## ABSTRACT

The effect of ion irradiation on evolution of microstructure and hardening of beryllium with different impurity levels was investigated using TEM and nanoindentation. High purity S-65 grade and less-pure S-200-F grade were implanted by helium ions at temperatures of 50°C and 200°C. 11 different energies were used, so as to create a quasi-homogeneous 3 µm irradiated layer with average radiation damage of 0.1 dpa and average He content of 2000 appm.

Nanoindentation experiments demonstrated that before irradiation, the S-200-F and S-65 grades have an average hardness of  $3.7 \pm 0.8$  GPa and  $3.4 \pm 0.8$  GPa correspondently. After implantation the hardness of both grades increased by about 60% for the 200°C irradiation and 100% for the 50°C irradiation. The crystallographic analysis of indented grains demonstrated that in the as-received materials the hardness is about 2.5 times higher when the indentation direction is close to the [0001] c-axis of beryllium compared to indentation perpendicular to [0001]. Hardness anisotropy significantly decreased after irradiation: the "soft orientation" was most sensitive to irradiation-induced hardening, with hardness increasing by about 140% after irradiation at 50°C and 100% after irradiation at 200°C, compared to about 15 - 20% for the "hard" orientation at both irradiation temperatures. The higher purity grade had smaller increase of the "soft orientation" hardness:  $2.5 \pm 0.3$  GPa for the S-65 and  $2.9 \pm 0.2$  GPa for the S-200-F.

At both temperatures in both grades, under TEM investigation the radiation damage appears as "black dots" which are likely to be small dislocation loops with the number density of  $\sim 10^{22} \text{ m}^{-3}$ . No bubbles were observed by TEM inside grains and at grain boundaries. Analysis of the possible hardening contribution demonstrated that the observed "black dots" could be responsible for up to half of the measured hardening, while the rest of the hardening should originate from helium bubbles with the size below the TEM resolution (at or below 1.5 nm).

## 1. Introduction

Due to a unique combination of mechanical and physical properties, beryllium is extensively used in a wide variety of nuclear facilities. For example, due to its high thermal conductivity, low chemical sputtering and oxygen gettering properties [1], beryllium is a plasma facing material (PFM) for the Joint European Torus (JET) tokamak [2,3] and the future ITER fusion test reactor [4,5]. Beryllium is also being considered as a neutron multiplier mate-

rial in the helium-cooled pebble bed (HCPB) design concept for the tritium-breeding blanket of the demonstration fusion power plant (DEMO) [6,7]. Due to its low nuclear interaction cross-section, beryllium is an excellent material for particle-beam windows, and, for example, was successfully used as a primary beam window in neutrino production targets of the "Neutrinos at the Main Injector" (NuMI) beamline [8]. It is also being considered as a material for different target components in a new generation of proton accelerator driven particle sources such as, for example, the Long Baseline Neutrino Facility (LBNF) [9,10].

In comparison to other nuclear materials, beryllium exhibits an extremely high transmutant helium accumulation rate. For exam-

ple, it is between 110 and 220 appm/dpa in the beryllium reflector of the ISIS neutron source (RAL, UK) and can reach 380 He-appm/dpa under neutron irradiation in fission reactors [11–13]. For comparison, a typical appm/dpa ratio for iron under neutron irradiation in fission pressurized-water reactor (PWR) is 0.35 appm/dpa [14] and for tungsten under neutron irradiation in fission high flux isotope reactor (HFIR) it is 0.0008 appm/dpa [15]. In fusion reactors, beryllium will accumulate helium with the rate of 670 He-appm/dpa [14] leading to build-up of 1,500 He-appm at ITER end-of-life [16] and more than 15,000 He-appm at DEMO end-of-life (HCPB concept) [17]. Even higher helium accumulation, up to 4000 He-appm/dpa, takes place in beryllium in high energy proton irradiation environments, for example in neutrino sources [18]. Both helium accumulation and displacement damage effects in beryllium are known to be highly irradiation-temperature dependent: for temperatures less than 400°C, irradiation induced hardening accompanied by a drop in plasticity is usually observed, whereas severe non-hardening embrittlement is observed for high-temperature irradiation [19–22]. It is generally considered that the determining mechanisms here are strengthening of the beryllium matrix by point defect clusters and helium accumulation at low temperatures; and helium segregation to grain boundaries at high temperatures [12,22–24].

Industrial purity beryllium grades used in nuclear facilities contain a wide variety of trace impurities, typically oxygen, iron, aluminium, nickel, copper, silicon, carbon and magnesium. The majority of these impurities have very limited solubility in beryllium, and have strong tendencies to create precipitates and to segregate to defects such as grain boundaries or dislocations [18,25]. While the effects of different impurities on mechanical properties of beryllium have been extensively studied in the past (see reviews [7,25] and references cited), the mechanisms underlying these processes are not always well understood. Moreover, data about the effects that impurities have on evolution of mechanical properties under irradiation is very limited, especially under the extreme conditions relevant to beryllium components of fusion reactors and particle accelerators.

The work reported here compares hardening introduced by helium implantation in two industrial beryllium grades: the high purity nuclear grade S-65 and the lower-purity structural grade S-200-F. The S-65 grade is being used as a plasma-facing component in Joint European Torus fusion experiment [3] and was selected as the reference material for use in ITER [7]. The S-200-F grade is also used in nuclear facilities, for example for beryllium frames and reflector elements in the Japan Materials Testing Reactor (JMTR) at JAEA [26].

We report data on hardening of beryllium after irradiation at 50°C and 200°C. The temperatures represent the lower boundary of the expected irradiation temperatures in Be for ITER first-wall applications, typical irradiation temperatures of the beryllium in the operating NuMI neutrino target [18] and the currently designed LBNF [9,10]. Considering the literature data [19–22], for both temperatures the “irradiation induced hardening” regime should dominate. Available experimental data on radiation damage effects in beryllium are mostly collected from materials irradiated by fission reactor neutrons. However, the applicability of the data for fusion reactor applications and accelerator driven particle sources is uncertain, since fission-spectrum neutrons do not induce sufficient levels of transmutation-produced helium [11–13]. In the current work, an ion beam accelerator was used to introduce radiation damage and about 2000 appm He, relevant to both fusion and accelerator applications and giving also the advantage of fast and relatively inexpensive materials irradiation without activating samples.

Nanoindentation is widely used for evaluation of local mechanical behaviour of materials at micro-scale and is particularly useful

for ion irradiated materials where only a shallow damaged layer is available. It has been successfully used for screening of irradiation induced hardening in different nuclear materials, including: ferritic-martensitic [27–29], austenitic [30] and RPV [31] steels, ODS alloys [32] and tungsten [33,34]. No nanoindentation data on radiation hardening of beryllium is available in the literature; however the applicability of the technique to examine the effects of impurities on the hardness of beryllium was recently demonstrated [35].

Micro and macro-hardness examinations of beryllium often show significant scatter of indentation results [35,36] that may complicate the determination of radiation-induced hardening effects. This originates from the high elastic and plastic anisotropy of beryllium [25,37]: the room temperature (RT) critical resolved shear stresses for  $\langle a \rangle$  basal slip (the primary slip system at RT) is 15 MPa, for the  $\langle a \rangle$  prismatic systems is 68 MPa and the secondary  $\langle c + a \rangle$  pyramidal systems is 2000 MPa [37,38]. Previous experiments [35,39,40] showed that indentation hardness coupled with crystallographic data from EBSD or XRD is a useful approach for comparing the effects of different treatments on beryllium. This approach is used here, with special attention being paid to the mitigation of any artefacts originating from localised plastic deformation of the surface around the indents (so-called pile-ups and sink-ins) which can significantly affect interpretation of nanoindentation data in beryllium [35].

The paper is structured as follows. First, the investigated beryllium grades, irradiation conditions, the nanoindentation hardness experiments and data treatment approaches are described. Then, the microstructure of the implanted layers is shown and discussed. Before hardness values are calculated, indentation contact areas for different samples and different crystallographic orientation of grains are analysed, considering any pile-up and/or sink-in, and the tip-indented surface contact area coefficients are reported. The resulting correction parameters are then used to calculate the nanoindentation hardness of beryllium grains of different purity and different crystallography before and after irradiation. After, the load - indentation depth curves from different beryllium states (material grade, irradiation condition) are presented and the pop-in events (horizontal plateaux observed on the load-displacement at some at some critical loads) are characterised to highlight differences between different states of the materials. This is followed by a general discussion of the origins of the observed irradiation induced hardening and the applicability and significance of the obtained data for engineering design considerations for nuclear facilities with beryllium elements under irradiation.

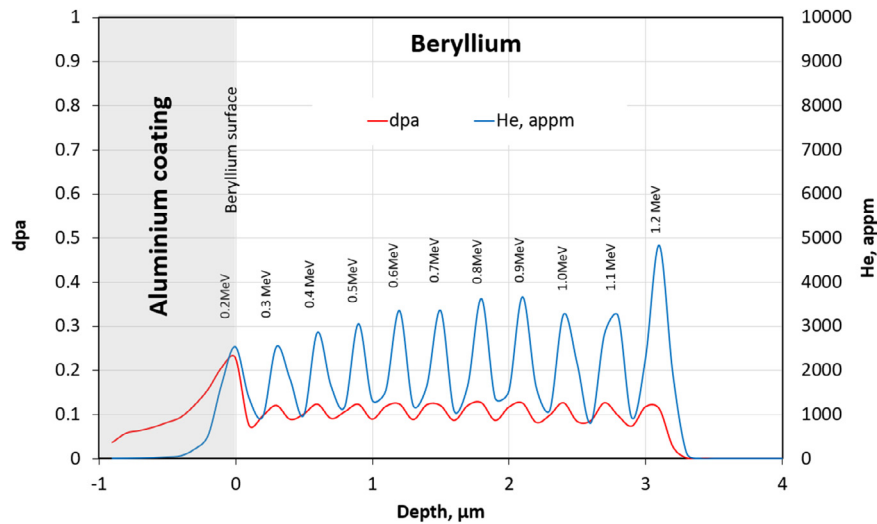

## 2. Materials and techniques

### 2.1. Materials

Two vacuum-hot-pressed industrial beryllium grades were investigated in this work: a high purity nuclear grade S-65 (Be > 99.2%) [41] and the lower purity structural grade S-200-F (Be > 98.5%) [42]. Microstructures of both types are reported in Ref. [35]. The grades have similar average grain diameters of  $7.2 \pm 4.4 \mu\text{m}$  [35]. Our previous STEM/EDS studies of beryllium [18] showed that grain boundaries of both grades are decorated by numerous precipitates enriched by oxygen, aluminium, iron, silicon, magnesium, titanium and other impurities, while the grain cores are mainly free of precipitates.

