## 9 **Abstract**

10 Improving the bulk quality of perovskite films is critical for achieving higher-  
11 performance photovoltaic devices. Chloride-containing additives, including lead  
12 chloride (PbCl<sub>2</sub>) and methylammonium chloride (MAcI)—standard additives  
13 widely adopted in perovskite photovoltaics—are effective for controlling  
14 crystallisation kinetics and grain morphology. However, the distinct impacts of  
15 different forms of chloride additives on nanoscale phase uniformity and  
16 luminescence homogeneity remains underexplored. Here, we provide new  
17 insights into how the choice and combination of chloride additives influence  
18 phase transitions and spatially uniform carrier dynamics within perovskite films.  
19 We demonstrate that strategically combining MAcI and PbCl<sub>2</sub> improves  
20 crystallinity and optoelectronic uniformity across dimensions spanning  
21 micrometres to millimetres. Leveraging these findings, we fabricated inverted (p-  
22 i-n) perovskite solar cells achieving certified quasi-steady-state efficiencies of  
23 26.4% and 24.5% at device areas of 0.05 and 1 cm<sup>2</sup>, respectively. Furthermore,  
24 these devices exhibit robust operational stability, retaining 88% of their initial  
25 performance after 1200 hours of continuous maximum power point tracking at  
26 elevated temperatures (65 °C) under simulated AM1.5G illumination. Our results  
27 elucidate the mechanistic differences between chloride additive forms, providing  
28 a viable strategy for advancing large-area, high-efficiency, and thermally stable  
29 perovskite photovoltaics.

## 30 **Introduction**

31 Metal-halide perovskites are semiconductor materials that can be fabricated via  
32 cost-effective solution-<sup>1,2</sup> or vacuum-based<sup>3,4</sup> methods. Their remarkable  
33 optoelectronic properties<sup>5,6</sup> have positioned them as promising candidates for  
34 photovoltaic devices capable of efficiently converting sunlight into electricity<sup>7</sup>. In

35 the past decade, substantial progress has been achieved in single-junction  
36 perovskite solar cells (PSCs), with power conversion efficiencies (PCEs) now  
37 exceeding 27%<sup>8-11</sup>—comparable to those of state-of-the-art silicon solar cells<sup>12,13</sup>.

38 Significant advancements in PSC performance have primarily resulted from  
39 reduced interfacial losses<sup>14-19</sup>, achieved through mitigating defect sites at  
40 perovskite heterojunctions and minimising nonradiative recombination losses<sup>20-25</sup>.  
41 To further enhance device performance, precise control over local composition  
42 and optoelectronic uniformity within the perovskite absorber is essential<sup>26-30</sup>.  
43 Recent studies have highlighted that inhomogeneous phase distributions from  
44 micro- to millimetre scales are detrimental to device efficiency and stability,  
45 particularly when upscaling to larger areas<sup>31-34</sup>. Within solution-processing  
46 methods, achieving balanced crystallisation among mixed-cation and mixed-  
47 anion components is critical to improve phase homogeneity<sup>30,35</sup>. Chloride-based  
48 additives have been proven effective for controlling crystallisation kinetics and  
49 improving the semiconductor quality of perovskite films<sup>6,36-40</sup>; however, their  
50 influence on local optoelectronic uniformity remains insufficiently understood.

51 Here, we investigate the influence of different forms of chloride additives on the  
52 phase distribution and optoelectronic uniformity in perovskite films. By  
53 comparatively evaluating two widely adopted chloride additives<sup>18</sup>—  
54 methylammonium chloride (MACl) and lead chloride (PbCl<sub>2</sub>)—we confirm that  
55 chloride incorporation notably accelerates the transition from the inactive yellow  
56 phase to the active black perovskite phase. We observe that MACl promotes the  
57 out-of-plane compositional heterogeneity, resulting in variable carrier dynamics  
58 at micrometre scales. In contrast, PbCl<sub>2</sub> more effectively incorporates chloride  
59 uniformly within grain interiors, homogenising local optoelectronic properties but  
60 introducing detrimental lead iodide (PbI<sub>2</sub>) grains that hinder charge transport. We  
61 demonstrate that a synergistic combination of MACl and PbCl<sub>2</sub> significantly  
62 improves overall film crystallinity and achieves spatially homogeneous carrier  
63 dynamics from microscale to millimetre-scale dimensions. Consequently, we  
64 fabricate inverted (p-i-n) PSCs that achieve efficiencies of up to 27.0% (certified  
65 26.4%) at an active areas of approximately 0.05 cm<sup>2</sup>, and 25.5% (certified 24.5)  
66 at 1-cm<sup>2</sup>. These devices retain 88% of their initial PCE after 1200 hours of  
67 continuous maximum power point tracking (MPPT) under simulated AM1.5G  
68 illumination at about 65 °C. Although the chloride-assisted crystallisation and the  
69 transition from yellow to black perovskite phases using MACl or PbCl<sub>2</sub> are well-

