highlights the importance of the phosphatase activity in CheA₃, and demonstrates that although it is specific for CheY₆-P, the phosphatase activity indirectly affects the concentration of the other RR-Ps and their signal termination rates as outlined above (Figure 3A). Removal of the phosphatase activity is therefore predicted to cause a general increase in RR-P levels, which could account for the non-chemotactic phenotype of the strains lacking phosphatase activity [48].

A phosphorelay pathway connects both chemotaxis clusters

We modeled the consequences of chemoeffector stimulation of either of the two chemotaxis clusters by either (i) turning off CheA₂ autophosphorylation (reaction (1) – parameter k_1 set to zero) to mimic attractant stimulation of the polar chemotaxis cluster or (ii) turning off the phosphorylation of CheA₃ by CheA₄ (reaction (2) – parameter k_2 set to zero) to mimic attractant stimulation of the cytoplasmic chemotaxis cluster (Figure 4). As expected, when CheA₂ autophosphorylation was turned off (case (i)) there was a reduction in the phosphorylation levels of each of the RRs (Figure 4) because CheA₂-P serves as a phosphodonor for all of the RRs. However, counter-intuitively, significant levels of all RR-Ps

Table 4. Comparison of RR-P autodephosphorylation rates with the RR-P dephosphorylation half-times predicted by the model.

	Autodephosphorylation half-time (s)*	Dephosphorylation half-time predicted by simulation (s) [†]						
		Wild type cells	$\Delta cheY_3$	$\Delta cheY_4$	$\Delta cheY_6$	$\Delta cheB_1$	$\Delta cheB_2$	No phosphatase [‡]
CheY ₃ -P	36±3	4.9	n/a	4.7	296	3.7	5.2	8.4
CheY ₄ -P	38±3	7.3	7.3	n/a	543	5.1	8.1	15.1

CheB ₁ -P	4046±150	4.2	4.2	4.0	309	n/a	4.5	8.1
CheB ₂ -P	52±4	4.8	4.9	4.8	430	4.1	n/a	6.3

*These values were calculated from the experimentally determined *in vitro* autodephosphorylation rate constants [48].

[†]The model was allowed to reach a steady state where CheA₂ autophosphorylation (reaction 1) and the phosphorylation of CheA₃ by CheA₄ (reaction 2) were both active. Then reactions 1 and 2 were turned off. These half-times represent the time taken for levels of each of the RR-Ps to fall to half of their steady state values. Deletion of RRs was simulated by setting their total concentration in the model to zero, e.g. for $\Delta cheY_3$, $Y_{3T}=0$ (Table 2).

[‡]Lack of CheA₃ phosphatase activity was simulated by setting $k_{15a}=k_{15b}=0$ (Table 2).

doi:10.1371/journal.pcbi.1000896.t004

remained, including CheY₃-P, CheY₄-P and CheB₁-P, which can only be generated by CheA₂-P.

Analysis of the modeling results from case (i) revealed that even though CheA₂ autophosphorylation had been turned off, significant levels of CheA₂-P were present and were being generated by the reversal of reaction (7) (Table 1) i.e. CheB₂-P was acting as a phosphodonor for CheA₂ (as demonstrated in Figure 2C). In this case, CheY₆ and CheB₂ were phosphorylated by CheA₃-P; CheB₂-P then served as a phosphodonor for CheA₂ i.e. CheB₂ transfers phosphoryl groups between CheA₃-P and CheA₂. The CheA₂-P generated in this way could then phosphorylate CheY₃, CheY₄ and CheB₁. This result suggests that CheA₃-P is linked to the RRs, CheY₃, CheY₄ and CheB₁, via a multistep phosphorelay i.e. CheA₃-P (His) to CheB₂ (Asp) to CheA₂ (His) to CheY₃/CheY₄/CheB₁ (Asp).

In case (ii), switching off the phosphorylation of CheA₃ by CheA₄ caused a reduction not only in the levels of CheY₆-P and CheB₂-P, but also in levels of CheY₃-P, CheY₄-P and CheB₁-P. Levels of CheY₃-P, CheY₄-P and CheB₁-P were affected because (a) they were dephosphorylated faster since the reduction in CheY₆-P levels was accompanied by an increase in the unphosphorylated CheY₆ levels which acts as a phosphate sink and (b) there was no input of phosphoryl groups at the cytoplasmic cluster for CheB₂ to transfer to these RRs via CheA₂. These results indicate that even when CheA₂ autophosphorylation is occurring, the bifunctional kinase/phosphatase in the cytoplasmic chemotaxis cluster makes a significant contribution to the phosphorylation levels of all of the RRs.