### 2.2. Irradiation conditions

Before helium implantation, surfaces of samples were mechanically ground and polished with SiC paper, diamond paste and finally colloidal silica. To avoid sputtering of beryllium during

**Fig. 1.** Helium implantation profile. 11 energies were used in the range from 0.2 to 1.2 MeV. The position of the Bragg peaks is marked with the corresponding implantation energy. The sample was coated by aluminium during implantation. The coating was removed before further analysis.

implantation, a 1  $\mu\text{m}$  layer of aluminium was deposited by sputter coating at the surface of samples. The aluminium layer was removed after implantation by polishing in colloidal silica.

Implantation was done at the National Ion Beam Centre (NIBC) at the University of Surrey. Sequential irradiation with  $\text{He}^+$  ions with eleven energies from 1.2 MeV down to 0.2 MeV with steps of 0.2 MeV was used to create approximately a 3  $\mu\text{m}$  deep damaged layer, as calculated with SRIM (Stopping and Range of Ions in Matter) [43,44]. Totally,  $8.8 \times 10^{20}$  (He)atoms/ $\text{m}^2$  were implanted. The irradiation dose calculation was done using a displacement threshold energy of 31eV [45] and the “Quick” Kinchin and Pease option. The calculated average damage is 0.1 dpa with an average dose rate of  $1.7 \times 10^{-4}$  dpa/s. The average helium content in the damaged layer is 2000 appm; however there are wide oscillations around the average value (see Fig. 1).

### 2.3. Experimental techniques

Indentations were conducted using a Keysight G200 nanoindentation system, with a diamond pyramid Berkovich tip, using the continuous stiffness measurement (CSM) technique [46] with a 42 Hz and 2 nm oscillation. The frame stiffness of the instrument and indenter tip was calibrated using a fused silica sample. An atomic force microscope Dimension D3100 was used for topographical investigation of the prints after indentation. The surface profiles were then obtained using the open source software Gwyddion [47]. These profiles were used to calculate the contact area between the indenter tip and the sample surface.

The nanoindentation hardness was calculated as

$$H = P/A \quad (1)$$

where  $A$  is the projected contact area between indenter tip and the sample at load  $P$  [48]. Two approaches were used for quantification of the contact area  $A$ : i) the method proposed by Oliver and Pharr [46] which forms the basis of the indentation testing standard [48] and ii) the method which uses the actual tip-surface contact area, corrected for effects due to pile-ups and/or sink-ins [49]. In the standard method proposed by Oliver and Pharr [46] the contact area is determined from the tip area function  $A(h_c)$  that expresses the indenter’s cross-sectional area in terms of the contact depth,  $h_c$ . The contact depth,  $h_c = h_{\text{max}} - h_s$ , is the difference between the measured total penetration of the tip into the surface,  $h_{\text{max}}$ , and the elastic surface displacement,  $h_s$ . The elastic displacement is calculated using the Oliver-Pharr model [46]:

$h_s = \varepsilon \frac{P_{\text{max}}}{S}$ , where  $P_{\text{max}}$  is the measured maximum load,  $S$  is the contact stiffness, which is computed as the slope of the unloading curve continuously evaluated in the CSM mode, and  $\varepsilon$  is the tip geometry coefficient (0.75 for a Berkovich tip) [50].

In the second method, the standard Oliver-Pharr algorithm for contact area calculation was modified in order to take into account the influence of the plastic deformation on the sample surface around indents during loading. The method is based on the approach proposed by Kiese [49] and modified to include sink-ins effects [35]. The method requires experimental measurement of the indent profile through the central point of indentation and the centre of each edge. Where pile-up is observed, the contact between the indent and the pile-up is determined and is then projected onto the direction of the free surface normal, giving the pile-up height. The contact area of each pile-up is then approximated as a semi-ellipse, with the major axis equal to the length of the side of the projected triangular area of the indent print, and the minor axis being measured on the indent profile image as the projected distance of the pile-up contact perimeter [49]. Similarly, to account for sink-ins, the reduction in contact area was also approximated as a semi-ellipse, with a major axis calculated in the same way, whereas the minor axis was measured on the indent profile image as the projected distance between the sink-in contact perimeter [35]. For the investigated indents the corrected projected area,  $A_{\text{corr}}$ , was calculated as the contact area determined by the Oliver-Pharr analysis [46],  $A_{\text{O-P}}$  plus (or minus) the area due to out-of-plane deformation near each edge for pile-ups (or sink-ins). In this paper  $H_{\text{O-P}}$  refers to hardness values obtained with the Oliver-Pharr algorithm, whereas  $H_c$  refers to hardness values obtained after the contact area correction.

At least 200 indents were made for each sample with a target maximum indentation depth of 400 nm. Surface position correction was made for each indentation before data analysis. For consistency, load data averaged between 320 and 360 nm indentation depth were used for indentation hardness calculations, avoiding the depth range within which there is a strong indentation size effect [27,50]. Crystal Plasticity FEM calculations for beryllium [35] predict that the plastic zone beneath indents extends to a depth  $\sim 7 \times$  larger than the Berkovich tip penetration depth. The selected penetration depth for hardness calculations is almost 10 times smaller than the thickness of the implanted layer, allowing minimisation of any possible influence of the non-irradiated substrate material on the radiation-induced hardening data.

Because of the high hardness anisotropy of beryllium [35], in this paper indentation data are presented and discussed according to the angle between the indentation direction and the [0001] axis of the indented grain, denoted as  $\theta$ . To investigate the crystallographic dependence of nanoindentation hardness, EBSD analyses of the indentation arrays were made, using a JEOL 840A scanning electron microscope equipped with the EDAX-TSL EBSD; OIM TSL software [51] was used for analysis of the EBSD data. Indents on or near to grain boundaries (no more than 2  $\mu\text{m}$  away) were not considered in analysis.

To investigate residual strains in samples after implantation and possible effects on nanoindentation data, a confocal Raman imaging microscope (WITec alpha300 AR) has been used to acquire Raman spectra and perform large area scans (3 mm  $\times$  3 mm). The analysis is based on determining the peak-shift corresponding to a  $E_{2g}$  stretching band [52] in beryllium. The peak shift is caused by small changes to the short-range order in the atomic arrangement of the implanted material. Therefore, it is indicative to the micro-strains created by implantation. During the experiments firstly, the structural and strains heterogeneity evidenced by a change in the spectral pattern have been determined, and then the main spectral components in homogeneous regions have been calculated. Thus, by accumulating a large number of pixels (600  $\times$  600 = 0.36  $\times$  10<sup>6</sup>), the position measurement error of the beryllium main peak is greatly reduced for the averaged spectral components. The TrueSurface feature enabled dynamic focusing of the confocal laser during scanning. Data acquisition was carried out with the conventional charge-coupled device (CCD) camera in the low-noise high-intensity detection mode with a dwell time of 0.5 s per pixel using a green laser ( $\lambda$  = 531.95 nm with an estimated penetration depth in beryllium of about 30 nm [52]), a 1800 g/mm grating and a Zeiss EC Epiplan-Neofluar 50  $\times$  long-distance objective to accommodate for topography variation during scans. The laser power was set at 15 mW. The system was pre-calibrated to maximise the intensity of the silicon main peak on a single crystal silicon reference sample. Resulting spectra were treated with a cosmic-ray removal procedure and a shape-based background subtraction algorithm in WITec Project FIVE 5.2 Plus post-processing software. Where applicable, a Lorentzian function was used for peak fitting of the background-subtracted data.

Samples for Transmission Electron Microscopy (TEM) were prepared by Focussed Ion Beam sectioning (FEI Helios NanoLab 600i). The 30keV Ga<sup>+</sup> ions have been used for lamellae lift-out and shaping and 5keV Ga<sup>+</sup> ions have been used for final thinning of lamellae. According to SRIM calculation, the final energy should create approximately 10 nm deep surface damaged layers and as it will be shown later, this greatly hindered displacement damage effect from helium ions implantation.

Observation of the irradiated layer was performed with the JEOL JEM-2100 TEM in the Materials Department of the University of Oxford.

### 3. Experimental results

#### 3.1. Microstructure of the implanted layer

The implanted layer was investigated by TEM. On bright-field images radiation damage appeared in the form of “black dots” (less than 10 nm diameter) arranged in lines parallel to the surface of samples, as shown in Fig. 2 for the S-65 sample irradiated at 50°C. Fig. 2(a) shows that the dark lines correspond to the peaks in “dpa” and helium implantation (Fig. 1), with energies from 1.2 MeV located in the lower right corner and nine lower energies down to 0.3 MeV in the upper left corner near the lift-out edge (see the simulated implantation profile in Fig. 1). These “black dots” are likely to correspond to small dislocation loops or point defect clus-

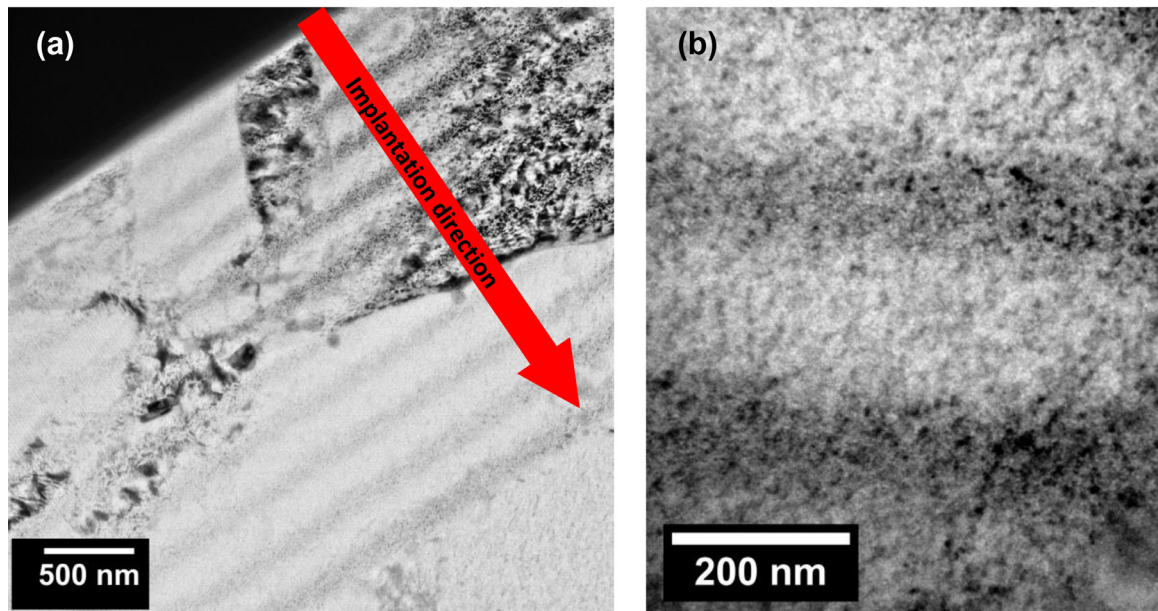

ters. While the dark areas correspond to approximately 1.2 dpa and 3000 appm of helium, the relatively bright areas in the implanted layer have approximately 0.8 dpa and 1000 appm of helium. The thickness of the dark lines is about 150 nm, separated by similar thickness bright areas with smaller number of defects (Fig. 2(b)). Note that the displacement damage peaks should be 50 to 100 nm closer to the surface than the helium peaks, but this was not resolved by TEM as there is no clear substructure of the dark bands. Comparison with the microstructure below the 1.2 MeV implantation Bragg peak, where only FIB damage is present, shows that gallium damage of the TEM samples during preparation by FIB creates similar “black dots” in beryllium, so it was difficult to make accurate quantitative analysis of the initial radiation exposure. Assuming homogeneous distribution of FIB induced loops and after subtraction of this background, the estimated number density of loops was between  $4 \times 10^{21} \text{m}^{-3}$  and  $1 \times 10^{22} \text{m}^{-3}$  inside bright bands and between  $2 \times 10^{22} \text{m}^{-3}$  and  $5 \times 10^{22} \text{m}^{-3}$  inside dark bands. The damaged layers of the samples exposed at 50°C and 200°C appeared very similar and no difference in substructure of the irradiated layers was noticed between two investigated beryllium grades. However, any differences could be being masked by FIB damage.