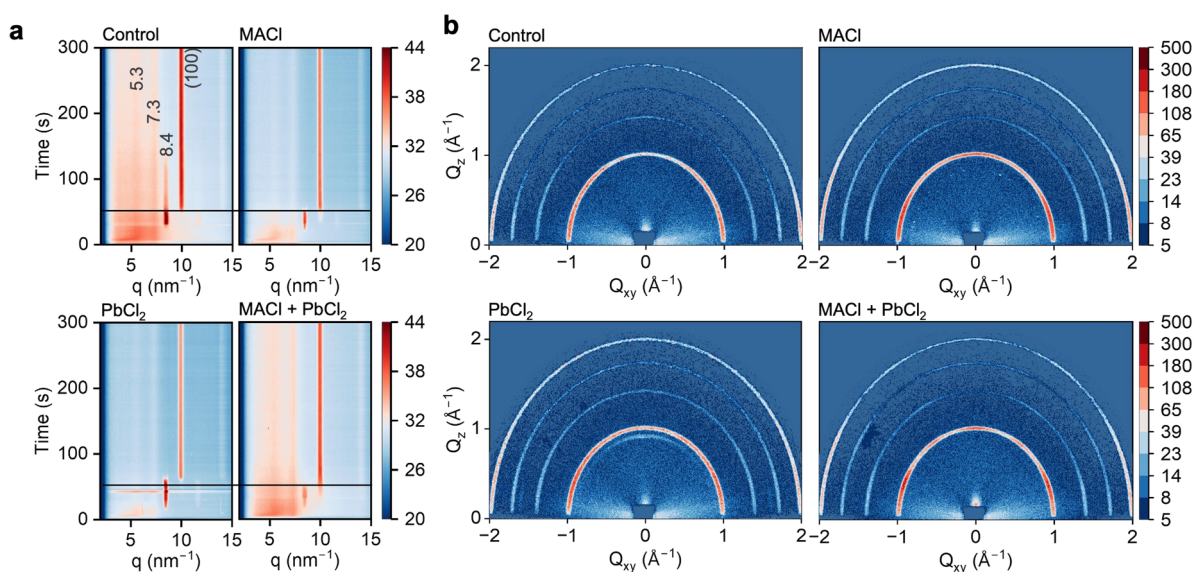

70 documented, our study provides a systematic investigation into their distinct  
71 impacts on compositional and morphological uniformity at both micrometre and  
72 millimetre scales. We demonstrate how these pathways govern local phase and  
73 luminescence homogeneity, as well as carrier dynamics, offering a mechanistic  
74 understanding of how high-efficiency and stable perovskite photovoltaics can be  
75 achieved using widely accessible and commonly utilised chloride additives.

## 76 **Results**

### 77 **Phase transition of chloride-engineered perovskites**

78 We prepared perovskite films with an initial composition of  $\text{Cs}_{0.05}\text{FA}_{0.90}\text{MA}_{0.05}\text{PbI}_3$   
79 (FA: formamidinium) using solution processing as control samples. To study the  
80 mechanism of chloride incorporation, we fabricated films with chloride additives:  
81 MAcl (13 mol%),  $\text{PbCl}_2$  (3 mol%), and their combination (13 mol% MAcl + 3 mol  
82 %  $\text{PbCl}_2$ , relative to  $\text{PbI}_2$ ) after initial device optimisation (**Supplementary Fig.**  
83 **1-2**). Synchrotron radiation-based in-situ grazing incidence wide-angle X-ray  
84 scattering (GIWAXS) was employed to track film crystallisation during spin  
85 coating and subsequent annealing (**Fig. 1a**). In the initial stage of spin coating  
86 (0 to 40 seconds), we observe two distinct diffraction peaks at scattering vectors  
87 ( $q$ ) of 5.3 and 7.3  $\text{nm}^{-1}$  regardless of using chloride additives, indicating low-  
88 dimensional intermediate phases composed of lead iodide-centred adducts with  
89 a specific number of solvent molecules or FAI-rich perovskite compounds<sup>41-43</sup>.  
90 Upon initiating antisolvent dripping at around 40 seconds, an additional  
91 diffraction peak emerges at  $q = 8.4 \text{ nm}^{-1}$ . Subsequently, as annealing  
92 commenced at around 60 s, a new diffraction develops at  $q = 10 \text{ nm}^{-1}$ . The  
93 diffraction peaks at 8.4 and 10  $\text{nm}^{-1}$  represent the hexagonal 2H polytype (yellow  
94  $\delta$ -phase) and the black 3D perovskite phase, respectively<sup>41</sup>. Notably, the control  
95 sample exhibits incomplete conversion from the yellow to the black phase,  
96 maintaining strong diffraction intensity of the 2H phase even after 150 seconds  
97 at 150 °C. In contrast, samples incorporating chloride additives display  
98 significantly reduced intensity and a shorter duration of the 2H phase,  
99 completely eliminating the peak at 8.4  $\text{nm}^{-1}$  within 60 seconds at 120 °C. We  
100 propose that the suppressed retention of the yellow 2H polytype is due to a  
101 kinetic effect introduced by chloride-containing additives. In the precursor stage,  
102 chloride ions can bind to the surfaces of the emerging face-sharing 2H  
103 crystallites<sup>44,45</sup>. Following antisolvent dripping, the chloride ions that coordinate  
104 with  $\text{Pb}^{2+}$  ions at the octahedral terminal corners destabilise the face-sharing