We performed a sensitivity analysis to look at the effect of varying each of the model parameters on levels of CheY₄-P when CheA₂

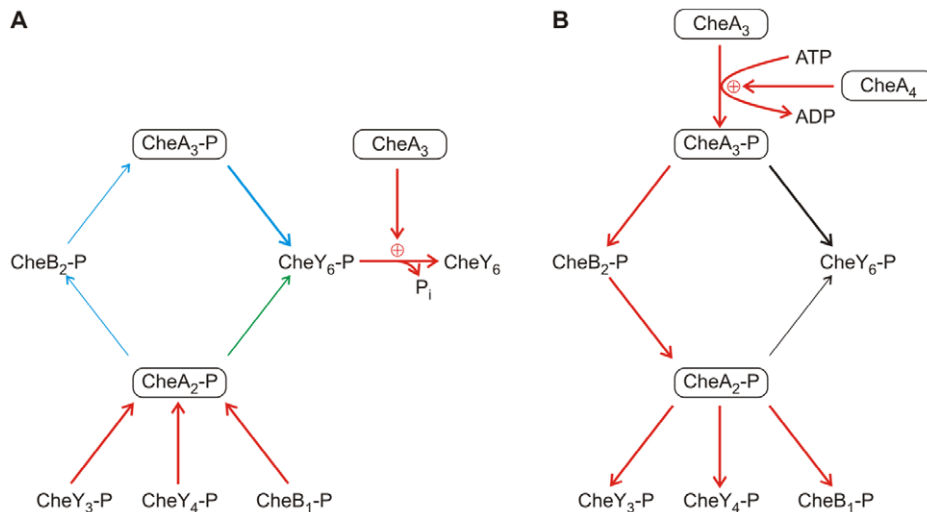

Figure 3. Summary of the phosphate-sink and phosphorelay pathways. (A) The phosphotransfer reactions that allow CheY₆ to work as a phosphate-sink for the other RR-Ps. CheY₃-P, CheY₄-P, CheB₁-P can act as phosphodonors for CheA₂. Phosphoryl groups can take either of two routes from CheA₂ to the CheY₆-phosphate-sink. CheA₂-P can directly phosphorylate CheY₆ (shown in green) or alternatively, can phosphorylate CheB₂, which can transfer the phosphoryl group to CheA₃ which then phosphorylates CheY₆ (shown in blue). CheY₆-P is rapidly dephosphorylated due to the specific phosphatase activity of the bifunctional enzyme CheA₃. For diagrammatic simplicity, reversible reactions are shown as operating in the direction that leads towards the sink. (B) Diagram summarizing the role of CheB₂ and CheA₂ in relaying phosphoryl groups from CheA₃-P to its non-cognate RRs, CheY₃, CheY₄ and CheB₁. The reactions necessary for this phosphorelay are highlighted in red. At the cytoplasmic chemotaxis cluster, phosphoryl groups are transferred from CheA₃-P to CheY₆ and CheB₂. CheB₂-P then diffuses to the polar chemotaxis cluster where it serves as a phosphodonor for CheA₂. CheA₂-P subsequently acts as a phosphodonor for CheY₃, CheY₄ and CheB₁. For diagrammatic simplicity, reactions which are reversible are shown as operating in the direction that leads towards the non-cognate RRs of CheA₃.

Table 5. Comparison of steady state levels of RR-P with and without CheA₃ phosphatase activity.

Protein	Fraction phosphorylated (%)	
	Wild-type cells	No phosphatase [‡]
CheY ₃	30	88
CheY ₄	75	98
CheY ₆	64	99
CheB ₁	33	91
CheB ₂	40	96
Total RR pool	55	97

[‡]Lack of CheA₃ phosphatase activity was simulated by setting $k_{15a} = k_{15b} = 0$ (Table 2).

doi:10.1371/journal.pcbi.1000896.t005

autophosphorylation is turned off; under these conditions CheY₄-P levels give a measure of the extent to which the phosphorelay is occurring (Table S2). The system was robust to changes in many of the parameters although as would be expected was sensitive to changes in parameters that directly affect either i) the rate of entry or exit of phosphoryl groups from the system e.g. rate of phosphorylation of CheA₃ by CheA₄, rate of CheY₆-P dephosphorylation (autodephosphorylation and phosphatase assisted), and the expression levels of CheA₃ and CheY₆ or ii) the functioning of the

phosphorelay e.g. the expression levels of CheA₂ and CheB₂, rates of phosphotransfer between CheA₃ and CheB₂, between CheB₂ and CheA₂, and between CheA₂ and CheY₄. However, despite this sensitivity in almost all cases at least some phosphorylation of CheY₄ was predicted indicating that the phosphorelay remained operational. In the two remaining extreme cases, where CheY₆ expression levels were ten times higher than usual or where the rate of phosphorylation of CheA₃ by CheA₄ was ten-fold lower than the measured rate, levels of all RR-Ps, not just CheY₄-P, were extremely low. These results indicate that the phosphorelay operates over a broad range of parameter space, although the extent to which it operates is sensitive to large changes in some of the parameters.