It should be also noted that in Fig. 2, only 10 out of 11 implanted layers are present since the first layer was polished-off during colloidal silica polishing of the aluminium coating after the implantation, but as will be discussed later, this was not the case for all the implanted samples.

Use of over-/under-focus imaging [53] did not reveal any objects which could be identified as cavities or helium bubbles in any of the investigated samples, including in grain boundary areas. Helium is therefore likely to be either in solid solution in the beryllium matrix or in a form of sub-nanometric bubbles too small to be resolved in TEM [53]. The observation is in agreement with other experimental studies of beryllium after neutron irradiation [11,20,54–56] or helium implantation [24] where, due to the low diffusive mobility of separate helium atoms or helium-based complexes, gas bubbles were not visible in TEM at temperatures below 400°C. It is also known that at very high helium contents (> 25000 appm) helium bubbles may be observed even at low temperatures in neutron irradiated [57] or helium implanted samples [58], but this level is well above the helium concentrations investigated in this work.

#### 3.2. Topography of indentation prints and contact area correction

The elastic, plastic and strain-hardening properties of a material can affect whether material will either plastically pile-up (typically observed when the most of the plastic deformation occurs near the indenter) or sink-in (typically observed when the plastic zone is spread deeper into the specimen material) around the indenter [50,59,60]; such topographical changes can significantly change the contact area between the indenter tip and surface. This deformation is not accounted for in the standard method of contact area determination proposed by Oliver and Pharr [46], so with this method the calculated indentation hardness would be too high if pile-up occurs (as the real contact area is greater than that calculated from the indenter profile and penetration depth) and too low when sink-in occurs (when the real contact area will be less than the calculated one). To estimate the out-of-plane plastic deformation of beryllium and hence to improve the analysis of the load-displacement data to give a true value of indentation hardness, direct imaging of the residual impressions was performed. Between 15 and 19 topography maps of indentation prints were made with AFM for each irradiated sample to cover the full range of indentation orientations for every investigated sample. Mapping was

**Fig. 2.** TEM image (bright field) of the S-65 irradiated at 50°C. The dark lines in (a) correspond to the peaks in “dpa” and helium implantation. Radiation damage appeared in the form of “black dots” with higher number density inside dark lines (b).

performed for the indents where the crystallographic orientation of the indented areas was confidently known (i.e., inside grains).

Fig. 3 shows examples of topography maps around indents into differently oriented grains in irradiated and non-irradiated samples. In the majority of indents plastically deformed surface zones were observed well outside the area of the final tip penetration. Fig. 4 shows changes in contact area between the indenter and the sample due to pile-ups and sink-ins, as a function of indentation angle, as a contact area correction coefficient,  $C$ , defined as:

$$C = \frac{A_{\text{corr}} - A_{\text{O-P}}}{A_{\text{O-P}}} \quad (2)$$

Here,  $A_{\text{corr}}$  is the measured projected contact area and  $A_{\text{O-P}}$  is the “ideal” contact area calculated from the indenter penetration using the Oliver-Pharr method.

The effects of pile-ups and sink-ins in non-irradiated beryllium have been reported by us previously [35]. It was shown that the pile-up / sink-in behaviour depends highly on the crystallographic orientation of the indented grain. For indentations into grains with surface normal close to [0001] ( $\theta < 15^\circ$ ) (hard orientations) sink-ins were predominant, as shown by the yellow “halo” around the indenter print in Fig. 3(a). The corresponding correction coefficient  $C$  was measured to be in the range of approximately -0.1 to -0.2. Indentation into grains with higher  $\theta$  produced both sink-ins and pile-ups, appearing as hills with height up to 250 nm on opposite sides of the indentation pit (see Fig. 3(c-d)). The contribution of pile-ups in determining the real contact area increased with  $\theta$ , and so the correction coefficient  $C$  gradually increases with indentation angle, reaching +0.25 for indents into grains with surface normal orientated perpendicular to [0001]. This variation of  $C$  with grain / indenter orientation for unirradiated Be is indicated by the shaded area in Fig. 4.

Pile-up behaviour was very different in the irradiated samples of both material types. After irradiation at 50°C, pile-ups dominated in all the mapped indents for all the crystallographic orientations of the indented grains as shown in Fig. 3(i-l) and no significant difference in behaviour of the two investigated grades was noticed. The corresponding average correction coefficients (black open markers in Fig. 4.) were around +0.15 for  $\theta$  up to 30°, in-

creasing slightly to a maximum of about +0.2 for  $\theta$  between 40° and 60°, and decreasing to +0.1 for  $\theta$  close to 90°.

Similarly, pile-ups dominated in the indents in the S-200-F grade irradiated at 200°C (Fig. 3(e-h)), but the overall contribution into the contact area was smaller with an average correction coefficient of about +0.1 for small  $\theta$ , a maximum of +0.15 for  $\theta$  between 40° and 60° and a minimum of +0.07 for  $\theta$  close to 90°.

