**Changing experience of adverse medical events in the National Health Service:
comparison of two population surveys in 2001 and 2013**

ABSTRACT

The objective of the study was to examine changes in the frequency and severity of adverse events associated with medical care in Great Britain over a 12-year period during which resources made available by government initially expanded and were subsequently constrained by the consequences of the global financial crash. Data on perceived adverse events arising from health care, collected from two population surveys representative of Great Britain's general population in 2001 and 2013, were analysed and compared. The samples consisted of 8,202 adults aged 15 and over in 2001 and 19,746 adults aged 15 and over in 2013, and the main outcome measures were self-reported illness, injury or impairment caused in the opinion of the respondent by medical treatment or care. Respondents were also asked about the perceived severity of harm in terms of health and work, and any actions taken in response to perceived harm. The proportion of all respondents reporting that over the last three years they had suffered some illness, injury or impairment that in their opinion was caused by their medical treatment or care was 2.5% (497/19746) in 2013, compared with 4.8% (391/8202) in 2001, a reduction of 33% after adjusting for age, gender, income and social class differences between the two surveys. Perceived impact on health and work of these events was similar in both surveys, as was the proportion of injured respondents who pursued a legal claim for financial compensation, at 11% (53/497) in 2013 and 10.5% (41/391) in 2001. We also report multivariate analyses of perceived harm rates and severity, and propensity to seek, and accept, compensation. The results of these surveys conducted with a 12-year interval suggest that the NHS became significantly safer when measured by patient perceived harm from medical care, after controlling for the impact of demographic

and socio-economic change.

Research highlights (will be submitted online:

- 1) Two similar surveys 12 years apart measure adverse events in health care
- 2) The proportion reporting an adverse event was lower in 2013 than in 2001
- 3) The perceived severity of adverse events was similar in both surveys
- 4) We did not observe an increased proportion seeking compensation
- 5) Our survey method offers a new approach to assessing health care safety, and trends in this over time

Keywords: Adverse events; medical errors; disease frequency surveys; quality indicators; compensation and redress

INTRODUCTION

Care quality (and how to encourage it) is of obvious importance to patients, but also to health care providers, who must strike a balance between treating each patient successfully and the need to allocate scarce resources across all patients. In many health care systems, this resource allocation problem includes the costs of compensating patients who are found to have suffered harm as a result of their treatment, and consequently interest has focused on the frequency and costs of adverse events associated with medical care.¹ Hospital-acquired infections became an election issue during the 2005 UK general election, and continuing concerns about safety and quality of care led to several inspection and regulation bodies being brought together in a new Care Quality Commission in 2009. Resources available for improving care quality do, of course, need to be considered in the wider context of total health care budgets, which have varied markedly depending on the state of the economy and the political context. In the UK this translated into a period of significant growth in real expenditures from 1997 to 2010, with a freeze in real growth subsequently. This makes it increasingly important to explore ways of monitoring changes in aggregate health care quality in such a way that the efficacy of new resources, as well as regulatory initiatives, can be assessed.

Despite its clear importance for health systems, care quality has proved a difficult variable to measure: not only is it impractical for researchers to observe/record every clinical intervention, but it often takes time for a subsequent health problem to arise and there may be differences of opinion about the role of any given intervention in producing an adverse event. As a result, the actual frequency of adverse events in health care is difficult to establish. A wide range of research methods has been employed, including analysis of registries and administrative data,² ethnographic analyses of routine clinical meetings³ and of clinical incidents,⁴ studies of complaint and litigation rates,⁵ and modelling using burden of disease

methodology.⁶ Using record review after hospital discharge,⁷ the Harvard Medical Practice Study reported in 1991 that 3.7% of American patients suffered some sort of adverse event during hospitalization,⁸ with error potentially responsible for 58% of these adverse events, and some form of negligent care for 28%. A similar study conducted in Utah and Colorado in 2000 found that adverse events occurred in 2.9% of non-psychiatric discharges, again with 58% attributable to some form of error.⁹ We return to these widely-quoted studies in the Discussion. No such studies have been published in the UK, but one pilot study suggested that almost 11% of inpatients may be harmed during their hospital stay.¹⁰ A systematic review in 2008 of all studies using a standard definition to evaluate the incidence of adverse events in adult hospital patients and that included a minimum of 1000 patient records identified eight such retrospective record reviews (3 USA, 2 UK, 1 each in Australia, Canada and New Zealand) and reported a median adverse event rate of 9.2%.¹¹