105 polytype and promote the formation of corner-sharing 3D-like structures. The  
 106 resulting seeding layer facilitates the complete conversion of black 3D phases in  
 107 the bulk material. The trends in the 3D structure conversion rate are consistent  
 108 with in-situ photoluminescence (PL) measurements, in which the MACl + PbCl<sub>2</sub>  
 109 film shows the fastest redshift and the highest 3D peak emission intensity, even  
 110 without thermal annealing<sup>46</sup> (**Supplementary Fig. 3-4**). Interestingly, the film  
 111 containing the combination of MACl and PbCl<sub>2</sub> (hereafter denoted as MACl +  
 112 PbCl<sub>2</sub>) maintains intermediate phases ( $q \leq 7.3 \text{ nm}^{-1}$ ) throughout annealing up to  
 113 300 seconds, similar to the control film. Conversely, films with only MACl or PbCl<sub>2</sub>  
 114 show reduced presence of these solvent-involved intermediate phases.  
 115 Preserving intermediate phases while facilitating rapid  $\delta$ -phase conversion can  
 116 positively impact the crystallisation pathway, leading to higher-quality perovskite  
 117 crystals<sup>42</sup>. Ex-situ GIWAXS measurements further assess the crystallinity of  
 118 annealed perovskite films (**Fig. 1b**). We observe no low-dimensional phases in  
 119 any films after annealing. Films containing MACl, particularly those with MACl +  
 120 PbCl<sub>2</sub>, exhibit a significantly enhanced (100) diffraction intensities in both in-  
 121 plane ( $Q_{xy}$ ) and out-of-plane ( $Q_z$ ) directions compared to the control film. In  
 122 contrast, PbCl<sub>2</sub> alone provides limited improvement in crystallinity and promotes  
 123 the undesirable formation of PbI<sub>2</sub> residue ( $q = 0.9 \text{ \AA}^{-1}$ )<sup>47-49</sup>. These crystallographic  
 124 analyses confirm that chloride additives universally facilitate the formation of the  
 125 desired 3D perovskite phase. Importantly, combining MACl and PbCl<sub>2</sub> effectively  
 126 preserves intermediate phases for an optimal duration, resulting in superior  
 127 crystallinity of the final perovskite films (**Supplementary Fig. 5-6**,  
 128 **Supplementary Table 1**).

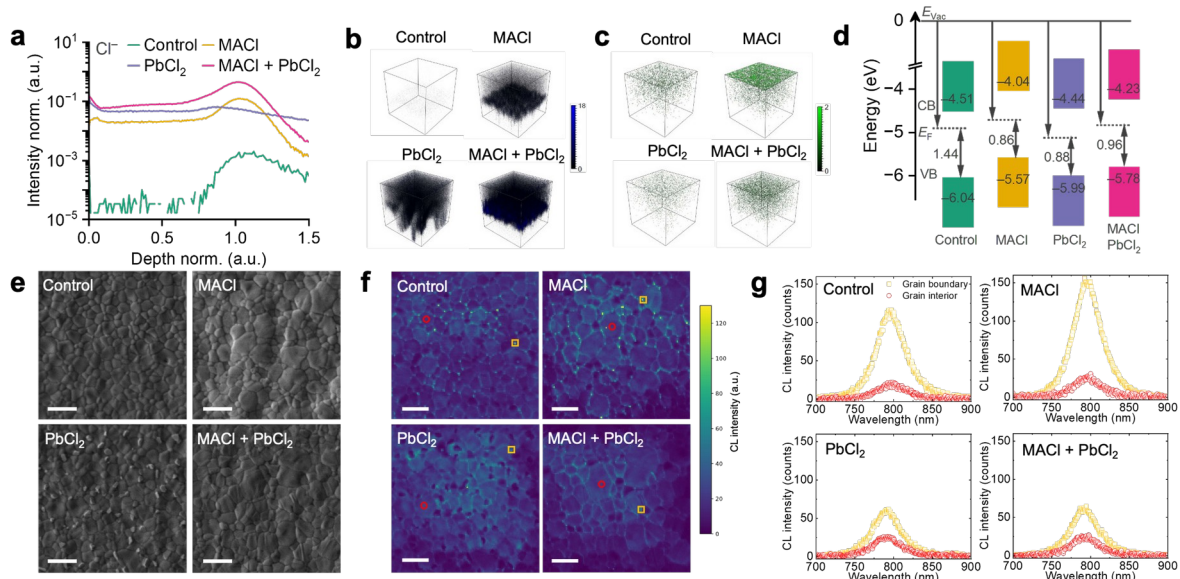

129

130 **Fig. 1 Film crystallization process.** **a**, In-situ ( $\psi = 0.4^\circ$ ) and **b**, ex-situ ( $\psi =$   
131  $0.4^\circ$ ) 2D GIWAXS patterns for the control, MACl, PbCl<sub>2</sub>, and MACl + PbCl<sub>2</sub>  
132 samples. For the in-situ measurements, the films are deposited on glass  
133 substrates in ambient air. The control sample is annealed at 150 °C for a full  
134 phase conversion and other samples are annealed at 120 °C. All films for ex-situ  
135 GIWAXS measurements are deposited under inert conditions with an annealing  
136 temperature of 120 °C.

### 137 **Phase distribution and nanoscale optical properties**

138 Following the crystallographic analysis, we investigate the influence of additives  
139 on phase distribution using time-of-flight secondary ion mass spectroscopy (ToF-  
140 SIMS). The perovskite film incorporating 3 mol% PbCl<sub>2</sub> exhibits a notably higher  
141 chloride content than the film containing 13 mol% MACl (**Fig. 2a** and  
142 **Supplementary Fig. 7-8**). This corresponds to a slight increase ( $\sim 20$  meV) in  
143 the photovoltaic bandgap (**Supplementary Fig. 9**), likely reflecting the efficient  
144 integration of PbCl<sub>2</sub> into the perovskite grain interiors<sup>50</sup>. Moreover, 3D  
145 tomographic analysis of the PbCl<sub>2</sub>-modified film reveals a uniform chloride  
146 distribution throughout its bulk (**Fig. 2b**). Conversely, the MACl-containing film  
147 displays pronounced chloride accumulation near the buried interface and  
148 enrichment of MA cations toward the top surface (**Fig. 2c**). This coincides with a  
149 modest increase in Cs<sup>+</sup> at the bottom interface and I<sup>-</sup> at the top surface,  
150 respectively, which may help retain local electroneutrality in the bulk film  
151 (**Supplementary Fig. 10**). We believe this phenomenon is due to the volatility  
152 of MACl during annealing. Chloride-containing species near the surface can  
153 escape more easily, while those deeper in the film are kinetically trapped<sup>51</sup>,  
154 leading to an apparent enrichment at the bottom. At the same time, MA-related  
155 species from both the MAI precursor and MACl additive can redistribute and are  
156 only partially vaporised, leaving some residual MA near the surface after  
157 annealing. These observations indicate that MACl is relatively inefficient at  
158 incorporating chloride within perovskite grains, resulting in significant  
159 compositional inhomogeneity. Additionally, we recognise that the chemical depth  
160 profile is sensitive to precursor stoichiometry and processing conditions.  
161 Changes in the intermediate adduct phases during antisolvent quenching and  
162 the redistribution of volatile species, such as MACl, during thermal annealing  
163 may lead to different apparent ion distributions<sup>52</sup>.