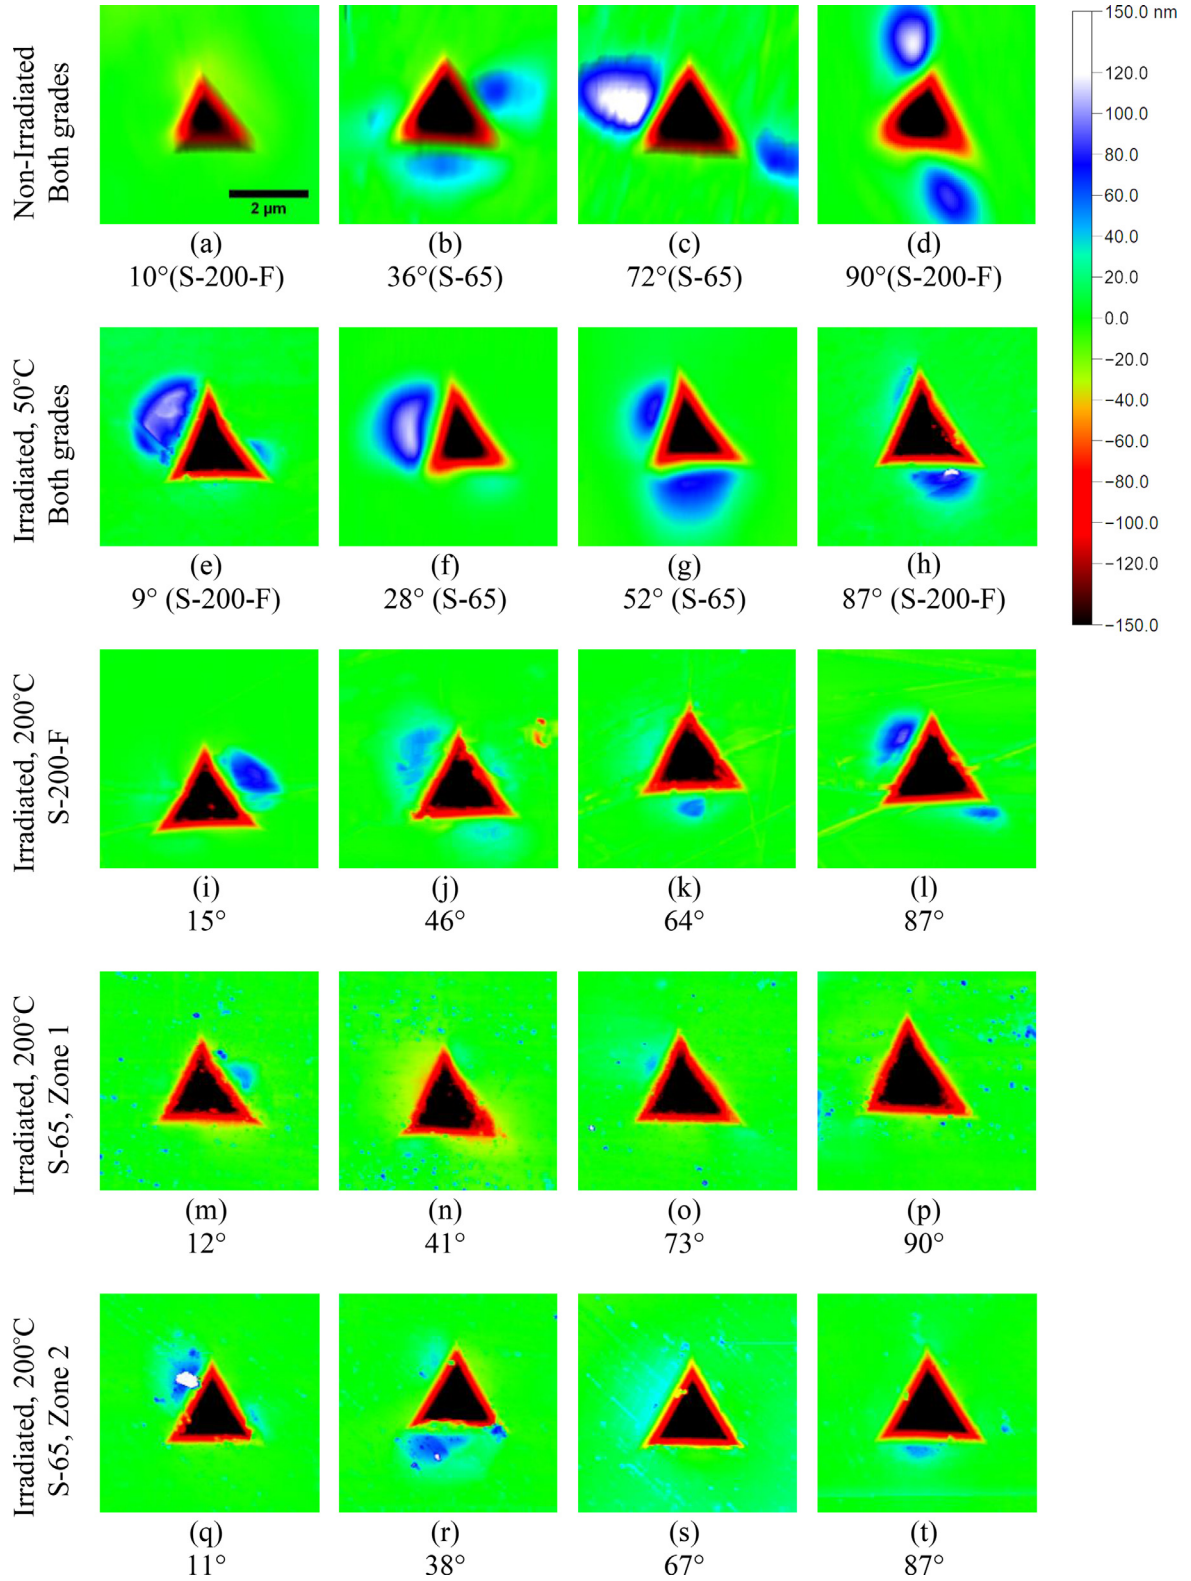

The S-65 sample irradiated at 200°C showed more complicated behaviour: in the area initially studied (Fig. 3(e-h)), denoted as “Zone 1”, sink-ins (Fig. 3(e-h)), rather than pile-ups, dominated the material’s indentation behaviour and correction of contact area. Because of this discrepancy, a smaller array of 75 indents was made in a different area of the sample (“Zone 2”), in which, similarly to other irradiated samples, pile-ups dominated behaviour around the indents (Fig. 3(e-h)). As is shown by blue markers in Fig. 4, in “Zone 1” of this sample the average correction coefficient  $C$  was near 0 for small  $\theta$ , had local maximum of about +0.05 for  $\theta$  between 30° and 40° and decreased to -0.1 for  $\theta$  close to 90°. In the second area (“Zone 2” in Fig. 4), the correction coefficient distribution was very similar to that observed for the S-200-F grade irradiated at the same temperature, with a somewhat lower local maximum in  $C$  of about +0.1 for  $\theta$  between 30° and 60°. The selection of the area for the second array was based on study of post-irradiation microstructures and their dependence on sample preparation and is discussed later in section 3.4.

### 3.3. Nanoindentation hardness

Hardness values for all of the investigated samples were calculated accounting for the contact area correction, using the measured pile-up and sink-in contribution coefficient  $C$  from Fig. 4, combining Eqs. (1) and (2):

$$H_c = \frac{H_{\text{O-P}}}{C + 1} \quad (3)$$

where  $H_{\text{O-P}}$  was extracted from the nanoindentation test data using the standard Oliver-Pharr method [46]. As was shown in our previous work [35], for unirradiated materials, the averaged correction coefficient as a function of indentation angle  $\theta$  (in degrees) between the  $c$  axis of the grain and the loading direction can be

**Fig. 3.** Examples of topography maps of 400 nm indents for S-65 and S-200-F grade in the as-received condition and after He implantation at 50°C and 200°C

fitted to a linear function:

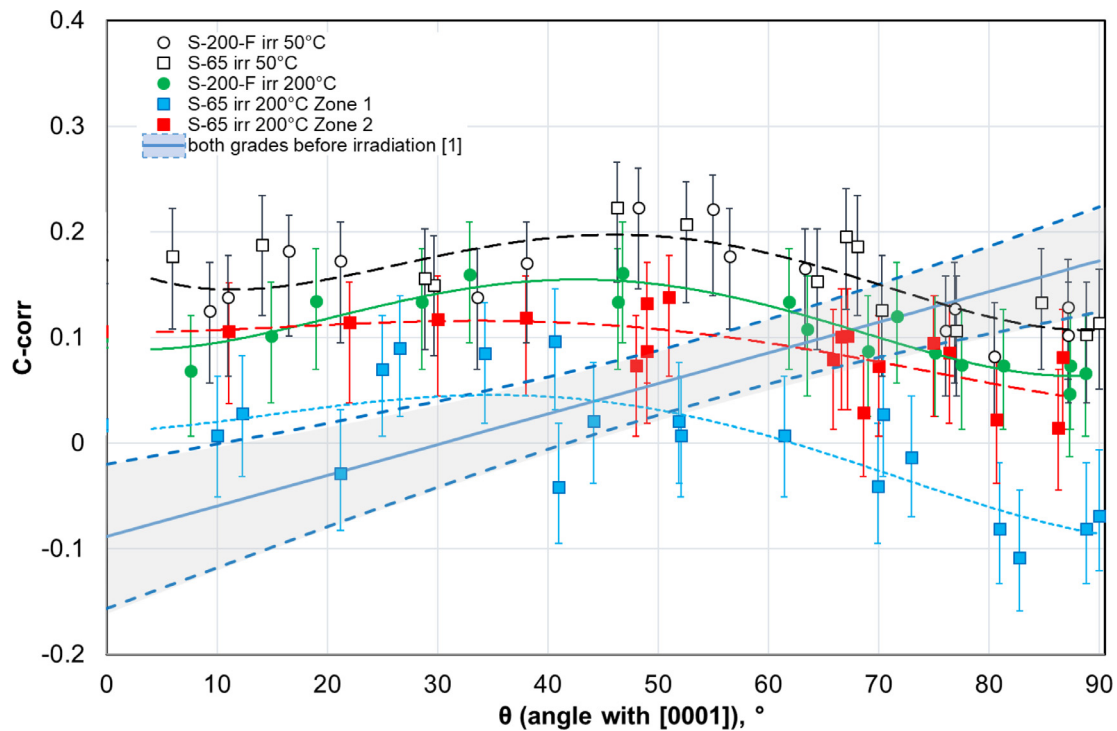

$$C = a_1\theta + a_0 \quad (4)$$

where coefficients  $a_1=0.0035$  and  $a_0= -0.123$  for the chosen indentation depth range [35]. To account for the more complex variation of  $C$  with orientation in the irradiated materials, a fourth-

degree polynomial function was used:

$$C = a_4\theta^4 + a_3\theta^3 + a_2\theta^2 + a_1\theta + a_0 \quad (5)$$

Best-fit values of the coefficients and the coefficients of determination  $R^2$  are given in Table 1.

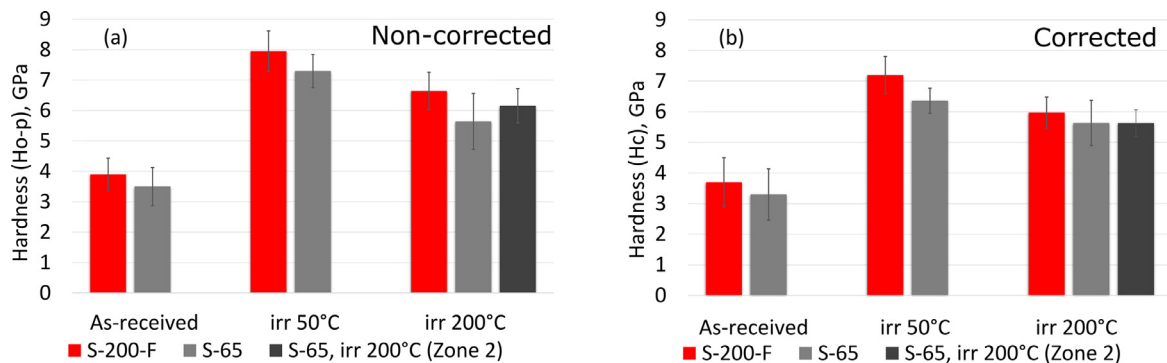

**Fig. 4.** Distributions of the contact area correction coefficient for different crystal orientations in as-received conditions [35] and after irradiation at 50°C and 200°C. **Fig. 5.** Average nanoindentation hardness from 2 beryllium grades before and after helium implantation at 50°C and 200°C. (a) – contact area corrected values vs (b) – obtained by standard method.

As anticipated, significant scatter in the hardness values was observed in both investigated beryllium grades. The data exhibit an extremely broad distribution, with values ranging from 2 to 6.5 GPa before irradiation, from 4.5 to 7.5 GPa after 200°C implantation and from 5.8 to 8.2 GPa after 50°C implantation. Fig. 5 shows the averaged nanoindentation hardness values for tests per-

formed in grain interiors only in as received and implanted samples and compares values before and after contact area corrections. The numeric values describing the observed trends are summarized in Table 2. The S-200-F has about 8% higher average hardness than the S-65 grade in as-received state and remained harder after helium implantations. The implantation at 50°C almost doubled

(4) and (3); (b) Oliver-Pharr method [46]. 0° corresponds to indentation into the basal plane parallel to the [0001] direction, 90° implies indentation perpendicular to [0001]. Only data from grains with the assigned crystallographic orientation are shown (no data from indents on or close to grain boundaries).

the average hardness and the irradiation induced hardening of the lower-purity grade was about 10% higher. The irradiation at 200°C led to 60% increase average hardness for both grades. However, this comparison in hardness values of different samples should be used with caution since, as it is demonstrated in Fig. 5 and Table 2, standard deviations of data are very large and it is between 6 and 24% for average hardness values and between 29 and 48% for the irradiation induced hardening values. Since this greatly complicates the grades comparison, a more detailed investigation of crystallographic dependence of indentation results was performed and reported below.

Note that the contact area correction led to about 10% decrease of the average hardness values and in general was slightly higher in the irradiated samples. It is important to note that while the average non-corrected hardness of the S-65 grade (200°C irradiation) in Zone 1 and Zone 2 was different, the contact area corrected values were identical, highlighting the importance of the nanoindentation artefacts mitigation for increasing accuracy of the experimental data.

Fig. 6 shows the crystallographic orientation dependence of nanoindentation data. For all samples, the curves have sigmoidal variation with indentation angle, with maximum and minimum hardness for indentation directions (test surface plane normals) parallel and perpendicular to [0001] respectively. Tsuya [40] and Hill and Jones [39] observed similar trends in micro- and macro-hardness tests of beryllium monocrystals.

Fig. 6 also compares area-corrected and O-P hardness distributions. In the non-irradiated samples, when corrected, the true hardness in “hard” orientations ( $\theta$  close to 0°) is higher than the uncorrected value, due to sink-ins, whereas the true hardness in soft orientations ( $\theta$  close to 90°) is lower than the uncorrected value, due to pile-ups. Therefore, hardness values derived from the O-P method underestimate the hardness anisotropy. A different behaviour was observed in the irradiated samples. Since the pile-up / sink-in effects were less dependent on crystallography, the corrected hardness values were mainly simply shifted in magnitude from the O-P method, only slightly affecting the measured hardness anisotropy.