The evidence on whether adverse events are becoming more or less common over time is even sparser. A detailed retrospective casenote study of 2341 admissions in 10 hospitals in North Carolina between 2002 and 2007 found no significant changes in the overall rate of harms per 1000 patient-days or the rate of preventable harms.¹² Vincent and colleagues reviewed trends in a range of safety indicators in the UK and found significant improvements in important measures such as in-hospital mortality and mortality after surgery, but rising trends in other measures such as health care acquired infections and drug administration errors.¹³

Our paper seeks to contribute to the literature on measuring adverse event rates, and to the evidence base on trends in the incidence of adverse events over time, with a view to commenting on the impact of changes to health care resourcing and care quality initiatives. Unlike the above studies, we use a large population survey to obtain self-reported rates of adverse events arising from medical care in the British National Health Service. An initial

survey was conducted in 2001 to inform the Chief Medical Officer's deliberations on reforming the approach to clinical negligence in the NHS,¹⁴ and a subsequent one was conducted in 2013, both to give more recent estimates of the rate and severity of adverse health care events and responses to such events, but also to permit direct comparisons with the earlier study and assess changes over time.

We argue that this survey approach complements existing literature, and trends in patient centred care, by providing a patient perspective on adverse events, and does so in a way that is in line with the increasing role of patient reported outcome measures in assessing the impact of treatment and the quality of care.¹⁵⁻¹⁷ Our approach has the important benefit of being consistent with widely accepted survey techniques in which large and representative samples can be obtained on a consistent and replicable basis, combining specific questions on adverse events with standardised information from respondents on demographic and other characteristics. The next section describes the survey methods and data. We then report the results before discussing the methods and findings.

METHODS AND DATA

A questionnaire was designed to provide data on the incidence of adverse events, where they happened, their severity in terms of health and employment, the response considered most appropriate, whether a legal claim was pursued, and the amount of compensation considered acceptable. In addition, demographic information was obtained on respondents' age, sex, region, ethnicity, level of qualification, social class, household composition and characteristics, and household income. The questionnaire was designed to be comparable with the one used in 2001, with some additional options and bands for specific questions, and a new question reflecting changes in the possible types of legal help available. Information was not obtained directly from respondents on the total number of NHS or private treatment

episodes they had experienced, and so when calculating adverse event rates per contact we rely on the sampling representativeness and size of the sample in assuming that overall rates of use corresponded to age- and sex-group norms.

The 2013 survey was administered using the IPSOS-MORI polling agency in face to face interviews by trained interviewers to a randomly selected sample of adults in ten waves at weekly intervals during January-April 2013. Approximately 2,000 individuals were interviewed in each wave, giving a total sample size of 19,746. The 2001 survey was also administered using MORI, in face to face interviews by trained interviewers to a randomly selected sample of adults in four waves at weekly intervals during October and November 2001, with a final total sample size of 8,202. In both surveys, responses were collated by IPSOS-MORI, and supplied to the researchers as anonymised data files.

Statistical analysis

The distributions of respondents by age, gender, region, income, education and social class are reported separately for each survey. Within each survey, we calculated the adverse event rate, defined as the proportion reporting that over the last three years they had suffered some illness, injury or impairment that in their opinion was caused by their medical treatment or care, using weights provided by the survey organization to reflect differential sample selection and non-response rates. To adjust for changes in income levels over time (over a period with significant wage inflation as well as real income changes), we mapped individuals from the income category in which they placed themselves in the surveys (8 categories in 2001, 15 in 2013) into the most closely corresponding quintile of the national income distribution in each of these years.

We made comparisons between the two surveys in the perceived severity of adverse events, the response considered appropriate, actions taken and their outcomes, using *t* tests and chi-

squared tests. To control for population changes over the 12-year time interval, and to assess the independent statistical effect of different factors, we used probit regressions to model the probability of reporting an adverse event. Survey year, age, gender, income, social class and region were used as covariates, with age, gender, income, social class and region entered directly and also interacted with survey year to capture the possibility that reporting behavior by different groups had changed over time.

RESULTS

Descriptive statistics for the sample by age, sex, social class, household income quintile, educational qualification and region, are given in Supplementary Table 1.