164

165 **Fig. 2 Phase distribution and nanoscopic emission of perovskite films.** **a**,  
 166 ToF-SIMS depth profiles of chloride anions. 3D tomography of **b**, chloride anion  
 167 and **c**, MA cation. **d**, Energy level diagram generated from the UPS spectra of  
 168 perovskite films fabricated without (control) and with additives. **e**, SEM, **f**, CL  
 169 emission intensity images, and **g**, CL spectra of grain boundary (yellow square)  
 170 and grain interior (red circle) regions of perovskite films fabricated without  
 171 (control) and with additives. Scale bars in **e** and **f** are 1  $\mu\text{m}$ . More CL spectra  
 172 from 10 different pixels are shown in **Supplementary Fig. 14**.

173 We further analyse the surface electronic structure using ultraviolet  
 174 photoelectron spectroscopy (UPS, **Fig. 2d** and **Supplementary Fig. 11**).  
 175 Compared to the control films, we identify the largest upward shift (0.47 eV) in  
 176 the valence band maximum (VBM) for the MACl-containing films, followed by a  
 177 smaller shift (0.26 eV) in the MACl + PbCl<sub>2</sub> films. The PbCl<sub>2</sub> film shows negligible  
 178 shifts near the band edges. Correlating with the ToF-SIMS data, we attribute the  
 179 pronounced VBM shift primarily to surface accumulation of MA cations, which  
 180 lowers the ionisation energy. Additionally, we observe a decreased offset  
 181 between the Fermi level ( $E_F$ ) and VBM in all chloride-engineered films, suggesting  
 182 the formation of a more intrinsic, electronically neutral top surface. Based on the  
 183 measured photovoltaic bandgap values, we estimate the conduction band  
 184 minimum (CBM) to be -4.51, -4.04, -4.44, and -4.23 eV for the control, MACl-,  
 185 PbCl<sub>2</sub>-, and MACl + PbCl<sub>2</sub>-added films, respectively. Considering the lowest  
 186 unoccupied molecular orbital (LUMO) energy level (-4.20 eV) of the electron  
 187 transport layer (ETL) C<sub>60</sub><sup>53</sup>, the film modified with MACl + PbCl<sub>2</sub> presents the  
 188 smallest interfacial energy mismatch on the electron extraction side.

189 To correlate film morphology with optical emission properties, we perform  
190 scanning electron microscopy (SEM) coupled with cathodoluminescence (CL)  
191 imaging at sub-micrometre resolution (**Fig. 2e–g**). Top-view SEM images show  
192 that chloride additives effectively increase the apparent average grain size from  
193  $298 \pm 96$  nm (control) to  $318 \pm 151$  (MAI),  $272 \pm 108$  ( $\text{PbCl}_2$ ), and  $412 \pm 171$   
194 nm (MAI +  $\text{PbCl}_2$ ) (**Supplementary Fig. 12**). Cross-sectional SEM images show  
195 that the film with only MAI has greater surface roughness due to the increased  
196 non-uniformity in grain morphology (**Supplementary Fig. 13**). Correspondingly,  
197 CL imaging under continuous electron beam excitation reveals distinct photon  
198 emission behaviours. For the control films, emission near 800 nm (associated  
199 with the 3D perovskite phase) is stronger at grain boundaries compared to grain  
200 interiors, observed across multiple grain regions (**Fig. 2f–g** and  
201 **Supplementary Fig. 14–16**). Interestingly, MAI-added films exhibit an even  
202 more pronounced contrast, with grain boundaries emitting up to six times higher  
203 intensity than the interiors. This observation is unexpected since grain  
204 boundaries generally harbour higher defect densities and are known as non-  
205 radiative recombination sites. However, we find no clear correlation between  
206 grain size and bulk non-radiative recombination rate, suggesting grain  
207 boundaries are not dominate in non-radiative recombination processes  
208 (**Supplementary Fig. 25**). Additionally, the overall averaged CL intensity and  
209 maximum emission wavelengths show minimal variations among the different  
210 samples (**Supplementary Fig. 17**), highlighting that the observed emission  
211 contrast is highly localised to grain boundaries. We rule out beam-induced halide  
212 segregation as a possible cause of brighter grain boundaries<sup>54</sup> since no energy  
213 shifts are detected between grain boundary and interior regions (**Fig. 2g** and  
214 **Supplementary Fig. 15–16**). While beam-induced degradation within the grain  
215 interiors may be a potential factor<sup>55</sup>, we propose enhanced surface roughness  
216 from MAI incorporation increases scattering and optical out-coupling efficiency,  
217 contributing to greater local emission brightness<sup>56,57</sup>.