Discussion

The experimental work leading up to this study produced an outline architecture of the complex signaling network controlling *R. sphaeroides* chemotaxis [30]. However, the mechanism of integrating the signals produced by each of the signaling clusters to control the flagellar motor was unclear. Mathematical modeling has provided considerable insight into the probable functioning of simpler chemotaxis pathways [2,5,55], and a control engineering approach has recently been used in *R. sphaeroides* to discriminate between several possible mechanisms of CheY control of the flagellar motor [56]. In this study, a mathematical model of *R. sphaeroides* chemotaxis was formulated that integrates *in vivo* and *in vitro* biochemical data on the kinetic preferences of the signaling reactions with *in vivo* measurements of protein copy number. Analysis of the model revealed two

Figure 4. The predicted variation in levels of RR-P throughout a simulated chemotaxis response. Initially, CheA₂ autophosphorylation in the polar cluster and the phosphorylation of CheA₃ by CheA₄ in the cytoplasmic cluster are occurring. To mimic attractant stimulation of the polar cluster, CheA₂ autophosphorylation is turned off ($k_7 = 0$) at the point labelled (A). This causes a drop in RR-P levels and a new steady state is reached. (B) Subsequently, CheA₂ autophosphorylation is turned back on and the system returns to its original steady state. At point (C), the phosphorylation of CheA₃ by CheA₄ is turned off ($k_2 = 0$) to mimic attractant stimulation of the cytoplasmic cluster. As a result of this, RR-P levels fall and a new steady state is reached. (D) Finally, phosphorylation of CheA₃ by CheA₄ is turned back on and the system returns to its initial steady state.

doi:10.1371/journal.pcbi.1000896.g004

interesting features of the signaling network, both of which rely on reversed phosphotransfer from RR-Ps to CheA. Firstly, rapid signal termination for all chemotaxis RR-Ps may be achieved by CheY₆ acting as a phosphate sink in addition to being the primary motor control protein (Figure 3A). Secondly, a novel phosphorelay involving CheB₂ appears to link the cytoplasmic and polar chemotaxis clusters (Figure 3B). Together these two network features provide the bifunctional kinase/phosphatase, CheA₃, with the means to increase or decrease the concentration of all of the chemotaxis RR-Ps and therefore to regulate the output of the two chemosensory clusters.

CheY₆ is a phosphate sink for all of the chemotaxis RR-Ps

Phosphate sinks provide an alternative mechanism for dephosphorylating RR-Ps [51,52], instead of simply hydrolyzing the phosphoryl group (as in autodephosphorylation or phosphatase-assisted-dephosphorylation), the phosphoryl group is transferred to a HPK, which subsequently transfers it to the “phosphate sink” RR. The phosphoryl group is then hydrolyzed from the “phosphate sink” by either autodephosphorylation or phosphatase-assisted-dephosphorylation. The model presented in this study predicted that signal termination occurs rapidly in *R. sphaeroides*, with all RR-Ps dephosphorylating with half-times of less than ~7 s (Table 4). This is consistent with the observed stimulus response time of 1 s for *R. sphaeroides* [50], since with a decay half-time of ~7 s, CheY-P levels could fall by ~10% during 1s, which, assuming that the *R. sphaeroides* motor is as ultrasensitive to changes in CheY-P levels as the *E. coli* motor [57], would be sufficient to give a significant change in motor rotation bias.

Prior to this study, it was known that CheY₆-P with the aid of its specific phosphatase, the bifunctional protein CheA₃, could dephosphorylate rapidly [48], however, the other RR-Ps were known to autodephosphorylate with half-times in excess of 36 s, with CheB₁-P taking over 4000 s. By removing each of the RRs in turn from the model, we found that CheY₆ was acting as a “phosphate sink” for the other RR-Ps, since cells lacking CheY₆ showed much slower dephosphorylation rates for the remaining RR-Ps (Table 4 and Figure 3A). Furthermore, we showed that removal of the phosphatase activity of CheA₃ from the model increased the dephosphorylation half-times of all of the RR-Ps, indicating that the phosphatase activity is required for efficient operation of the CheY₆ phosphate sink and rapid signal termination. This phosphate sink role for CheY₆ is additional to its primary role as a direct regulator of flagellar rotation [39].