Before irradiation, the lower purity S-200-F grade had slightly higher hardness for the same crystallographic orientations than the high purity grade S-65. This was especially noticeable for the “soft” orientations (see Table 2). Since only limited data were available for indentations close to [0001] and given the observed scatter, the “hard” grain hardness may not be accurately compared. Aldinger [25] found that the critical resolved shear stresses (CRSS) for both basal and prismatic slip in beryllium is proportional to the impurity concentration as  $c^{2/3}$ , (where  $c$  is the impurity concentration in wt%), so the less pure S-200-F would be expected to have increased in CRSS and thus higher hardness.

In both grades and for both implantation temperatures the largest irradiation hardening effect was observed in “soft” orientations perpendicular to [0001] (Fig. 6). Starting from  $2.5 \pm 0.3$

GPa and  $2.8 \pm 0.2$  GP in as-received S-65 and S-200-F grades respectively, the hardness doubled after irradiation at  $200^\circ\text{C}$  and was 130–140% higher after irradiation at  $50^\circ\text{C}$ , as demonstrated by black (for the S-65 grade) and red (S-200-F grade) data points in Fig. 6(b). In absolute values the irradiation induced hardening for the “soft” orientation after  $50^\circ\text{C}$  irradiation in both grades was about  $3.7 \pm 0.3$  GPa; and after  $200^\circ\text{C}$  irradiation was  $2.5 \pm 0.3$  GPa for the S-65 and  $2.9 \pm 0.2$  GPa for the S-200-F. While the uncertainty of the data is still high, the measured hardness values imply a possible higher irradiation induced hardening of the less pure grade. After the  $50^\circ\text{C}$  irradiation, the average hardness of the S-200-F was higher than of the S-65, but the crystallographic analysis demonstrated that this was due to a larger number of grains with “hard” orientation being tested in the S-200-F. These effects demonstrate the importance of the use of crystallographic information in studies of the hardness of beryllium and other highly anisotropic materials. The “hard” orientation hardness values were less affected by irradiation, therefore, implantation led to decrease of the anisotropy of beryllium hardness.

The high hardness anisotropy of beryllium originates from the very high anisotropy of the CRSS required for activation of different slip systems [35,39,40]. The CRSS is relatively low for the  $\langle a \rangle$  basal and prismatic systems which both provide slip perpendicular to the  $c$ -axis, but it is very high for the secondary  $\langle c + a \rangle$  pyramidal systems [37,38] responsible for deformation parallel to the  $c$ -axis, especially under compression [25]. Point defect clusters, helium-vacancy clusters (and potentially, sub-nanometric He bubbles) are likely to increase the CRSS values of all slip systems by roughly the same absolute amount, and so to decrease the relative differences between CRSS values of the slip systems. A similar effect was observed by Hill and Jones [39], who demonstrated that work hardening of beryllium single crystals led to highly non-uniform increases of Vickers hardness: about 350 MPa for basal plane indentations and about 660 MPa for indentations on prismatic planes.

### 3.4. Indentation pop-ins

Fig. 7 shows examples of curves of indentation load as a function of depth for S-65 (unirradiated and irradiated at  $50^\circ\text{C}$  and  $200^\circ\text{C}$  “Zone 2”); the behaviour of the S-200 grade material was very similar. Four curves at different indentation orientations are shown per state. Most of the curves exhibit discrete displacement bursts, the so-called “pop-in” effect, at different stages of indentation, as highlighted by black arrows Fig. 7. This pop-in behaviour has been widely observed in different materials [27,61–63]; in the early stages of indentation ( $< 50$  nm indentation depth) pop-ins are typically associated with plasticity bursts caused by dislocation source nucleation in previously defect-free material [27,61–63]. In our experiments these early-stage pop-ins were observed in non-irradiated samples in both grades (Fig. 7(b)) but were absent after helium implantation at both temperatures Fig. 7(d, f). This could be explained by the high number density of defects (in our case point defect cluster, He-vacancy complexes or He bubbles) which can potentially serve as nuclei for dislocation sources; similar effects have been found in indentation of ion-irradiated Fe-Cr [27] and W [64] and polycrystalline Fe after plastic deformation [63].

Sometimes large pop-ins were observed at relatively high indentation depths ( $> 100$  nm); see Fig. 7 (a, c, e.). This behaviour was strongly affected by the sample condition: while only about 7% of load displacement curves in the non-irradiated materials had any of these pop-ins, the behaviour was observed up to 6 times more often in the helium-implanted samples. Such large pop-ins at relatively high indentation loads have also been observed in polycrystalline iron [63]; it was concluded that these events were closely related to the presence of a grain boundary in the stress

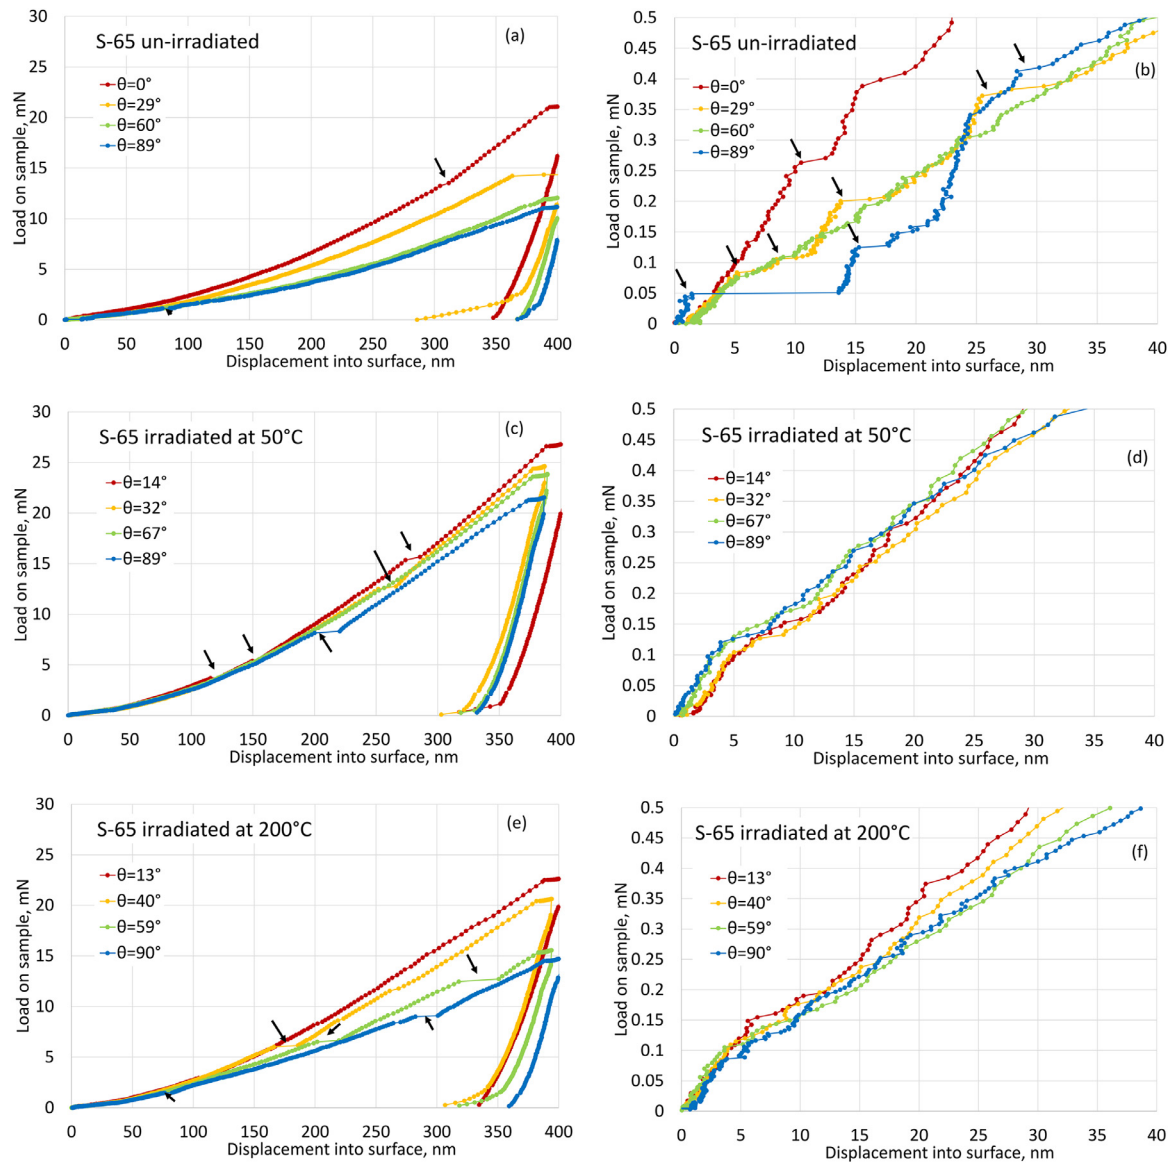

zone of the indentation and has been rationalised in terms of preferred emission of dislocations from the grain boundaries. Such grain-boundary related pop-ins have also been observed in Au/Si samples [62] and Fe-C alloy [65]. Our investigations in beryllium consider indentations made in grain centres as observed at the surface by EBSD. It is, however, possible that the indentations are interacting with grain boundaries under the surface, invisible to SEM/EBSD, which might possibly introduce some pop-ins observed in beryllium in this work. However, in that case, the pop-in behaviour should be a statistical process dependent on presence of grain boundaries (i.e., grain size), and not be dependent on irradiation condition, since the grain size did not change during the implantations. Currently this behaviour is not understood. It is possible to propose that the substructure of the implanted layer with sequence of “softer” and “harder” bands can cause avalanche-like deformation when the stress zone reaches deeper “soft” layers.