218 In contrast,  $\text{PbCl}_2$ - and MAI +  $\text{PbCl}_2$  films exhibit significantly narrower  
219 variations in CL emission intensity across grain boundaries and interiors. This  
220 enhanced uniformity in emission characteristics reflects improved morphological  
221 and optoelectronic homogeneity. However,  $\text{PbCl}_2$ -added films featured distinct  
222 needle-shaped features attributed to excess  $\text{PbI}_2$ , visible in CL maps filtered  
223 within the 510–550 nm spectral range (**Supplementary Fig. 18–20**). Combined  
224 with our ToF-SIMS analysis, these results indicate MAI alone promotes

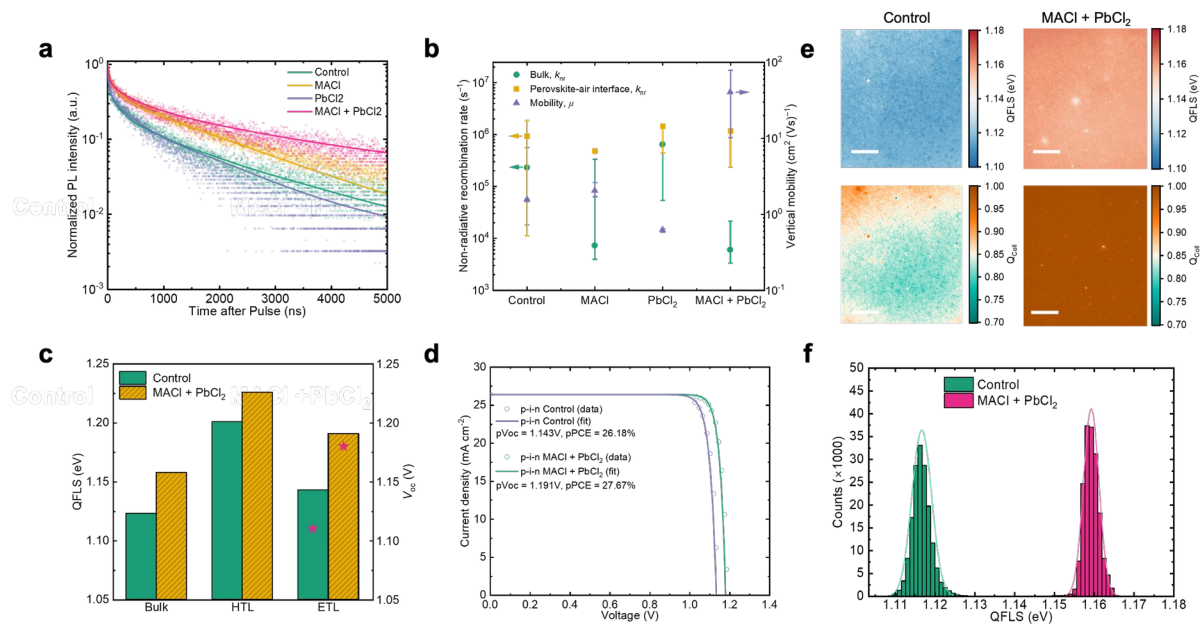

225 morphological disorder and nonuniform optoelectronic properties, whereas  $\text{PbCl}_2$   
226 contributes to uniform emission properties but introduces unwanted  $\text{PbI}_2$  phases.  
227 Ultimately, the combination of  $\text{MACl}$  and  $\text{PbCl}_2$  additives provides a balanced  
228 approach, yielding highly uniform carrier dynamics across micrometre-scale  
229 regions.

### 230 **Carrier dynamics of perovskite films and devices**

231 We further investigate the carrier dynamics within perovskite films using time-  
232 resolved photoluminescence (TRPL) measurements. Consistent with our previous  
233 approach<sup>58</sup>, we acquire four TRPL decay curves using two different excitation  
234 fluences ( $1.3 \times 10^9$  and  $1.3 \times 10^{10} \text{ cm}^{-2}$  per pulse) on both the top and bottom  
235 surfaces of the perovskite samples (**Fig. 3a** and **Supplementary Fig. 21-24**).  
236 Employing a comprehensive physical model coupled with Bayesian inference, we  
237 extract eight device-relevant parameters, including the bulk and surface  
238 recombination velocities. We calculate the median bulk recombination rates to  
239 be  $2.3 \times 10^4$ ,  $7.1 \times 10^3$ ,  $6.3 \times 10^4$ , and  $5.9 \times 10^3 \text{ s}^{-1}$  for the control,  $\text{MACl}$ ,  $\text{PbCl}_2$ ,  
240 and  $\text{MACl} + \text{PbCl}_2$  samples, respectively. We interpret that improved film  
241 uniformity does not necessarily lead to a reduced average bulk recombination  
242 rate. While  $\text{PbCl}_2$  facilitates more uniform chloride incorporation, it also promotes  
243 the formation of  $\text{PbI}_2$  phases (**Supplementary Fig. 6 and 20**), which can  
244 introduce non-radiative recombination centres. Interestingly, the  $\text{MACl} + \text{PbCl}_2$   
245 condition balances these competing effects, resulting in highly crystalline, phase-  
246 pure films with homogeneous carrier dynamics and reduced non-radiative bulk  
247 recombination. In comparison, median surface recombination rates are found to  
248 be  $9.2 \times 10^5$ ,  $4.7 \times 10^5$ ,  $1.4 \times 10^6$ , and  $1.2 \times 10^6 \text{ s}^{-1}$  for the control,  $\text{MACl}$ ,  $\text{PbCl}_2$ ,  
249 and  $\text{MACl} + \text{PbCl}_2$  samples, respectively, suggesting a comparatively minor  
250 influence of chloride treatments on surface recombination processes (**Fig. 3b**).  
251 Additionally, we estimate the vertical charge-carrier mobility of the films,  
252 considering spectral changes caused by self-absorption during pulsed  
253 photoexcitation (**Methods** and **Supplementary Fig. 26**)<sup>58,59</sup>. Remarkably, the  
254  $\text{MACl} + \text{PbCl}_2$ -modified film shows enhanced vertical mobility of  $40.2 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$   
255 compared to substantially lower values ( $0.6\text{--}2.0 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ ) in other films. Hence,  
256 the combined use of  $\text{MACl}$  and  $\text{PbCl}_2$  considerably improves charge transport  
257 properties beneficial for photovoltaic applications.