In both surveys the sample was designed to be representative of the general population of Great Britain. When weighted for representativeness and response rates, there were no significant differences between the surveys in age distribution, gender, or region, but income distribution and levels of educational qualification in the general population and so in the sample had changed significantly, as expected, with more respondents in the highest categories: for example, the proportion with degree or higher degree qualifications rose from 5.1% in 2001 to 28.6% in 2013. The survey organization was satisfied that the sample met all tests of representativeness.

In the 2013 survey, 2.5% of those interviewed (497/19746) believed that over the last three years they had suffered some illness, injury or impairment that in their opinion was caused by their medical treatment or care, 171 people (0.9%, or about one-third as many as those who said “yes”) were not sure, refused to answer or did not know, and 19,078 (96.6%) reported no adverse event (Table 1).

In the 2001 survey, in response to the same question, 4.8% of those interviewed (391/8202) believed that over the last three years they had suffered some illness, injury or impairment

that in their opinion was caused by their medical treatment or care, 8 people (0.1%) were not sure, refused to answer or did not know, and 7803 (95.1%) reported no adverse event. This difference in the proportion reporting an adverse event was highly statistically significant, ($z=9.72$, $p < 0.01$). Including the “not sure” responses from the 2013 survey with the “Yes” category increases that proportion from 2.5% to 3.2%, but the difference over time remains highly statistically significant ($z=6.36$, $p < 0.01$).

Table 2 shows the proportions reporting an adverse event in 2001 and 2013 by gender, age group, social grade and household income quintile. There was no evidence of significant differences in this response by gender in 2001, with some evidence of a slightly higher adverse event rate amongst women in 2013. There was evidence of an association between the proportion reporting an adverse event and age, this proportion declining with age in 2001 and increasing with age in 2013. There was also weak evidence that the reported adverse event rate was inversely associated with social grade.

Only approximately two-thirds of respondents who reported an adverse event were prepared to report their household income in 2001 or 2013. There was no evidence of statistically significant differences across income quintiles in 2001, but evidence of a trend in 2013, with highest rates of reported injury in the lowest income quintiles.

Supplementary Table 2 shows the location of reported incidents of injury, harm or impairment. The majority of incidents occurred in NHS hospitals, followed by general practitioner contacts; there was no evidence of significant changes in this pattern over time.

Using population age-sex specific use rates for NHS hospitals, GPs and dentists, it is possible to estimate total health care contacts by the sample during the period covered by the survey, and then express the reported adverse events as proportions of health care use rates. Table 3 shows these results, which suggest that 0.94% of all NHS in-patient episodes, 0.79% of all day cases, and 0.06% of all out-patient visits in 2013 resulted in an adverse event. We cannot

disaggregate the location of adverse events within NHS hospitals in 2001, but summing across all types of hospital contact (inpatient + outpatient + daycase), the overall adverse event per hospital contact was 0.62% in 2001 and 0.3% in 2013.

Comparable data for the private sector are sparse, but estimates of the volume of surgical inpatient and daycase activity – the largest single category of activity in this sector – allow us to estimate that in 2013 approximately 2.82% of private sector inpatient admissions and 0.33% of private daycases resulted in an adverse event. The proportion of all general practitioner consultations resulting in an adverse event fell from 0.08% in 2001 to 0.03% in 2013 ($p<0.01$), as did the adverse event rate for dental consultations (from 0.07% to 0.03%, $p<0.01$).

Table 4 shows the reported impact of the reported events on respondents' health and on their work. There were no significant differences in the reported impact on health between 2001 and 2013, with between 44% and 50% of reported adverse events classified as resulting in permanent or major disability. Responses to the impact on work were also similar: 35% in 2001 and 33% in 2013 reported having to take one month or more off work, retire, or move to a less demanding job.

When respondents were asked what kind of response they considered would have been most appropriate to the event that occurred (Table 5), the responses were highly stable over time, the most commonly suggested response being an apology or explanation (34% in 2001, 33% in 2013), followed by an inquiry into the causes (18% in 2001, 16% in 2013), and support in coping with the consequences (12% in both surveys). The proportion who considered that financial compensation was the most appropriate response was just 8% in 2001 and 6% in 2013.

There was some relationship in both surveys between the severity of the event and the response considered most appropriate: for example, as the severity increased the proportion

of respondents in 2013 who considered that an apology or explanation would be the most appropriate response fell from 45% to 15%, while the proportion expressing a preference for support in dealing with the consequences rose from 5% to 35%. The proportion stating that financial compensation is the most appropriate response to the event increased with the severity of the event, but did not rise above 15% in any severity category.