### 3.5. Investigating the complex behaviour of S-65

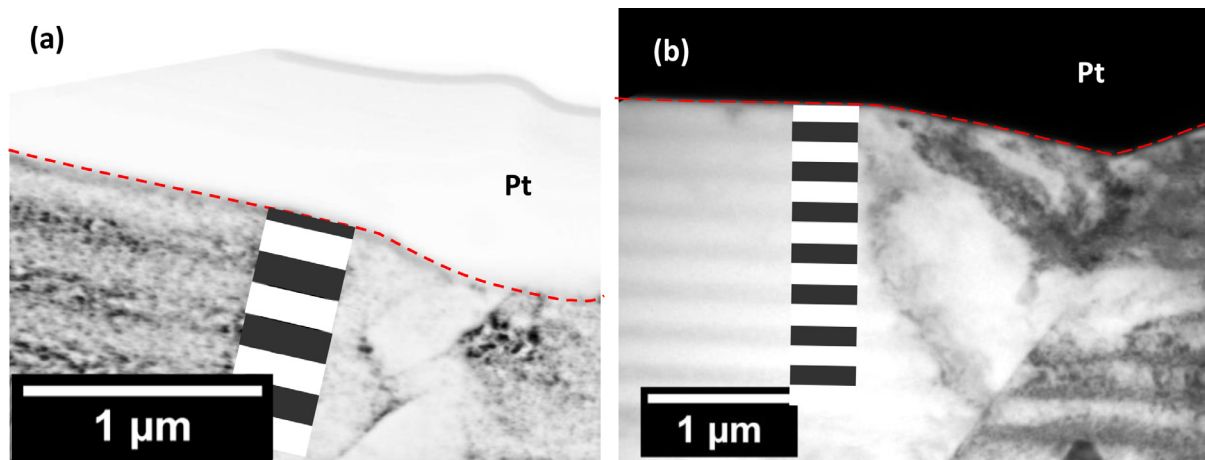

It was observed that irradiation highly affected pile-up/sink-in behaviour of beryllium: it became less crystallographically dependent with increased domination of pile-up (see Fig. 3 and Fig. 4). However, the S-65 sample irradiated at  $200^\circ\text{C}$  have more complicated behaviour: in one area (denoted as “Zone 1”), sink-ins were mainly observed, while in a second area of the sample (“Zone 2”), similarly to other irradiated samples, pile-ups dominated. For better understanding of the behaviour, several TEM lift-outs were made from the indents in the S-65 and S-200-F grades irradiated at both temperatures. Results for the  $200^\circ\text{C}$  irradiations are shown in Fig. 8. The surface layers of the samples are different, due to differences in the degree of polishing away of the aluminium layer after irradiation but before indentation (see Section 2 for details of the sample preparation). In the S-65 grade sample ( $200^\circ\text{C}$  implantation, “Zone 1” indentations) (Fig. 8a), the surface is in the middle of the dark line with an increased number density of black dots (and, from Fig. 1, high helium content) while in lift-outs from other sample (S-200) the surface layer was inside the bright band with fewer point defect clusters (and lower He content). Note that the S-65 sample irradiated at  $50^\circ\text{C}$  had the bright near-surface layer was (Fig. 2a).

This may be the origin of the observed differences in pile-up/sink-in behaviour after  $200^\circ\text{C}$  irradiation. It is known that pile-up / sink-in can be more pronounced for indentations in materials with a thin coating of different mechanical behaviour to the underlying substrate [50]. For indentation into hard coatings on a soft substrate promotes surface sinking-in, as observed by Tayebi et al during indentation of  $\text{SiO}_2$  films on Al substrate [66], whereas for indentation in a soft coating on a hard substrate promotes surface pile-ups, as, for example, was demonstrated in the aluminium-on-glass system by Tsui et al [67]. The behaviour will be more complicated in the case of the heterogeneous layered irradiated substructure of the implanted layer of the investigated samples: the dark bands with increased black dot number density are likely to be harder, and possibly with a lower work-hardening rate, than the relatively bright areas between them. However, the surface layer of the S-200-F after  $200^\circ\text{C}$  irradiation shown in Fig. 8b (and the other irradiated samples, which had a similar surface layer) should be softer than the material under it, corresponding to the “soft coating on the hard substrate” scenario (promoting pile-up), while for the S-65 “Zone 1”  $200^\circ\text{C}$  irradiation shown in Fig. 8a, corresponds to the converse “hard coating on the soft substrate”, promoting sink-in, as observed. However, it is difficult to make a definitive conclusion on this, since only a few lift-outs were prepared and analysed with TEM from these samples.

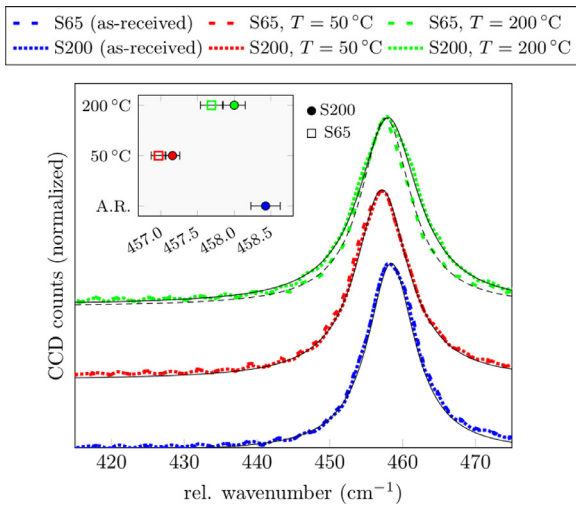

To further investigate this assumption, Raman spectroscopy analysis was performed on both materials in the as-received state

**Fig. 7.** Typical load-indentation depth data produced from the as-received S-65 beryllium grade (a-b) and after helium implantation (c-f); black arrows indicate pop-in events. Curves in (b), (d) and (f) are initial stage fragments of curves in (a), (c) and (e) correspondently.

**Fig. 8.** TEM images of the (a) S-65 irradiated at 200°C (inverted colour dark field image) and (b) S-200-F, irradiated at 200°C (bright field image) taken near the indenter prints. The sequence of the dark and bright layers is highlighted by black and white lines. The near-surface layer is "black" in the S-65 sample, and it is "white" in the S-200 sample.

**Fig. 9.** Raman spectra from two grades of beryllium (S-65 and S-200-F) in the as-received (A.R.) state and after helium implantation at 50°C and 200°C. Each spectrum was acquired by averaging over  $0.36 \times 10^6$  individual spectra from  $3 \text{ mm} \times 3 \text{ mm}$  surface regions, thus reducing the noise originating from near-surface defects. The inset shows the peak positions, determined by fitting a Lorentzian function to the 420–490  $\text{cm}^{-1}$  spectral region for each spectrum. The error bars reflect a systematic error introduced by the choice of the fitting function.

and after implantation at temperatures of 50°C and 200°C. A high-frequency acoustic mode is characteristic to beryllium, which results in a highly intense Raman peak (stretching band) [52,68]. Fig. 9 shows the Raman spectra of Be samples in as-received state and after helium implantation. When plotted in linear scale, both types of spectra consisted of a single peak, which suggests the signal from impurities such as oxygen is weak. This beryllium peak is initially positioned at  $458.5 \pm 0.1 \text{ cm}^{-1}$  in the as-received samples. Both samples implanted at a temperature of 50°C have shown a shift in the band position of  $-1.4 \text{ cm}^{-1}$  in the S-200-F grade and  $-1.5 \text{ cm}^{-1}$  in the S-65 grade, while the corresponding shift in the same grades implanted at 200°C was  $-0.5 \text{ cm}^{-1}$  and  $-0.8 \text{ cm}^{-1}$ . This suggests some recovery of radiation defects already at 200°C when compared to lower-temperature implantation.

As a general rule, a shift in the position of the stretching band indicates a change to the local vibration modes, resulting in a slightly different short-range order of the beryllium atoms. Shifts similar in direction and magnitude have been observed in deuterium-implanted beryllium [52]. According to [69] downshifts of the stretching band can be attributed to tensile strains. Helium-vacancy (He-V) complexes as well as self-interstitial clusters and loops may have a positive relaxation volume [70], thus producing tensile strains in the irradiated material. The relaxation volumes of the radiation induced defects in beryllium are not currently known and it is a subject of our ongoing collaborative numerical modelling studies.

In contrast to other investigated samples where the beryllium stretching band position had not experienced spatial variation, the shift in the S-65/200°C irradiation specimen had a distinct striped substructure consisting of regions with average band shift of about  $-0.6 \text{ cm}^{-1}$  (yellowish areas in 10(a)) and regions with average band shift of  $-1.2 \text{ cm}^{-1}$  (brownish areas in 10(a)). This substructure suggests varying surface tensile strains which are likely to correspond to the alternation of surface-breaking layers of high defect density and low defect density. This could have been caused by polishing-removal of the aluminium layer being at a shallow angle to the initial surface plane, as schematically shown in Fig. 10(b). The “Zone 1” indentation array in the S-65 sample implanted at 200°C was located in the “brownish” band in Fig. 10(a) with a high

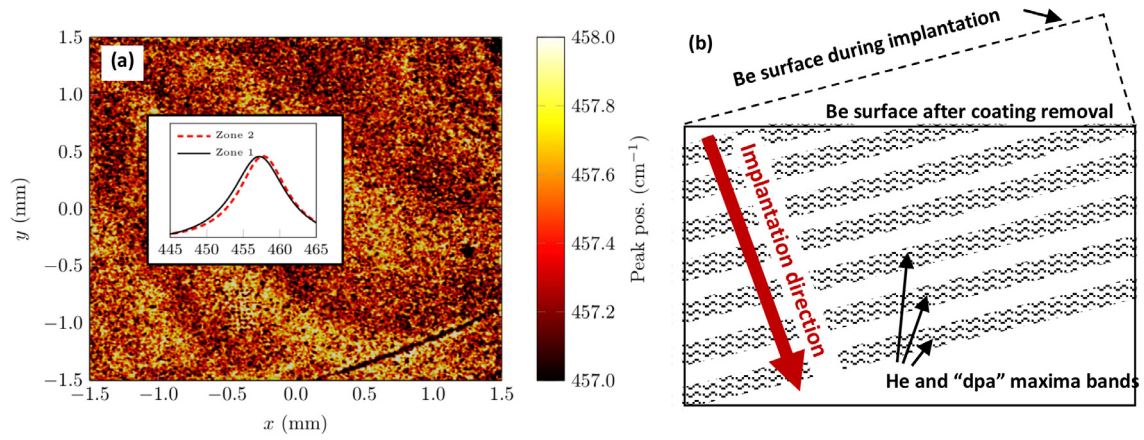

defect density, as seen by TEM in Fig. 8(a). As discussed earlier, this corresponds to the “hard coating on soft substrate” scenario favouring the observed sink-ins. The “Zone 2” array was made in the “yellowish” area in Fig. 10(a) corresponding to the “soft coating on hard substrate” scenario favouring the observed pile-ups. For S-65 “Zone 2”, the downshift is almost equal to that for the S-200-F grade irradiated at the same temperature, as are the pile-up behaviour and the corresponding area correction function  $C$ . This supports our assumption that in the S-65 sample after 200°C irradiation that the contrasted pile-up/sink-ins behaviours are due to the surface preparation of the sample and that in the implanted samples evolution of the pile-up behaviours (at least for the 200°C irradiation) is highly sensitive to the homogeneity and structure of the implanted layer. It should be noted that separate, more controlled experiment with implantation to different depths (at surface and below surface), without protective layers and preferably with broader Bragg peaks (as for example W self-ion implantation) should be performed to elucidate further the role of the damaged layer substructure on the pile-up/sink-in behaviours.