258 We subsequently perform quasi-Fermi level splitting (QFLS) analysis via absolute  
259 PL to evaluate the intrinsic efficiency potential of perovskite films, without the

260 influence of series resistance losses (**Fig. 3c**). Comparing neat films processed  
 261 on bare glass with those integrated into half-cells using NiO<sub>x</sub>/[4-(3,6-dimethyl-9H-  
 262 carbazol-9-yl)butyl]phosphonic acid (Me-4PACz) as the hole transport layer (HTL),  
 263 we observe QFLS enhancements of 78 and 68 meV for the control and MACl +  
 264 PbCl<sub>2</sub>-modified films, respectively. Correspondingly, the implied open-circuit  
 265 voltage (*iV*<sub>OC</sub>) reaches 1.201 V in the control sample and 1.226 V in the MACl +  
 266 PbCl<sub>2</sub> film, consistent with the passivation effect from the self-assembled  
 267 monolayer<sup>25</sup> and suggests better optoelectronic quality for the latter samples.  
 268 Interestingly, the subsequent deposition of a C<sub>60</sub> layer (forming a p-i-n structure)  
 269 tremendously reduces the *iV*<sub>OC</sub> of the control sample to 1.143 V, whereas the  
 270 MACl + PbCl<sub>2</sub> sample retains a much higher *iV*<sub>OC</sub> of 1.191 V. Simultaneously, the  
 271 control sample allows for a pseudo-fill factor (*p*FF) of 86.8%, compared with a  
 272 higher 88.1% obtained for the MACl + PbCl<sub>2</sub> device. This indicates that the MACl  
 273 + PbCl<sub>2</sub> additive reduces nonradiative recombination and restores fast charge  
 274 extraction when in contact with a C<sub>60</sub> layer atop<sup>25</sup>. Accordingly, pseudo-current  
 275 density-voltage (*pj*-*V*) characteristics imply efficiency potentials of 26.18% for  
 276 control and 27.67% for MACl + PbCl<sub>2</sub>-based device.

277

278 **Fig. 3 Optoelectronic properties of perovskite films.** **a,b**, Representative  
 279 TRPL response (**a**), the inferred non-radiative bulk and surface recombination  
 280 rate, and the vertical mobility (**b**) for the control, MACl, PbCl<sub>2</sub>, and MACl + PbCl<sub>2</sub>  
 281 perovskite deposited on glass/ITO/HTL substrates. For clarity, only one TRPL  
 282 measured from the glass side is shown (excitation fluence 1.3 × 10<sup>9</sup> cm<sup>-2</sup>). The  
 283 fitted curves from our global inference are shown in **Supplementary Fig. 21-**

284 **24.** In **Fig. 3b**, the solid dots represent median inferred values and the error bars  
285 indicate the first and third quartiles. **c**, QFLS of control and MACl + PbCl<sub>2</sub>  
286 perovskite films deposited on bare glass, HTL half stack and p-i-n layout. The  
287 stars represent the measured device  $V_{OC}$  prepared in the same batch. **d**, Pseudo  
288  $J$ - $V$  characteristics of control and MACl + PbCl<sub>2</sub> films processed in a p-i-n layout.  
289 **e**, QFLS imaging recorded at  $V_{OC}$  conditions and the charge collection quality  
290 mapping by comparing the PLQY at  $V_{OC}$  and  $J_{SC}$  conditions for control and MACl +  
291 PbCl<sub>2</sub>-added PSCs. The scale bars are 1 mm. **f**, QFLS histograms of samples  
292 displayed in **Fig. 3e**.

293 To bridge local optical properties with macroscopic device performance, we  
294 perform absolute PL imaging on complete solar cells under 1-sun equivalent  
295 illumination, both at open-circuit (OC) and short-circuit (SC) conditions  
296 (**Methods**). At OC, the MACl + PbCl<sub>2</sub> device exhibits a higher mean QFLS (1.16  
297 eV) compared to 1.12 V for the control device (**Fig. 3e, f**). This aligns with the  
298 PLQY data and suggests that the MACl + PbCl<sub>2</sub> device exhibits improved  
299 luminescence quality over millimetre length scales. We note that a reduced  
300 surface energy level mismatch from the UPS data may also contribute to the  
301 increased  $iV_{OC}$ <sup>60,61</sup>. At SC, devices with higher charge extraction efficiency should  
302 exhibit lower PL signals<sup>61,62</sup>. Therefore, comparing the QFLS maps at OC and SC  
303 allows us to spatially resolve the charge collection quality ( $Q_{coll}$ ) of the solar  
304 cells<sup>62</sup>. We observe that the control device displays more inhomogeneities,  
305 resulting in an approximate  $Q_{coll}$  of 85%. In comparison, the MACl + PbCl<sub>2</sub> device  
306 shows more uniform morphology, achieving an increased  $Q_{coll}$  of about 95%.  
307 These findings align closely with the CL analysis, underscoring that enhanced  
308 luminescence uniformity in MACl + PbCl<sub>2</sub> films promotes efficient charge  
309 extraction and higher achievable device  $V_{OC}$ .