CheY₆ differs in several ways from the prototypical phosphate sink, CheY1 from *S. meliloti* [51]. CheY₆ directly controls flagellar motor rotation by binding FlIM [39,49], and has a dedicated phosphatase, in contrast, *S. meliloti* CheY1 does not bind FlIM and appears to function only as a “phosphate sink”. Another fundamental difference is the rate of dephosphorylation; CheY₆-P dephosphorylates much faster than the autodephosphorylation rates of the RRs for which it acts as a sink whereas *S. meliloti* CheY1-P does not autodephosphorylate any faster than the motor binding RR, CheY2-P, for which it is a sink. The *S. meliloti* sink does not need to dephosphorylate quickly because it does not directly affect flagellar rotation and so phosphoryl groups can be stored on it until autodephosphorylation occurs, in contrast, *R. sphaeroides* CheY₆ is a key regulator of flagellar rotation and therefore requires rapid signal termination.

A CheB₂ mediated phosphorelay connects the polar and cytoplasmic signaling clusters

As part of our interrogation of the model, we simulated attractant stimulation of the polar chemotaxis cluster by turning off autophosphorylation of CheA₂, while allowing phosphorylation

of CheA₃ by CheA₄ to occur (Figure 4). Interestingly under these conditions, even though CheA₃-P cannot directly phosphorylate CheY₃, CheY₄, and CheB₁, the model predicted non-zero concentrations of these RR-Ps. This is the result of the action of a phosphorelay where phosphoryl groups from CheA₃-P (His) are transferred to CheB₂ (Asp) then to CheA₂ (His) and subsequently to either CheY₃, CheY₄ or CheB₁ (Asp) (Figure 3B). Direct testing of the *in vivo* importance of this phosphorelay is confounded by the dual role of CheB₂, firstly as a chemoreceptor methylesterase and secondly as a potential intermediate in the phosphorelay. The methylesterase activity of CheB₂ is required for normal chemotaxis and it is not possible to block the phosphorylation of CheB₂ by mutagenesis without impairing the control of this methylesterase activity. It is therefore not known the extent to which this CheB₂ mediated phosphorelay operates *in vivo*; however, the model does incorporate both *in vitro* kinetic preference data and *in vivo* protein expression levels, and this suggests that the phosphorelay may operate *in vivo*, allowing the cytoplasmic cluster to make a significant contribution to phosphorylation levels of the non-cognate RRs; CheY₃, CheY₄ and CheB₁.

The model in this study does not include adaptation as this is a poorly understood process in *R. sphaeroides*, with little experimental data. However, it is possible that the adaptation pathway could act to reduce the elevated RR-P levels caused by a constant influx of phosphoryl groups to the polar cluster from the cytoplasmic cluster by modifying the polar receptors in such a way as to reduce the autophosphorylation rate of the polar kinase, CheA₂ i.e. the cell could adapt to constant signals from the cytoplasmic cluster. Although when cells are performing chemotaxis and swimming through gradients of chemoeffector, signals from the cytoplasmic cluster will vary over time and will make a significant contribution to RR-P levels. The relative contribution of this phosphorelay to levels of CheY₃-P, CheY₄-P and CheB₁-P will be modulated by signals coming through the transmembrane chemoreceptors that directly control the rate of CheA₂ autophosphorylation and would be greatest when the autophosphorylation rate of CheA₂ is low and the rate of phosphorylation of CheA₃ by CheA₄ is high. These conditions could arise when cells are swimming up a gradient of a specific attractant which is sensed by the transmembrane chemoreceptors, while the metabolic state of the cell is worsening due to, for example, decreasing concentrations of an essential nutrient (for which there may not be a transmembrane chemoreceptor). Under such conditions, the increased rate of phosphorylation of CheA₃ by CheA₄, coupled with the CheB₂/CheA₂ mediated phosphorelay, could raise levels CheY₃-P, CheY₄-P and CheY₆-P, allowing cells to override their favourable response to the extracellular attractant and swim away from these unfavourable environments.

Numerous examples of other two-component systems employing phosphorelays have been described [58–61]; however, to the best of our knowledge this is the first example of a phosphorelay involving two distinct HPKs localized to different regions of the cell, and also, the first phosphorelay to be found in a chemotaxis signaling pathway. Given that over 50% of bacteria with any *che* genes have more than two *cheAs* [31,32,48], it seems likely that phosphorelays allowing communication between different CheA homologues could be involved in chemotactic signaling in a wide range of bacterial species.