## 4. Discussion

### 4.1. Pile up/ sink-in behaviour

In bulk materials it is generally observed that a high yield stress to elastic modulus ( $\sigma_y/E$ ) ratio and a high strain-hardening rate both promote a spread of deformation deeper into the specimen and the surface around the indenter sinks-in; while the converse (low ( $\sigma_y/E$ ) values and low strain hardening) favour localisation of deformation around the indents and the creation of pile-ups [50,59]. The pile-up/sink-in behaviour in anisotropic hcp metals like Be [35] or Ti [71] is highly sensitive to the crystallographic orientation of the indented grains. The observed crystallographic dependence of pile-up/sink-ins in non-irradiated beryllium is in good agreement with crystal plasticity finite element modelling (CPFEM) results [35], which demonstrated that the stress field and geometrically necessary dislocations (GND) penetrate deeper into the material in the “hard” orientation relative to the “soft” orientation, consistent with a higher ( $\sigma_y/E$ ) ratio, also the plastic strain under the “hard” indent is also higher consistent with high GND hardening.

Irradiation can induce hardening or softening, changing the ( $\sigma_y/E$ ) ratio, and can change a material's strain hardening rate. Hence, as observed in this study and in other studies on different materials, the pile-up behaviour can be changed by irradiation. In this work, in most of the investigated indentation print, helium implantation led to more often observation of pile-ups then before implantation (Fig. 4) that implies the tendency of the irradiated samples to deform in closer proximity to the indented surfaces compared to the unirradiated state of the material. Similar to our observations, many studies report increased domination of pile-ups after irradiation. For example, Hardie et al [27] observed an increase in pile-ups heights after self-ion irradiation of iron-chromium alloys. Similarly, a substantial increase in pile-up heights was observed in a helium-implanted single crystal tungsten by Das et al. [72] and in tungsten-rhenium alloys by Beck et al [33]. However, in contrast, Armstrong et al. [73] observed a suppression of pile-ups in tungsten-tantalum alloys after self-ion implantation. In our work we also observed that for the softest crystallographic orientations the contribution of pile-ups into the contact surface with indenter is slightly decreased after irradiation (Fig. 4). This discrepancy highlights that before a reliable model for prediction of pile-up / sink-ins behaviour is developed, measurements of contribution of these artefacts are highly desirable for accurate measurements of irradiation induced hardening.

**Fig. 10.** (a) Raman peak shift in the S-65 beryllium grade sample after irradiation at 200°C, shown by applying a centre-of-mass filter to the background-subtracted spectra from a large area scan. Averaged Raman spectra corresponding to the high and low-wavenumber regions are plotted in the inset as (Zone 1) and (Zone 2) respectively. (b) schematic representation of the possible origin of the non-homogeneous Raman peak shift is the polishing of the sample after implantation at shallow angle to the initially implanted surface

#### 4.2. Hardening

Although no obvious differences were noticed by TEM investigation between samples irradiated at 50°C and 200°C, that is highly likely the consequence of the FIB damage, the nanoindentation results demonstrated much higher hardening for the lower temperature irradiation. This is in agreement with other hardness and yield strength data of beryllium irradiated at different temperatures (see [24,74] and review [75]). For example, Snead [74] performed Vickers hardness measurements of the S65-C grade neutron irradiated in high flux beam reactor (HFBR) up to 0.34 dpa and 250 appm He and observed about 480 MPa (converted from HV) hardness increase after irradiation at 95°C, about 335 MPa increase for  $T_{irr}=205^\circ\text{C}$  and about 265 MPa increase for  $T_{irr}=278^\circ\text{C}$ . These data was in good agreement with the yield strength increase which was 75 MPa, 55 MPa and 40 MPa correspondently [74]. Kesternich and Ullmaier [24] investigated tensile properties of high purity beryllium implanted by helium (220 appm, 0.02 dpa) and observed 175 MPa increase in the yield strength after implantation at 100°C, which was about 90 MPa after 300°C implantation.

Both helium and lattice defects introduced during the implantation are likely to act as obstacles to dislocation motion. While helium solubility in beryllium has not been measured, this inert gas generally has an extremely low solubility in metals [76]. Ab initio simulations [77] showed that helium is highly insoluble in beryllium and it is strongly trapped by vacancies. According to the ab initio calculations of Zhang et al. [78] the presence of vacancies enhances solubility of helium in the beryllium lattice and between 1 and 12 He atoms can be trapped inside one vacancy in beryllium. Therefore, He is likely to be either trapped by vacancies, increasing the CRSS for dislocation movement by solid solution strengthening; or precipitated into sub-nanometric helium bubbles (too small to be resolved by our TEM), where a precipitation hardening mechanism will govern dislocation pinning and CRSS increase. Kesternich et al [24] investigated the influence of helium on yield strength of beryllium and concluded that for low temperature irradiation (100°C), even if bubbles are not visible, the Orowan mechanism for dislocation pinning at precipitates (small bubbles) should be applied for description of radiation induced hardening. Kesternich et al [24] did not include hardening analysis from the observed dislocation loops.

The dispersed barrier hardening model was used to correlate the irradiation hardening and microstructure observed by TEM:

$$\Delta\sigma_y = \alpha M \mu b \sqrt{N \cdot d} \quad (6)$$

$$\Delta H = 3 \Delta\sigma_y \quad (7)$$

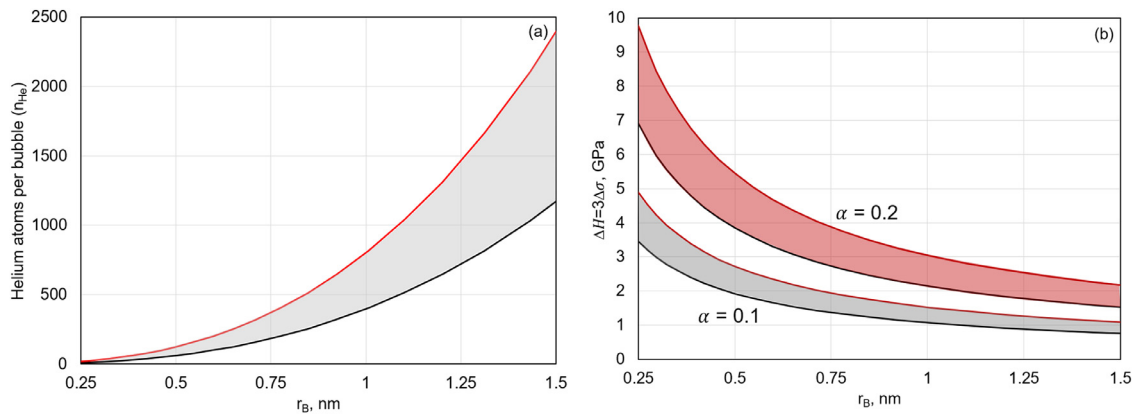

where,  $M = 4.3$  [79],  $\mu = 132.8$  GPa [37,38] and  $b = 0.228$  nm ( $\langle a \rangle$  slip) [25] are the Taylor factor, shear modulus and Burgers vector, respectively,  $N$  is the number density and  $d$  is the mean diameter of obstacles (considered to be 5 nm for this estimation).  $\alpha$  is the dimensionless obstacle strength factor in the range of  $0 \leq \alpha \leq 1$ . To estimate the possible hardening, as a guidance we used the  $\alpha$  values of different types of defects summarised for steels by Lucas [80]: i) weak barriers like small bubbles, loops, vacancy clusters with  $\alpha < 0.25$ , ii) intermediate barriers such as Frank loops with  $0.33 < \alpha < 0.45$ , and iii) strong barriers such as voids and large precipitates with  $\alpha \approx 1$  obstacles. Taking the average number density for the observed loops, the Eqs. (6) and (7) yields  $\Delta H \approx 0.85$  GPa if  $\alpha = 0.2$  (case of small loops is steels [80,81]) or,  $\Delta H \approx 1.7$  GPa if  $\alpha = 0.4$  (case of Frank loops is steels [80,81]). Comparison with the radiation induced hardening data from Table 2 implies that between about 1.4 and 2.4 GPa of hardness increase should originate from the other radiation induced obstacles, not observed by TEM and potentially related to helium. To analyse this, we considered two marginal scenari: i) helium is homogeneously distributed in beryllium and cause solid solution hardening; ii) helium agglomerates and creates clusters with vacancies which act as barriers for dislocation movement.

In the case (i), it is possible to estimate the solid solution hardening using the equation proposed by Fleischer [82]:

$$\Delta\sigma_y = \frac{M}{760} \mu \cdot \delta^{\frac{3}{2}} \cdot c_{He}^{\frac{1}{2}} \quad (8)$$

where,  $\delta$  is a parameter characterising interaction between solute atoms and dislocations and  $c_{He}$  is a concentration of helium atoms. With the Taylor factor  $M = 4.3$  [79], shear modulus  $\mu = 132.8$  GPa [37,38],  $\delta = 1$  [24] and  $c_{He} = 2 \times 10^{-3}$ , Eqs. (8) and (7) yield  $\Delta H \approx 0.1$  GPa. This is one order of magnitude less than the anticipated contribution from helium; therefore, the observed hardening cannot be attributed to solid solution hardening by helium atoms.

The dispersed barrier hardening model (Eq. (6)) can be used to estimate hardening from helium bubbles. As no bubbles were observed by TEM we assumed that the hypothetical bubbles should have diameter less than 3 nm as this is the approximate size of the first bubbles observed in beryllium containing 2000 appm of helium during in-situ annealing inside TEM at 350°C [83]. Considering this size range, we estimated the corresponding number density of bubbles which can be created by 2000 appm of helium atoms. The approach was based on comparison of the expected

**Fig. 11.** (a) Correlation between quantity of helium atoms in the bubble and the size based on the Benedict equation of state; (b) calculated contribution of helium bubbles into the irradiation hardening for different sizes and different obstacle strength factors.

pressure in bubbles depending on the properties of the materials (surface tension, shear modulus and Burgers vector) with the calculated pressure in bubbles of a specific size expected from the ratio between helium atoms and vacancies described by the equation of state. From one hand, assuming spherical bubbles, pressure ( $P$ ) inside helium bubbles should be bound by the inequalities [84]:

$$\frac{2\gamma}{r_B} \leq P \leq \frac{2\gamma + \mu b}{r_B} \quad (9)$$

where  $r_B$  is the radius of the bubble and  $\gamma = 1.83 \text{ J/m}^2$  is [85] the bubble surface tension,  $\mu = 132.8 \text{ GPa}$  is the shear modulus [37,38],  $b = 0.228 \text{ nm}$  is the Burgers vector [25]. The lower boundary is determined by the equilibrium pressure in a bubble of gas determined by Young–Laplace equation, and the upper boundary is determined by the loop-punching stress at which pressure in growing bubbles is relieved by “punching out” dislocation loops [84]. These calculations show that the pressure in bubbles may vary from 2.3 GPa to 21 GPa for the bubbles with  $r_B = 1.5 \text{ nm}$ , and increases to the range from 14 GPa to more than 70 GPa for  $r_B = 0.25 \text{ nm}$ .