## 310 **Photovoltaic performance**

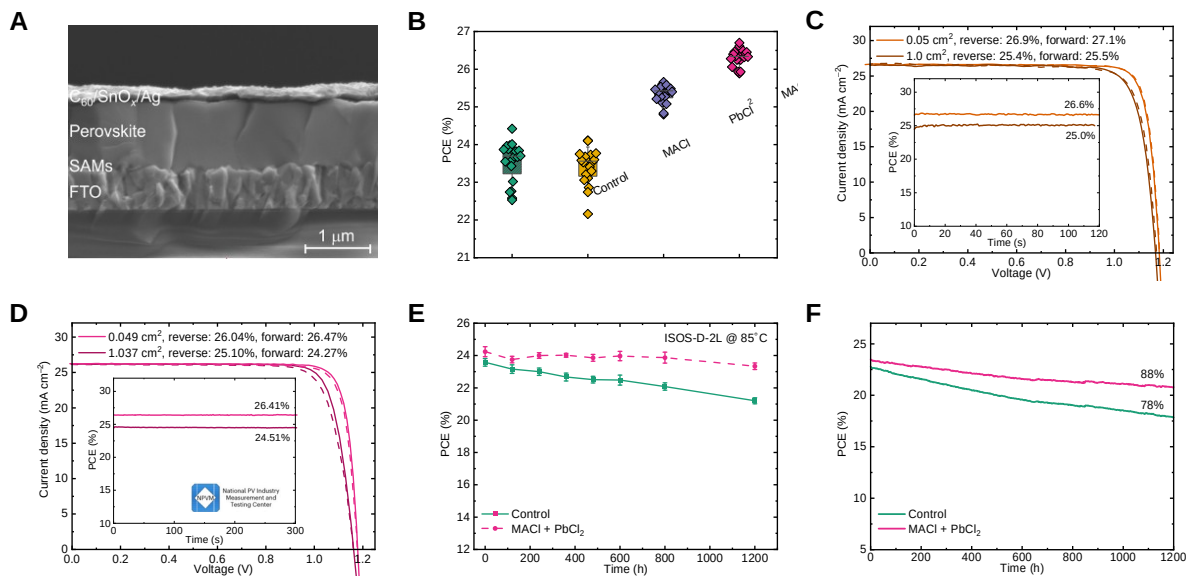

311 To evaluate the impact of chloride additives on the photovoltaic performance, we  
312 fabricate p-i-n PSCs with the architecture of  
313 FTO/NiO<sub>x</sub>/2PACz:Me-4PACz/perovskite/C<sub>60</sub>/SnO<sub>x</sub>/Ag (**Fig. 4a**). The thickness of the  
314 perovskite layer is approximately 1  $\mu$ m. Statistical analysis of 20 devices  
315 prepared in the same batch indicates a notable increase in PCE, rising from 23.5  
316  $\pm$  0.5% (control) to 25.3  $\pm$  0.2 (PbCl<sub>2</sub>-treated) and further to 26.3  $\pm$  0.2% (MACl  
317 + PbCl<sub>2</sub>-treated) (**Fig. 4b**). Correspondingly, both the averaged  $V_{OC}$  and FF are  
318 improved from 1.11 V (control) to 1.16 (PbCl<sub>2</sub>) and 1.18 V (MACl + PbCl<sub>2</sub>), and

319 from 0.79 (control) to 0.82 ( $\text{PbCl}_2$ ) and 0.84 ( $\text{MACl} + \text{PbCl}_2$ ), respectively  
320 (**Supplementary Fig. 27**). The enhancement in FF can be attributed to reduced  
321 transport losses, compared to the resistance-free pseudo-FF values (**Fig. 3d** and  
322 **Supplementary Table 5**). We attribute the superior photovoltaic performance  
323 of the  $\text{MACl} + \text{PbCl}_2$  devices to enhanced film uniformity and efficient charge  
324 extraction across micro- to millimetre scale dimensions. We note that the change  
325 in bandgap due to the chloride addition (20 meV, **Supplementary Fig. 8**) is  
326 modest compared to the substantial  $V_{\text{OC}}$  increase in the  $\text{PbCl}_2$  and  $\text{MACl} + \text{PbCl}_2$   
327 treated devices. Interestingly, devices treated solely with  $\text{MACl}$  show limited  
328 performance gains despite improved film crystallinity. As shown in the UPS data  
329 (**Fig. 2d**), a cliff-like band alignment between the  $\text{MACl}$  perovskite and  $\text{C}_{60}$  may  
330 facilitate electron transfer but can lower the  $V_{\text{OC}}$  due to increased interfacial non-  
331 radiative recombination<sup>63</sup>. In contrast, for  $\text{PbCl}_2$ , a moderate spike-like offset with  
332  $\text{C}_{60}$  can help suppress recombination by blocking the backward flow of injected  
333 electrons while still allowing for efficient carrier extraction<sup>64,65</sup>. In our case, films  
334 made with only  $\text{MACl}$  also show increased roughness and local heterogeneity,  
335 which exacerbates interface-limited losses in the p-i-n architecture. To  
336 disentangle the specific role of additional MA and Pb cation from chloride effects,  
337 we fabricate reference devices incorporating 13 mol% MAI, 3 mol%  $\text{PbI}_2$ , or their  
338 combination (13 mol% MAI + 3 mol%  $\text{PbI}_2$ ), relative to Pb (**Supplementary Fig.**  
339 **28**). We find that individual addition of MAI or  $\text{PbI}_2$  adversely affects device  
340 performance; only their combination slightly increases the PCE from  $23.1 \pm 0.2\%$   
341 (control) to  $24.1 \pm 0.4\%$ . These results confirm that performance gains primarily  
342 result from chloride incorporation rather than additional MA or Pb cations.