The proportion of respondents reporting an adverse event who stated they actually pursued a legal claim for financial compensation remained constant at 10.5% in 2001 and 10.7% in 2013 (Table 5b). This proportion was directly associated with the reported severity of the event, but even in the most severe category of permanent major disability the proportion seeking compensation did not rise above 18% in 2013. This is broadly consistent with replies to our question about responses considered appropriate, in which no more than 15% of respondents in any severity category considered financial compensation to be the most appropriate course of action.

Respondents who reported having experienced an illness, injury or disability as a result of their medical care were also asked about the amount of compensation that would have satisfied them, using a closed scale. A total of 99 respondents (20%) volunteered a positive figure in 2013, and 99 (25%) in 2001, and Table 5c shows the distribution of willingness to accept estimates for these respondents.

In both survey years the most commonly selected compensation amount was between £1,000 and £5,000. Setting the willingness to accept quantities at the midpoints of each range and the over £100,000 category as equal to £200,000, the mean amount of compensation that respondents seeking some positive amount were willing to accept was £36,700 in 2013 and £37,300 in 2001. Including at £0 the respondents who did not want financial compensation, but excluding respondents who refused to answer or did not know what would be acceptable,

260 the expected value of willingness to accept across everyone who reported an adverse event
261 was £7,300 in 2013 and £9,400 in 2001.
262 Finally, we conducted a multivariate analysis of the effect of income, age, sex, severity of
263 event, social grade and region on whether or not a respondent reported an adverse event, the
264 results of which are reported in Supplementary Table 3.
265

Results are shown using three definitions of an adverse event having occurred: 1) an event anywhere, including only those who said yes; 2) an event anywhere, including those who said yes or not sure; 3) an event in an NHS hospital, including only those who said yes. In comparison with reported adverse event rates in 2001 using these three definitions of 0.048, 0.048, and 0.027 (4.8%, 4.8% and 2.7%), the results indicate that, controlling for any age, gender, income and social class differences between the two surveys, rates were lower in 2013 by 0.016 (33%), 0.009 (19%) and 0.009 (36%) respectively. For comparison, the unadjusted rate of those reporting yes to an event anywhere fell from 0.048 to 0.025, a reduction of 48% (Table 1). There is no evidence that the fall in reported adverse events between the two years varies by gender, age or social grade, but in comparison with the lowest income quintile, quintiles 2-5 showed a larger reduction in the reported event rate across all three definitions examined, suggesting that the reported adverse event rate in the lowest income quintile showed much less change. This is in line with the univariate analysis reported in Table 2, showing a higher reported adverse rate in income quintile 1 in 2013.

DISCUSSION

Despite strong public and policy interest in adverse events related to medical care, quantitative information on their frequency, characteristics and variations over time has been sparse. We have reported here population-based estimates of the number of adverse events occurring in Great Britain as a result of medical care received, the severity of these events measured in various ways including the amount that respondents were willing to accept in financial compensation for their injury, the course of action that respondents considered appropriate as a response to an event, and the course of action pursued. Our questionnaire allows us to compare results in 2013 with results from a similar survey in 2001.

290 Our 2013 survey found that 2.5% of the adult population believed that, over the previous
291 three years, they had suffered some illness, injury or impairment that in their opinion was
292 caused by their medical treatment or care. This compared with a rate of 4.8% in 2001.
293 Controlling where possible for socio-demographic differences between the two surveys, the
294 reduction in the reported adverse event rate was 33%, and even after classifying all “Not
295 Sure” responses as “Yes” in 2013, a significant reduction of 19% was observed.
296 Our results suggest that only 2 or 3 in every 10,000 general practitioner or dental
297 consultations in 2013 resulted in some form of adverse event, compared with around 8 per
298 10,000 in 2001. For NHS hospital care the estimated rate per inpatient episode in 2013 was
299 just under 1%, and for private sector inpatient care was approximately 2.8%; there are of
300 course substantial differences in casemix between these sectors. These rates can be compared
301 with rates of 3.7% and 2.9% in the widely-quoted Harvard and Utah/Colorado studies, which
302 were based on record analysis of hospitalized patients and of course include events classified
303 as errors which may not have resulted in any actual immediate or long-term harm to patients,
304 whereas our survey specifically asked about subsequent “illness or injury”. The rates
305 reported in these studies will therefore be inflated by events not included in our study;
306 conversely, these studies will exclude adverse events that were not apparent during the
307 hospital episode, but manifested themselves after discharge and are reported in our study.
308 Concerning responses to adverse events, we found that barely one in ten people who felt they
309 had experienced an adverse event considered financial compensation to be the most
310 appropriate response, and a similar proportion actually pursued a legal claim for
311 compensation. These numbers have remained stable over time, as has the mean amount of
312 compensation deemed acceptable to those who considered that compensation was an
313 appropriate response. This consistency makes it less likely that the differences detected

across our two surveys in perceived harm for medical care can be explained away by the survey samples or methods.