From another hand, the ratio between the pressure, quantity of helium atoms and size of a bubble (i.e., number of vacancies in the bubble) can be described by the equation of state. In this work we used the Benedict equation of state [86] parametrised by Mills, Liebenberg, and Bronson [87] as this approach demonstrated good results in predicting helium bubbles behaviour in tungsten [84]. The equation has a form of:

$$\frac{V}{n_{He}} = f_1(T)P^{-\frac{1}{3}} + f_2(T)P^{-\frac{2}{3}} + f_3(T)P^{-1} \quad (10)$$

where  $V$  is a volume of a spherical bubble,  $n_{He}$  - number of helium atoms in a helium bubble, and  $f_1(T)$ ,  $f_2(T)$  and  $f_3(T)$  are the functions dependent on the temperature, the details and parameters of which can be found in [87]. The volume of the bubble may be approximated as [84]:

$$V = n_V \Omega = \frac{4\pi r_B^3}{3} \quad (11)$$

where  $\Omega = 8.09 \times 10^3 \text{ nm}^{-3}$  is the atomic volume of beryllium and  $n_V$  - number of vacancies in a bubble.

Combination of Eqs. (9), (10) and (11) allowed estimation of the ranges of ratio between bubbles radii and quantity of helium atoms in the bubbles (Fig. 11a). The range of about 1300 to 1660 He atoms per bubble is expected for  $r_B = 1.5 \text{ nm}$  ( $n_V \approx 2000$ ), this decrease to  $n_{He} \approx 400$  to 800 for  $r_B = 1.0 \text{ nm}$  ( $n_V \approx 530$ ) and  $n_{He} \approx 60$  to 125 for  $r_B = 0.5 \text{ nm}$  ( $n_V \approx 65$ ). The presented numbers were calculated for the room temperature (RT) and there was only a little difference (<6% for the average  $n_{He}$  values) between data

at RT, 50°C and 200°C. The generated equation of average between the minimal and maximal quantities of helium atoms per bubble as a function of quantity of vacancies (bubbles size) was obtained by fitting and can be estimated by:  $n_{He} = 2.8n_V^{0.87}$ .

Considering the implanted 2000 appm of helium and quantity of helium atoms per bubble of a specific size from Fig. 11b, it is possible to estimate the range of the corresponding number densities of the bubbles: about  $1.2 \times 10^{23}$  and  $1.9 \times 10^{25} \text{ m}^{-3}$  for bubbles with radii of 1.5 and 0.25 nm correspondently. The calculated number densities were used for estimation of the induced hardening Eqs. (6) and (7). The results of the expected helium bubbles contribution into hardening  $\Delta H$  are summarised by the red area in Fig. 11b for the case the obstacle strength factor  $\alpha = 0.2$  (weak obstacles after Lucas [80]). As between 1.4 and 2.4 GPa is expected from these objects, it is possible to note that with the chosen calculation parameters, this corresponds to relatively large bubbles with the radius of 0.8 - 1.5 nm. However, as demonstrated in [81], the strength factor of cavities is highly dependent on the size and for the case of stainless steel may decrease to the values of  $\alpha$  between 0.02 and 0.1 if the cavities are smaller than 2 nm in diameter. The value of  $\alpha = 0.1$  was also obtained for the helium bubbles with diameters of 1–1.5 nm in irradiated ferritic-martensitic steels [88]. The results of the expected helium bubbles contribution into hardening  $\Delta H$  for  $\alpha = 0.1$  are demonstrated by the grey area in Fig. 11b, and the observed 1.4 and 2.4 GPa hardening will correspond to the helium bubbles with the radii in the range between about 0.4 and 1 nm.

Considering the obtained distribution of hardening for the bubbles of different sizes, it is possible to suggest that the differences between hardening at 50°C and 200°C observed in our work could be explained by differences in spacing between the bubbles (i.e., number density of bubbles and their size), i.e., bubbles after 200°C implantation are larger than after the 50°C implantation, but still below the TEM resolution (1–2 nm in diameter). It should be added that the ratio between vacancies and helium atoms may alter the bubbles strengthening factor  $\alpha$ . For example, as it was shown by Schaublin and Chiu [89] in the case of bcc iron, a 2 nm He bubble is a weak obstacle when the He content is low, at 1 to 2 He atoms per vacancy, but beyond 2 He atoms per vacancy, the resistance of the He bubble increases with increasing He content (and pressure) and at 5 He atoms per vacancy, the He bubble becomes a much stronger obstacle. While no detailed investigation of helium bubbles strengthening factors in beryllium is known, the scenario that increase of helium to vacancy ratio may increase strength factor of bubbles is likely. Due to this, it is possible to suggest that bubbles in the samples irradiated at 50°C may have higher H/V ratio (and potentially, higher strengthening factor) that the bubbles in the samples irradiated at 200°C.

The increased irradiation induced hardening of the lower-purity grade after exposure at 200°C may possibly originate from an influence of impurities on redistribution of helium or point defects, however, creation of impurity clusters which act as obstacles for dislocations could be also considered. According to recent ab initio calculations of Klimenkov et al. [90] some typical beryllium impurities like aluminium, silicon and manganese have strong binding with vacancies and therefore, can retard vacancy diffusion, prevent their recombination with interstitials and play important role in gas bubble nucleation. Potentially this may lead to the increased number density of defects clusters increasing irradiation induced hardening as observed in our work. We should note that the chemistry effect on radiation resistance of beryllium was never systematically studied, and the available data is scattered. For example, similarly to our observation, Kupriyanov et al [55] demonstrated that after neutron irradiation in the CM-3 reactor at 130–180°C the lower purity TIP-30 and TE-30 beryllium grades experienced higher radiation-induced increase of yield strength than the higher purity TshG-56. However, the results of Snead [74] demonstrated lower irradiation induced hardening of the lower purity P0 grade than of the higher purity S-65C grade irradiated in the high flux beam reactor (BNL) at temperatures between 105 and 275°C.

Currently, the high purity S-65C grade has been selected as the reference plasma-facing material in ITER on the basis of its excellent thermal fatigue and thermal shock behaviour, and a good available database on its properties [7]. Our results support this choice, demonstrating that at a helium content that corresponds to the end-of-life of plasma-facing beryllium in ITER [16], the properties of this grade exhibit higher radiation stability, e.g. smaller irradiation-induced hardening than the lower purity grade. However, the mechanism(s) responsible for this are not known. A detailed fine scale high resolution TEM analysis, complimented by fine scale chemical analysis, for example with Atom Probe Tomography, and preferably Positron Annihilation Spectroscopy to elucidate the helium atom distribution, would be required to understand the hardening mechanisms from individual features in the irradiated microstructure.

The results are also important for the particle accelerator community. The irradiation conditions and hardening effects used in this study represent the average operating temperatures of beryllium windows in the operating NuMI beamline (50°C) [18] and the currently-designed LBNF (200°C) [9,10]. So far, the high purity PF-60 grade (similar purity to S-65, but with different grain size and texture) has been successfully used as a beam window material in the NuMI beamline, accumulating during operation up to 2000 appm of helium [18]. The result of this work demonstrates that in the future LBNF, the similar pure grade exposed to comparable doses to NuMI, but at higher temperature (200°C), should undergo smaller radiation-induced hardening and that accumulation of up to 3000 appm of helium at this temperature does not lead to creation of cavities or bubbles (including at grain boundaries) which are known to be often responsible for the severe loss of ductility in beryllium.

## 5. Conclusion

Two industrial beryllium grades, higher-purity S-65 and lower-purity S-200-F, were investigated in the non-irradiated state and after helium implantation at 50°C and 200°C. The main conclusions that can be drawn from this work can be summarized as:

- At both temperatures in both grades, under TEM investigation the radiation damage appears as “black dots” (<10 nm in diameter) which are likely to be small dislocation loops with the number density of  $\sim 10^{22} \text{ m}^{-3}$ . No voids or bubbles were observed by TEM inside grains and at grain boundaries.

- Before irradiation, the S-200-F and S-65 grades have an average hardness of  $3.7 \pm 0.8 \text{ GPa}$  and  $3.4 \pm 0.8 \text{ GPa}$  correspondently. In both grades the implantation at 50°C almost doubled the average hardness, and at 200°C led to a 60% hardness increase, compared to the average hardness of the non-irradiated material.
- Analysis of the possible hardening contribution demonstrated that the “black dots” at observed number densities could be responsible for up to half of the measured hardening, while the rest should originate from helium bubbles with the size below the TEM resolution (<1...1.5 nm). It is expected that the bubbles are relatively weak obstacles with the strengthening factor  $\alpha < 0.2$ . Solid solution hardening by helium atoms is unlikely to significantly contribute to the observed hardness increase.
- By combining nanoindentation with EBSD it was possible to separate out the influence of crystal orientation on hardness. In the non-irradiated materials the hardness is about 2.5 times higher when the indentation direction is close to the [0001] c-axis of beryllium, compared to indentation perpendicular to [0001]. Grades with “soft orientation” were most sensitive to irradiation induced hardening, which increased almost 3 times after 50°C implantation and 2 times after exposure at 200°C. The higher purity grade had smaller increase of the “soft orientation” hardness after 200°C irradiation:  $2.5 \pm 0.3 \text{ GPa}$  for the S-65 and  $2.9 \pm 0.2 \text{ GPa}$  for the S-200-F. Hardness anisotropy significantly decreased after helium implantation as “hard orientation” hardness values were less affected by irradiation.
- Near-indentation surface topography, which is not accounted for in the standard “Oliver-Pharr” analysis, can have a strong influence on the extraction of true hardness values from nanoindentation data. A combination of nanoindentation with EBSD, to give a contact area correction, is an important procedure in such cases, for example here in the investigation of radiation damage effects in different beryllium grades.
- Topography mapping of indentation prints demonstrated that localised surface deformation around indents (pile-up and sink-in) is highly crystallographically dependent in the as-received state (sink-in behaviour dominated in hard grains close to the c-axis while pile-ups dominated in soft grains orthogonal to the c axis). After implantation this crystallographic dependence of topography is less prominent and either pile-ups or sink-ins may be observed. TEM and Raman microscopy indicate that whether either pile-ups or sink-ins occur in a particular specimen can be related to the detailed layered substructure of the implanted material: when the surface layer is softer (with smaller helium content) pile-ups are mainly observed, while in the opposite case (harder surface layer with higher helium content) sink-ins are dominant.

## Declaration of Competing Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.