343 As a result, the optimised  $\text{MACl} + \text{PbCl}_2$  device exhibits a maximum PCE of 27.1%  
344 ( $0.05 \text{ cm}^2$ ) and features a  $V_{\text{OC}}$  of 1.185 V, a FF of 0.858, and a  $J_{\text{SC}}$  of  $26.6 \text{ mA cm}^{-2}$ ,  
345 with minimal hysteresis (**Fig. 4c**). The corresponding  $1 \text{ cm}^2$  device exhibits a  
346 maximum PCE of 25.5%, with a  $V_{\text{OC}}$  of 1.172 V, a FF of 0.816, and a  $J_{\text{SC}}$  of  $26.7 \text{ mA}$   
347  $\text{cm}^{-2}$ , with minimal hysteresis. Certified quasi-steady state (QSS) efficiencies of  
348 26.4% and 24.5% are obtained for device areas of  $0.05$  and  $1 \text{ cm}^2$ , respectively,  
349 validated by the National Photovoltaic Industry Measurement and Testing Center  
350 (NPVM) (**Fig. 4d** and **Supplementary Fig. 29-30**). Furthermore, accelerated  
351 durability tests (ISOS-D-2I) at elevated temperatures show enhanced stability for  
352 encapsulated  $\text{MACl} + \text{PbCl}_2$  devices, retaining over 96% of initial performance  
353 after 1200 h at  $85 \text{ }^\circ\text{C}$ , compared to 90% for control devices. Additionally, under  
354 continuous maximum power point (MPP) operation at  $65 \text{ }^\circ\text{C}$  and  $\sim 50\%$  relative

355 humidity, MA<sub>2</sub>Cl + PbCl<sub>2</sub>-treated devices maintain 88% of initial PCE after 1200  
356 hours, significantly outperforming control devices (78% retention). The enhanced  
357 stability of MA<sub>2</sub>Cl + PbCl<sub>2</sub> devices can be attributed to the improved phase purity  
358 and more uniform optoelectronic properties of the perovskite absorber<sup>40</sup>.  
359 Chloride additives help accelerate the transition from the yellow 2H to more  
360 stable 3D phase. In our case, they also improve film crystallinity, luminescence  
361 uniformity, and vertical charge transport. These improvements are expected to  
362 reduce local recombination centres and suppress interfacial charge accumulation  
363 during operation, which can otherwise lead to ion migration and degradation  
364 under thermal and light stress. This interpretation is consistent with recent  
365 research indicating that optimising the chloride distribution can enhance both  
366 device performance and operational stability<sup>52</sup>.

367 We would like to point out that chloride-containing additives cover a diverse  
368 range of chemical options, and in many cases, the accompanying cation can  
369 influence crystallisation and interfacial chemistry beyond merely supplying Cl<sup>-</sup>  
370 ions. In this study, we select MA<sub>2</sub>Cl and PbCl<sub>2</sub> as model systems because they are  
371 among the most commonly used chloride additives across p-i-n and n-i-p device  
372 architectures. This allows us to compare different pathways for chloride  
373 incorporation without introducing extra functionalities and perovskite phases.  
374 Our findings indicate that beyond MA<sup>+</sup>, substituting larger organic ammonium  
375 cations, such as propylammonium (PA<sup>+</sup>)<sup>44</sup> and phenethylammonium (PEA<sup>+</sup>), leads  
376 to decreased performance in our p-i-n devices (**Supplementary Fig. 31**). This  
377 correlates with a greater tendency to form mixed reduced-dimensional  
378 perovskite phases, which can hinder charge collection<sup>66</sup>. Despite this, our  
379 findings indicate that Cl<sup>-</sup> anions generally lead to better device performance in  
380 compared to I<sup>-</sup> anions. These results underscore that while Cl<sup>-</sup> typically has a  
381 beneficial effect on enhancing the quality of the perovskite absorber, the  
382 molecular structure of the cation becomes crucial when it leads to the formation  
383 of lower-dimensional perovskites.

384

 386 SEM of a p-i-n cell stack. The scale bar is 1  $\mu\text{m}$ . **b**, PCE statistics (reverse scan)  
 387 for 20 control, MACl,  $\text{PbCl}_2$ , and MACl +  $\text{PbCl}_2$  added devices. **c,d**,  $J$ - $V$  curve of the  
 388 champion devices ( $\sim 0.05$  or  $1.0 \text{ cm}^2$ ) measured in-lab and at the National PV  
 389 Industry Measurement and Testing Center. The insets display steady-state PCEs  
 390 under MPPT. **e**, ISOS-D-2L device stability during storage at  $85 \text{ }^\circ\text{C}$ . Statistics are  
 391 taken from 8 devices for each condition. **f**, MPP stability tracking of the  
 392 encapsulated device under simulated 1-sun illumination at  $65 \text{ }^\circ\text{C}$ .

### 393 Conclusion

394 In this study, we elucidated the critical role of chloride-based additives in  
 395 controlling phase uniformity, compositional homogeneity, and luminescence  
 396 properties of perovskite films, revealing their significant influence on  
 397 photovoltaic device performance. We demonstrated that MACl additives increase  
 398 compositional heterogeneity, causing spatially nonuniform carrier dynamics  
 399 within perovskite grains. Conversely,  $\text{PbCl}_2$  proved more effective in  
 400 homogenising local optoelectronic properties across the films but introduced  
 401 undesirable  $\text{PbI}_2$  phases, detrimental to efficient charge extraction. Importantly,  
 402 the strategic combination of MACl and  $\text{PbCl}_2$  enabled optimal crystallinity and  
 403 uniform carrier dynamics extending from the microscale to millimetre-scale  
 404 regions. Consequently, this approach significantly reduced interfacial  
 405 recombination losses, enabling efficient charge-carrier extraction and achieving  
 406 exceptionally high photovoltaic performance.

407 Although the chloride additives investigated here are standard in perovskite  
408 photovoltaics, our study offers new mechanistic insights by distinguishing the  
409 impacts of these commonly used additives. We reveal that the different forms of  
410 chloride additives introduce unique pathways for enhancing perovskite film  
411 quality, emphasising the importance of additive form and combination  
412 strategies. Our findings underscore the possibility of achieving exceptionally high  
413 efficiencies using widely accessible additives, thus opening new avenues for  
414 further optimisation and scalable deployment of high-performance perovskite  
415 solar cells.