Signal integration by the cytoplasmic cluster

The polar cluster senses extracellular signals while the cytoplasmic cluster is believed to sense the metabolic state of the cell [30]. The concentration of each RR-P depends not only on polar kinase activity but also on the balance of kinase and phosphatase activity in

the cytoplasmic cluster. The kinase activity of the cytoplasmic cluster resides in CheA₄ and the phosphatase activity resides in CheA₃; both proteins have P5 (regulatory) domains and it is therefore likely that both activities will be regulated by environmental stimuli [48,62]. A stimulus that increases phosphatase activity would have the effect of reducing levels of all RR-Ps, since the action of the phosphatase would directly accelerate CheY₆-P dephosphorylation leaving more unphosphorylated CheY₆ to function as a phosphate sink for the other RR-Ps. Such a mechanism could allow the cytoplasmic cluster to tune or modulate signals coming from the polar cluster since increased phosphatase activity would lead to a general decrease in chemotaxis RR-P levels. In contrast, a stimulus that increased kinase activity at the cytoplasmic cluster would increase levels of all RR-Ps because CheA₃-P would phosphorylate CheY₆ and CheB₂ directly; CheB₂ would then shuttle the phosphoryl groups to CheA₂ and from there onto the other RRs while phosphorylation of CheY₆ would reduce its capacity as a phosphate sink resulting in a general increase in RR-P levels. Therefore the overall sensory output of the pathway depends critically on the relative activity of CheA₃ and CheA₄, and potentially provides a mechanism for signals about the metabolic state of the cell to modulate signals regarding the extracellular environment.

Materials and Methods

Mathematical model

Full details on the mathematical model are included in Text S1. Briefly, the law of mass action was applied to the reactions detailed in Table 1 to produce a system of non-linear ordinary differential equations (ODEs), which were solved using Matlab (MathWorks). The model was parameterized with data from the literature [39,43,45,48,63–65] and our own experiments as detailed in Tables 2&3. A parameter fit of the phosphotransfer rates between each kinase and RR (time course data) with that of a mathematical model describing the *in vitro* reactions was performed. A number of local, global and genetic algorithm optimisation procedures were employed (simulated annealing, Hooke and Jeeves, least squares, Levenberg-Marquardt, Nelder-Mead, steepest descent and the genetic algorithm) to obtain a robust set of parameters (Table 3).

Plasmids and strains

The plasmids and strains used are shown in Table S3. *E. coli* strains were grown in LB medium at 37°C. Where required, antibiotics were used at concentrations of 100 µg ml⁻¹ for ampicillin and 25 µg ml⁻¹ for kanamycin.

Protein purification

His-tagged and GST-tagged *R. sphaeroides* CheA, CheY and CheB proteins were purified as described previously [66]. Protein purity and concentration was measured as described [45]. Purified proteins were stored at -20°C.

Preparation of CheA₃P1-³²P

CheA₃P1 was phosphorylated using [γ -³²P] ATP and CheA₄, and purified as described previously [48]. The final preparation of CheA₃P1-³²P was free of ATP and CheA₄.

Detection of phosphotransfer from the response regulators to CheA₂

Assays were performed at 20°C in TGMNKD buffer (50 mM Tris HCl, 10% (v/v) glycerol, 5 mM MgCl₂, 150 mM NaCl, 50 mM KCl, 1 mM DTT, pH 8.0). CheA₃P1-³²P was used to phosphorylate the RRs, CheY₆ and CheB₂, in these assays because it is a good phosphodonor for these proteins and even after prolonged incubation (>1 hour) CheA₃P1-³²P does not act as a direct phosphodonor for CheA₂ (Figure 3A); therefore any CheA₂-P generated in these assays is due to phosphotransfer from RR-P to CheA₂ rather than direct phosphotransfer from CheA₃P1-P to CheA₂. 30 µM CheA₃P1-³²P was mixed with 5 µM CheA₂ prior to the addition of 10 µM RR. Following the addition of RR, reaction aliquots of 10 µl were taken at the indicated timepoints and quenched immediately in 5 µl of 3 X SDS-PAGE loading dye (7.5% (w/v) SDS, 90 mM EDTA, 37.5 mM Tris HCl, 37.5% glycerol, 3% (v/v) β-mercaptoethanol, pH 6.8). Quenched samples were analyzed using SDS-PAGE and phosphorimaging as described previously.

Protein expression levels

Protein expression levels were measured in wild-type *R. sphaeroides* cells grown under microaerobic growth conditions using quantitative immunoblotting as described previously [65,67–69].