Our finding of a reduction in adverse event rates between 2001 and 2013 may seem contrary to a widespread perception that patient safety is an increasing problem, with an ever-rising tendency for health care providers to be sued for clinical negligence. As Figure 1 shows, the total number of new clinical negligence claims opened against the National Health Service Litigation Authority (NHSLA) actually fell substantially between 2001 and 2006 before rising again after 2008 to the earlier level. In addition, figures reported by the Compensation Recovery Unit, which has a statutory responsibility to recover costs incurred by NHS hospitals and Ambulance Trusts for treatment from injuries from personal injury claims, show¹⁸ a substantial annual decline in clinical negligence claims that were closed over the period 2001 to 2008, followed by an increase thereafter (Figure 1). In both cases, the increase in claims from 2008 is arguably the consequence of the rise in no-win, no-fee lawyers entering the clinical negligence market and encouraging a higher propensity to claim.¹⁹ Such complex and conflicting patterns of improvement and deterioration revealed by different safety measures were commented on in the Introduction.¹³ Nevertheless, the marked fall in patient claims against the NHS after 2001 is consistent with our survey findings, and yet is often forgotten in the modern policy debate which takes a decline in hospital safety as a given.

It should also be borne in mind that, during most of the period covered by our two surveys, real expenditure on the NHS was increasing at a much higher than average rate: 6.4% annually between 1996/97 and 2010/11, compared with 4.0% over the entire NHS history up to 2011 and just 0.1% over the period from 2011/12 to 2014/15.²⁰ This growth in real spending was accompanied by improved staffing levels, higher investment in equipment and buildings, and an increased emphasis on patient-centred care including shorter lengths of stay

and shorter waiting times. In addition, a series of institutional and contractual changes were implemented during this period, including enhanced hospital quality inspections, risk registers, new consultant contracts emphasizing clinical governance, and the establishment of the National Patient Safety Agency in 2001 and (as noted earlier) the Care Quality Commission in 2009. It would be disappointing if the increased real expenditure and these safety initiatives had no impact on quality of care. Over this same period, satisfaction with the NHS as measured in the British Social Attitudes survey rose from 42% in 2000 to over 60% by 2013, while the proportion of the population reporting that the NHS was the most important issue facing the country fell from 51% in 2000 to 24% in 2013; Figure 2 displays these trends and places the two surveys in that context. It is of course possible that the recent much slower rate of real expenditure growth may have reduced or reversed the trend towards improved patient safety suggested by our study, despite the continuing presence of the enhanced inspection and regulation bodies; our data cannot confirm or contradict that, but a repeat survey could test that hypothesis.

In illustrating that adverse event rates can change substantially over relatively short periods, our results also lend support to the idea that there is considerable scope for the NHS to invest in interventions that cost-effectively reduce harm to patients.

We conclude by reflecting briefly on our method of estimating adverse event rates, based on patient self-reporting. This approach will miss adverse events of which the patient was unaware, and errors such as “near misses” which did not result in perceived injury or impairment but which might have been detectable in patient notes. Qualitative work is required to obtain a better understanding of what respondents have in mind when they report a perceived injury or impairment. This particular population survey method will also omit the most serious adverse events that result in death or institutionalization. However, our method may capture adverse events that only became apparent after discharge from hospital –

for example, some post-operative wound infections – which may not have been captured by studies based on analysis of hospital notes. Our method is also relatively cheap (despite delivering a large representative sample with a large number of relevant co-variates), and can easily be replicated nationally or internationally. It is only one of many possible indicators of overall health system performance, but it is focused on quality of outcomes, based directly on the actual experience of users of NHS services, and in line with the increasing use of patient reported outcome measures. As such it could provide a valuable contribution to the monitoring of trends in health-care related adverse events and the impact of patient safety initiatives.
